In Fig. 1, Diagram III., is represented the mechanism by which we can conceive the production of sorbite to the exclusion of pearlite, owing to relatively rapid cooling in passing through the critical stage. The steel is now ferrito-sorbitic, while the amount of ferrite it contains is but half the amount of that constituent present in the ferrito-pearlitic metal (Fig. 1, Diagram I.), the necessary time for its complete separation having been denied. In its ferrito-sorbitic condition the steel is decidedly more tenacious, but less ductile, than when ferrito-pearlitic. It is also harder, has a higher elastic limit, and is in a better condition to resist shocks and alternate stresses. A ferrito-sorbitic structure is readily produced in allowing small pieces to cool in air, or larger ones in oil. It may also be obtained by quenching the metal from above its critical range in water or oil, thereby securing a fine structure, followed by reheating to some 600° C. to cause the transformation into fine sorbite of any existing troostite or martensite.

In Fig. 1, Diagram IV., the cooling has been so rapid that, on emerging from its critical range, the metal is caught in a ferrito-troostito-sorbitic state, only a small amount of ferrite, moreover, being present. The metal is now harder and has lost much of its ductility because of the presence of troostite. This structure may be produced by quenching small pieces in oil, or larger ones in water, or by a suitable tempering of hardened pieces.

In Fig. 1, Diagram V., the steel has been cooled so quickly that some martensite, as well as troostite, remains undecomposed on reaching the bottom of the critical range, while but a very small amount of ferrite has had time to separate. In this ferrito-troostito-martensitic condition the metal is hard and deficient in ductility. A structure of this type may be produced by quenching small pieces in water.

The retention of martensite to the exclusion of troostite, and, *a fortiori*, the retention of austenite, is quite impossible in mild steel. While martensitic structures, moreover, are those needed in high-carbon steel for the production of cutting tools, for instance, they are never wanted in low-carbon steel, the structures depicted in Fig. 1, Diagrams I., II. and III., being the only ones of interest to the users of such steel.

Fig. 3 is a composite photo-micrograph showing the various types of structure mild steel may be made to acquire. The legend makes it self-explanatory.

ALASKA RAILWAY SURVEYS.

Good progress is being made with the surveys for the Government railway in Alaska, and it is possible that a preliminary report on the undertaking will be ready for submission to President Wilson late in October or early in November. At the present time parties are working south from the Tanana River, while engineers are working north. Work is also in progress at Portage Bay and Seward and along the line to the head of Cooks' Inlet. The surveys are being made for a route from the coast through the Susnita Valley to the Tanana. This, in general, follows the line of the Alaska Northern Railway to Grand View, 45 miles from Seward, the coast terminal of the railway. Cross-sectioning was started two or three weeks ago on the new route surveyed from Grand View to Turnagan Arm. The coast terminals under consideration at present are Seward and Portage Bay.

Editorial

"*Business as Usual*"

ABOUT A MORATORIUM.

In these strenuous days engineers in Canada are inquiring as to the meaning and scope of a moratorium. It is a temporary and emergency measure and provides for the postponement of the settlement of certain debts. Its duration and the debts to which it shall apply are specified by government proclamation. The time and scope of moratorium laws in various countries, since the declaration of war, have varied considerably. In England the moratorium first was declared for one month to September 4th. Then it was extended another month to October 4th, although of 8,000 replies received to an inquiry of Mr. Lloyd George, Chancellor of the Exchequer, 4,500 were against an extension. A moratorium has not been declared in Canada; but the necessary legislation has been provided for its declaration, if thought necessary. It should be made clear that a moratorium does not cancel, but merely postpones a debt. In England, the press is advising the people to pay their debts whenever possible. That is good advice.

ENGINEERING ENGLISH.

Dr. Chas. H. Snow, Dean of the School of Applied Science of the University of New York, once said in an address to an assembly of young engineers: "The success of the engineer is influenced practically as much by a knowledge of English as by a knowledge of mathematics." Coming from one whose prominence in the advancement of engineering education has marked him as an authority, his audience had, therefore, no occasion to disbelieve.

It must be true that too many engineers do not know how to use good English. The appeal for a remedy comes, not from professional cranks always looking for the impossible and never satisfied with any attainable training, but from reasonable, practical men, at or near the head of their profession—men whose chief desire it is to try to better existing conditions. The appeal cannot, therefore, be disregarded by our engineering schools. It indicates that advancement is needed on their behalf in the interests of engineering education, that perfection has not been reached or the time at hand for a relaxation of united effort in this direction. The subject has been touched upon occasionally in these columns. The motive is by no means a reflection upon the present status of engineering, but it is an endeavor to emphasize that one of the sorest needs in our engineering schools to-day is the need for adequate instruction in English.

By "adequate" is meant sufficient attention being paid to it throughout the entire technical course (and carried even into the graduating thesis) until the student has become proficient in the subject. Every spoken and written report which he is called upon to make should receive proper consideration from the instructors as to its wording and its grammatical construction.

Let us place the facts clearly before our engineering schools and the students themselves. Among the most important deficiencies noted by practising engineers in the technical graduate is his inability to express himself correctly and forcibly in either writing or speaking. The English spoken by many graduates of technical institutions has occasionally been termed atrocious, their letters are awkward, misspelled, and ungrammatical, and their ability to write reports, specifications and contracts is deplorably lacking.

Who is to blame if all this is true? Who is responsible for the lack of good English among our engineers? Why is there a need for engineers to know good English? What is the remedy? These are questions that received some serious consideration at the meeting in Philadelphia some weeks ago of the Society for the Promotion of Engineering Education, an organization to which a great deal of the advancement of engineering education is due.

Three factors within the institutions of learning are concerned, viz.: the department of Engineering, the department of English, and the student. All three, individually and collectively, are to blame. The student, entering from the technical school, is not generally well-prepared, and his weakest subject is, invariably, English. Those technical schools which boast of courses of instruction in English confine it largely to the first year. To the student it appears of minor importance. He is seeking instruction in engineering and studies English as sparingly as possible. The result is that the subject is neglected, and when the stage is reached where it no longer forms a part of the curriculum, it is ignored outright.

The department of English recognizes this attitude of the student towards the subject and makes no attempt to alter it, for the instructor in English is, generally speaking, no more in sympathy with his engineering students than they are with his subject. He knows little or nothing of engineering and makes no attempt to acquaint himself with such a woefully practical study. Is it any wonder that this class of engineering students seek the merest margin of a past in his subject? Does he, with his disinclination to associate with such uncultured students, desire to restrain the delinquent ones for another term under his instruction?

The department of Engineering is disposed to nonchalantly observe that the student is extremely deficient in his English, and that it is regrettable since in the study of engineering there is no time for him to retrace his steps over past studies. Further, the department errs in not recognizing the value of English to the student and in not putting more of it into his work. More than this, the lack of co-operation with the department of English removes the last stepping stone toward retrievement.

It would appear, therefore, that upon the co-operation between the departments of Engineering and English, hinges a matter of gravest importance in the training of the engineering student. It is a mutual problem, and to turn out thoroughly efficient engineers it must be solved.

SURGE TANK PROBLEMS—IV.

BEGINNING A STUDY OF THE INFLUENCE OF A SPILLWAY BUILT IN THE SURGE TANK.

By PROF. FRANZ PRASIL.

Authorized Translation by E. R. Weinmann and D. R. Cooper, Hydraulic Engineers, New York City.

PART 2.

Special Case D—Involving Spillways.

In order to decrease the surge in the surge tank, a spillway may be introduced in the surge tank or in the main conduit. The problem of interest, then, is to determine at what elevation and with what capacity such a spillway should be designed in order that the surge shall not exceed a certain elevation. The case will be investigated under the following assumptions: The spillway is

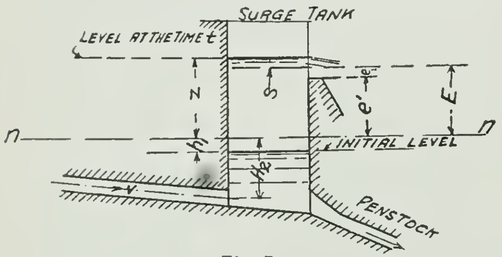

Fig. 7.

attached to the surge tank (Fig. 7). The crest of the spillway is at the distance e' from the static level $n-n$; e' is positive if the crest is above $n-n$ and negative if below. The width of the spillway is b'. The outflow of Q cubic feet per second is suddenly interrupted.

We must take care of several periods of movement. Following a complete shut-down, the water surface in the surge tank will rise to the height of the spillway crest, as is described in case (A).* Next, the rise will continue, but water will flow over the spillway up to a maximum elevation, then decrease to the elevation of the spillway crest. At this moment, the outflow ceases. The movement then takes the form of the case (A), and retains this form thereafter, provided the crest of the spillway is not reached again. Otherwise, the same cycle is repeated or the condition remains one of constant overflow. Therefore, for the first phase the following equations are effective:

$$z = R.e^{-\frac{t}{2T_0}} \sin\left(\beta + \frac{t}{T_1}\right)$$

$$s = -\frac{R}{T} e^{-\frac{t}{2T_0}} \sin\left(\gamma - \beta - \frac{t}{T_1}\right) \quad \text{with } tg\,\gamma = \frac{2T_0}{T_1}$$

The integration constants R and β are obtained for the conditions $t = o$, $z = -h_1$, $s = c_1$. The final value of z is in this period of movement e'. From this we determine the time $t_{e'}$, which is necessary for the rise up to the level of the spillway crest and by means of the second equation we determine the final velocity $s_{e'}$. In the second period of movement now beginning, we have overflow on the spillway, that is, according to the familiar formula for spillways $q = \frac{2}{3}\mu\, b'\, h'\, \sqrt{2gh'}$ where $h' = z - e'$ represents the overflow height and we get

$$\frac{q}{A} = c = \frac{2}{3}\mu\, b' \frac{\sqrt{2g}\,h'^{3/2}}{A} \qquad (82)$$

The introduction of this formula and its derivation in the principal equation (23) would lead to a differential equation higher than the first degree, the integration of which might be accomplished by development in series. For practical purposes, however, an easier but sufficiently exact approximation may be obtained in the following manner:

If we plot the different values of h' computed for the width b' on a rectangular co-ordinate system, the values h' as abscissæ, and the values of q as ordinates (see Fig. 8), we obtain a parabolic curve, passing through the origin. The velocity $s_{e'}$ (which is the final value of the velocity of the surface at the end of the first period of movement) together with A determines a quantity of water $s_{e'}.A$, which is certainly larger than the maximum value of the overflowing quantity during the second period. If we now draw tangents from the point of the quantity curve, which corresponds to $As_{e'}$ and assume as a preliminary approximation that within the heights of

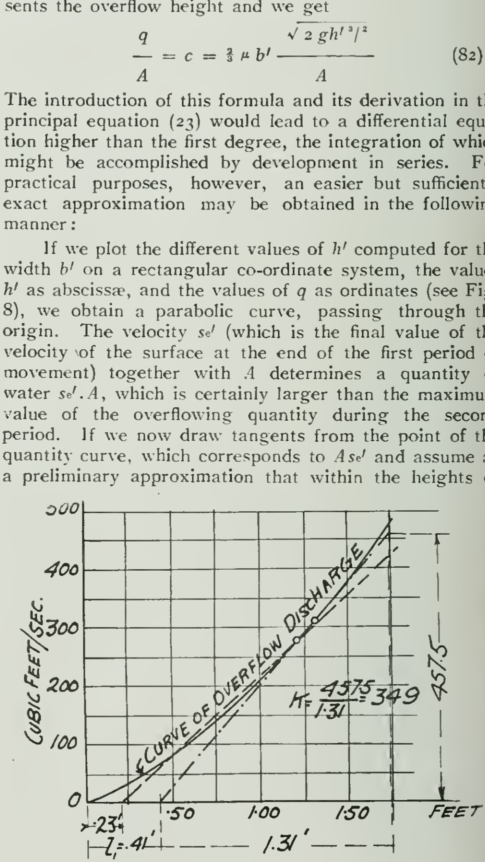

Fig. 8.

the overflow, which corresponds to the intersection of the tangent with the axis of the abscissæ, the overflowing quantity equals zero, which is the same as if we move the elevation of the spillway crest higher up by the same amount, and if we take from this location the water quantity proportional to the height of this new elevation of the spillway crest corresponding to the tangent, then

*See *The Canadian Engineer* for Aug 20, pp. 327-9 and Aug. 27, pp. 368-70.

we get a linear equation for the determination of the water quantity, whereas the differential equation for the determination of the elevations also becomes linear.

The results thus obtained from these equations are naturally only approximate ones, as the overflowing quantities are introduced as too small. The computed values of z exceed the actual values. For practical purposes, this first approximation is generally sufficient, but we have no difficulties using the results of the first approximation for a second computation, drawing the tangent on that point of the overflow curve which corresponds to the maximum value of the elevation found in the first computation and repeating with these results the computation as before. We may use this second approximation in the first computation if instead of the value for the point in the curve, we take a somewhat smaller value, say, $u\,A\,s_e'$, when $u = 0.7$ to 0.8. We use the latter method in the following:

The overflow height, which gives an overflow of $u.A.s_e'$, is determined by

$$h_u = \left(\frac{3}{2}\frac{u}{\mu}\cdot\frac{s_e'A}{b'\sqrt{2g}}\right)^{2/3}$$

The proportional factor k for the linear variation of q is obtained by differentiation of q with respect to k. Therefore:

$$k = \frac{dq}{dh^1} = (\text{as } h' = h_u) = \mu\,b'\sqrt{2g\,h_u} = \sqrt[3]{3/2\,\mu^2\,b'^2\,2g\,u\,s_e'A}$$

k has the dimension $l^2.t^{-1}$, and the value of the abscissa e_1, which is the difference between the true elevation of the spillway crest and that obtained by approximation, is

$$e_1 = h_u - \frac{u.s_e'.A}{k} \qquad e_1 = \sqrt[3]{\frac{19}{12}\left(\frac{u\,s_e'\,A}{\mu\,b'\sqrt{2g}}\right)^{2/3}} \qquad (84)$$

The values are easiest obtained graphically from the curve of the overflow quantities.

Therefore, with e_1 the height of the ideal spillway crest above the static level $n - n$, (that is $E = e' + e_1$) once determined, the computation of the first period of movement must be extended to the elevation E.

We obtain from the previously mentioned formulæ $z_e = E$ and s_e. These are initial values for the second phase, from which beginning we measure the time anew.

$$c = \frac{q}{A} = \frac{k}{A}(z - E) \qquad \text{and therefore } \frac{dc}{dt} = \frac{k}{A}\frac{dz}{dt}$$

and the equation 23 becomes

$$\frac{d^2z}{dt^2} + \left(\frac{1}{T_e} + \frac{k}{A}\right)\frac{dz}{dt} + \left(\frac{1}{T^2} + \frac{k}{A\,T_0}\right)z - E.\frac{k}{A.T_0} = 0$$

Introducing $y = z + m = z - \dfrac{E}{\dfrac{A\,T_0}{k\,T^2} + 1}$ and abbreviating

$$\frac{1}{T_e} + \frac{k}{A} = \frac{1}{T_e^1}; \quad \frac{1}{T^2} + \frac{k}{A\,T_0} = \frac{1}{(T^1)^2} \text{ we get}$$

$$\frac{d^2y}{dt^2} + \frac{1}{T_e^1}\frac{dy}{dt} + \frac{y}{(T^1)^2} = 0 \qquad (85)$$

Corresponding to the investigations regarding the form of the general integral of this differential equation, we must investigate whether the difference

$$\frac{1}{(T_1^1)^2} = \frac{1}{(T^1)^2} - \frac{1}{(2\,T_e^1)^2} \text{ is positive or zero, or negative,}$$

which we obtain by substituting the values of $\dfrac{1}{T_e^1}$ and $\dfrac{1}{(T^1)^2}$

$$\frac{1}{(T_1^1)^2} = \frac{1}{T_1^2} + \frac{k}{2\,A}\left(\frac{1}{T_0} - \frac{k}{2\,A}\right)$$

by which formula the investigation mentioned may be carried out and the corresponding form of the general integral may be used.

The integration constants must be determined with the initial values

$$t = 0; \quad z_e = E; \quad s_0 = s_e$$

The duration of the second period of movement is obtained from the equation for z, which is given by that value of t for which z becomes E once more. If that does not occur in a case of non-periodic movement, for instance, if the spillway crest lies below the level $n - n$, then the duration of the second period of movement is only limited by a new occurrence of any kind of outflow. Otherwise, the final values of the second period are the initial values of a following period, which must be handled the same as the first case. (Case A.)

The method of computation may be shown best by an example. Using the former example, we consider a spillway of 65.7 feet width, the crest of which is at the static level $n - n$. That is, for this assumption $e' =$ zero. The flow of 530 cubic feet per second is suddenly stopped.

From the results of case (A) we get

$$z_e' = 0; \qquad t_e' = 106 \text{ sec.}; \qquad s_e' = +\ .075 \text{ feet/sec.}$$

The velocity s_e' corresponds to the flow in the surge tank at the time t_e' of $q_e' = .075 \cdot 5380 = 404 \dfrac{\text{cu.ft.}}{\text{sec.}}$. For a spillway width of 65.7 feet and for $\mu = 0.6$, we get from the spillway formula $q \dfrac{\text{cu. ft.}}{\text{sec.}} = 208\,h'\,\sqrt{h'}$ and therefore for

$$u\,.\,q_e' = 282 \frac{\text{cu. ft.}}{\text{sec.}} \quad (u = .7)$$

an overfall height of $h' = 1.22$ feet and a proportional factor $k = 3/2\,.\,208\,.\,h_u^{\frac{1}{2}} = 345 \dfrac{\text{sq. ft.}}{\text{sec.}}$ and therefore as the distance of the ideal spillway crest from the static level $n - n$ because $e' =$ zero; $E = .410$ and with the results of case a for $z = E$

$s_e = +\ .073$ feet per second

In order to determine which integral formula to use, we have

$$\frac{1}{(T_1^1)^2} = \frac{1}{T_1^2} + \frac{k}{2\,A}\left(\frac{1}{T_0} - \frac{k}{2\,A}\right) = -\frac{1}{34.6^2}$$

(therefore $\frac{1}{T_2^2} = -\frac{1}{(T^1)^2} = \frac{1}{(2\,T_0^1)^2} - \frac{1}{(T^1)^2}$ is positive)

which shows that we should use the third form of the general integral which is

$$y = \left(R_1\,e^{+\frac{t}{T_2}} + R_2\,e^{-\frac{t}{T_2}}\right) e^{-\frac{t}{2\,T_0^1}}$$

Further, $m = \dfrac{-E}{\dfrac{A\,T_0}{k\,T^2} + 1} = -.354$ feet

$T_0^1 = 14.3$ sec. $T^1 = 51$ sec. $T_2 = 34.6$ sec., so that

$$z = +.354 + 1.33\,e^{-\frac{t}{165}} - 1.27\,e^{-\frac{t}{15.65}}$$

$s = -.00805\,e^{-\frac{t}{165}} + .0810\,e^{-\frac{t}{15.65}}$ which values give the following table:

Seconds $t =$	0	50	100	150	200
feet $z =$	+.41	+1.282	+1.079	+.881	+.746
feet per sec. $s =$	+.073	—.00261	—.0044	—.0032	—.0024

The time of the highest elevation is determined with $s = o$ from equation $o = -.00805\,e^{-\frac{t_1}{165}} + .0810\,e^{-\frac{t_1}{15.65}}$

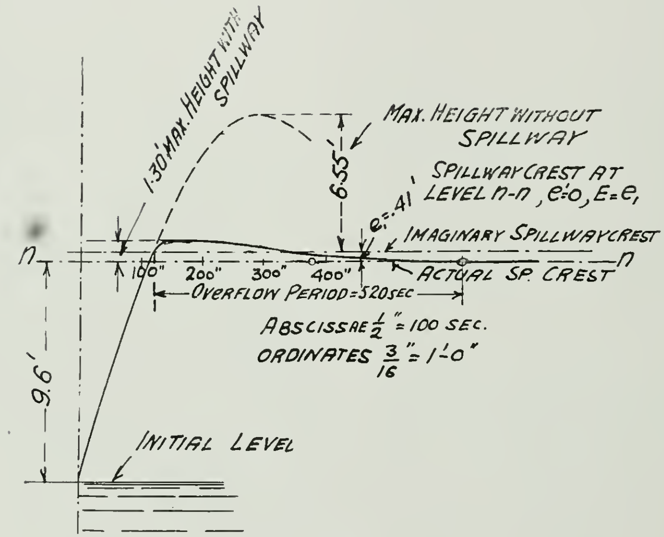

Fig. 9.

$$z = +.354 + \left[R_1\,e^{+\frac{t}{34.6}} + R_2\,e^{-\frac{t}{34.6}}\right] e^{-\frac{t}{28.6}}$$

$$= +.354 + R_1\,e^{-\frac{t}{165}} + R_2\,e^{-\frac{t}{15.65}}$$

$s = \dfrac{dz}{dt} = -\dfrac{R_1}{165}\,e^{-\frac{t}{165}} - \dfrac{R_2}{15.65}\,e^{-\frac{t}{15.65}}$ and for $t = o$

$+.410 = +.354 + R_1 + R_2$; $.073 = -\dfrac{R_1}{165} - \dfrac{R_2}{15.65}$;

therefore, $R_1 = 1.33$ feet and $R_2 = -1.27$ feet

to $t_1 = 40$ seconds and z max. follows:

$$z \text{ max} = +.354 + 1.33\,e^{-\frac{40}{165}} - 1.27\,e^{-\frac{40}{15.65}} = 1.30 \text{ ft.}$$

This water level corresponds to an overflow quantity of 300 cubic feet per second. For the determination of the ideal overflow height and the factor of proportionality, we used the maximum overflow quantity of 282 cubic feet per second. It is therefore shown that the assumption made that $u = 0.7$ is correct. The duration of the overflow period follows from

$$.41 = +.354 + 1.33\,e^{-\frac{t}{165}} - 1.27\,e^{-\frac{t}{15.65}}$$

and is $t_x = 520$ seconds.

And therefore the velocity s_x with which the water level reaches the ideal overflow elevation is:

$$s_x = -.00805\, e^{-\frac{520}{165}} + .0810\, e^{-\frac{520}{15.65}} = -.000346 \frac{\text{feet}}{\text{sec.}}$$

With these initial values the movement in the third period may be determined. Because we assumed that the spillway crest is at the elevation of the static level $n-n$, the overflow period goes further but with smaller fluctuations of water level and overflow quantities.

If the spillway is built not in the surge tank, but in the main conduit, the principal equation requires a supplement. According to Fig. 10, a shaft at the distance L' from the beginning of the conduit is driven down to the conduit with a section A', through which water from the conduit goes over a spillway whose ideal overflow crest is as before the distance E from the static level $n-n$. At the distance L'' is the surge tank with the section A''. In the hydraulic equilibrium with Q_1 cubic feet per second discharge through the penstocks, the water surface in the overflow shaft will be below the static level $n-n$ by the distance $h_1' = n'.v_1$; in the surge tank by h_1'' $(n' + n'')$ v_1. v_1 is the velocity in the conduit of the area a which corresponds to the discharge

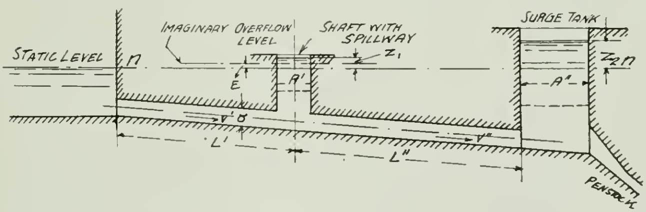

Fig. 10.

Q_1. n' and n'' are the function coefficients corresponding to the distances L' and L''. For flow fluctuations the distance z_1 and z_2 from the static level $n-n$ at the velocities v_1' and v_1'' and the water surfaces in shaft and surge tank will have different levels and there will be overflow in the shaft as soon as the water surface reaches the spillway crest. It is sufficient to carry through the solution of the principal equation for the latter period and to handle the first period as a special case of it.

For the purpose of simplifying the work, we consider only the case of sudden total shut-down. For both parts of the conduit, we get the following movement equations:

$$\frac{L'\, dv_1'}{g\, dt} + z_1 + n'.v_1' = o$$

$$\frac{L''\, .dv_1''}{g.dt} + (z_2 - z_1) + n''\, v_1'' = o \qquad - \qquad (86)$$

The equations which express continuity follow from the consideration that from the upper conduit in a unit of time dt, a quantity of water must flow into the shaft which is equal to the algebraic sum of—

1st—the quantity which flows away in the lower conduit, which is equal to $a.v_1''.dt$.

2nd—the simultaneous filling of the shaft with the quantity $A'.v_1'.dt$.

3rd—the simultaneous overflow quantity $k\,(z_1—E)\,dt$. But the water quantity which flows through the lower conduit in the time dt is also equal to the simultaneous filling $A''v_1''$dt in the surge tank. The following two equations express, therefore, the continuity

$$a.v_1' = a.v_1'' + A'\, s_1 + k\,(z_1 - E)$$

and

$$av_1'' = A''s_2 \qquad - \quad - \quad - \quad - \quad (87)$$

The motion equations and the second equation for continuity reach their values before as well as after the overflow on the spillway. The second equation for continuity is correct for $k = o$, for periods without any overflow. If we consider that $s_1 = \frac{dz_1}{dt}$ and $s_2 = \frac{dz_2}{dt}$ we may, with the aid of the continuity equations, eliminate the velocities v_1', v_1'' and their derivations. We get then two simultaneous differential equations of the second order, from which we eliminate again z_1 and its derivations, whereas for the determination of z_2 we get a linear differential equation of the fourth degree with constant coefficients, the integration of which does not involve any great difficulty.

In order to make the spillway especially efficient, we manage it so that the spillway crest lies below the static level $n-n$, and this in a distance which is equal to or a little less than $h_1' = n'.v_1$. In this case, after the shut-down is finished, a very rapid overflow will occur in the spillway and will continue, and finally there exists a constant flow over the spillway, whereby naturally as much flows through the upper conduit as goes away over the spillway and where the water level in the shaft, as well as in the surge tank lies at a distance under $n-n$, which corresponds to the hydraulic slope necessary for the flow through the upper conduit.

If in this case A' and the spillway widths are small enough with reference to the hydraulic slope, to keep the preceding fluctuations so near the static level of the water surface in the shaft, that the variation of the inflow to the shaft may be neglected, the problem becomes simplified, because the first motion equation drops out and in the first equation for continuity, the values $a.v_1'$ become constant and equal to q.

Considering that $s_1 = \frac{dz_1}{dt}$ and $s_2 = \frac{dz_2}{dt}$, we get from the first equation of continuity (87)

$$A'' \cdot \frac{dz_2}{dt} + A' \frac{dz_1}{dt} + k\,(z_1 + E) = q. \qquad (88)$$

and the second motion equation becomes zero.

$$\frac{L''}{g} A'' \frac{d^2 z_2}{dt^2} + r_2 A'' \frac{dz_2}{dt} + a\,(z_2 - z_1) = o \qquad (89)$$

From this last equation, z_1 and its derivative may be determined and substituted in equation 30c. For the solution of z_2 we get a linear differential equation of the third degree which may readily be integrated. The results of such an investigation are apparent in Fig. 11; we see that at the time of the highest water elevation in the surge tank the height of water flowing over the spillway is directly proportional to the height of the water in the surge tank above the static level, but the quantity of water is greater during the time the level in the surge tank is falling and continues until the level in the surge tank has reached its lowest elevation. The extent of the fluctuations is not only dependent upon the conduit, surge tank and spillway dimensions, but, naturally, also depends upon the area A'. The complete computation of the case would exceed the space available here.

(To be continued.)

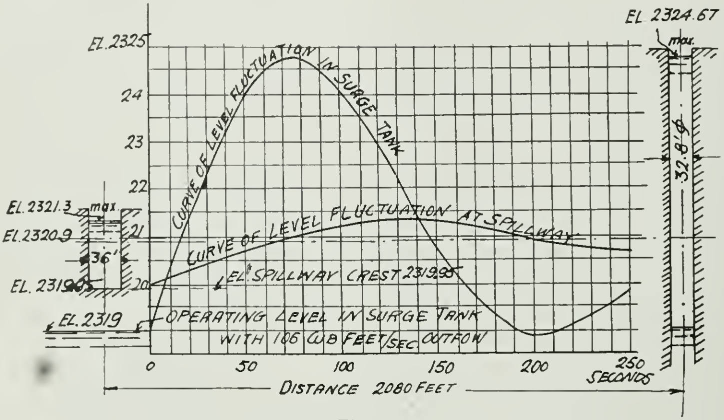

Fig. II.

FIRST INTERNATIONAL ENGINEERING CONGRESS.

THE first international assemblage of engineers to be known as the International Engineering Congress, and to be held at the Panama-Pacific International Exposition, San Francisco, from September 20-25, 1915, will be presided over by Col. George W. Goethals, who has accepted the office of honorary president. The sessions will be held in the new $1,000,000 auditorium now being constructed in the civic centre of San Francisco, the main hall of which has a seating capacity of 10,000. Section meetings will be held in the eleven minor halls in the great convention building.

The International Engineering Congress is to be conducted under the auspices of five national associations, viz.: the American Society of Civil Engineers, the American Institute of Mining Engineers, and the Society of Naval Architects and Marine Engineers, assisted by a committee of eighteen of the foremost engineers of California.

The vast scope of the congress is indicated by the fact that it will be divided into eleven groups of sub-congresses, the reports of which it is calculated will fill eleven large volumes. Chief among these branches will be that dealing exhaustively with the problems worked out in the construction of the Panama Canal, and the influence of the canal on world commerce, commercial trade routes and general transportation problems. Colonel Goethals will have charge of the presentation of all canal topics, and his papers and discussion will carry with them the authority and value of official reports. Aside from general engineering topics, the section devoted to the canal will be treated under 22 heads, as follows:

(1) Col. Goethals' general report; (2) Dry Excavation of the Panama Canal, by Col. Goethals; (3) Dredging the Canal; (4) Terminal Works, Dry Docks and Wharves of the Canal; (5) Meteorology and Hydrology of the Zone; (8) Designs of Locks, Dams and Regulating Works; (9) Methods of Construction of Same on the Atlantic Side; (10) Same on the Pacific Side; (11) Designs of Locks, Walls and Valves; (12) Spillways; (13) Gates of the Canal; (14) Electrical and Mechanical Installation; (15) Emergency Dams Above Locks; (16) Municipal Engineering and Domestic Water Supply in the Zone; (17) Reconstruction of the Panama Railroad; (18) Aids to Navigation of the Canal; (19) Geology of the Canal Zone; (20) The Working Force of the Canal; (21) Sanitation in the Zone; (22) Purchase of Supplies for the Canal.

Following Colonel Goethals' personal reports, each of these topics will be treated by the heads of departments or other attachés who were responsible for that part of the canal construction. These addresses and papers will constitute practically the official technical record of that great engineering feat. It will be published, forming the only printed record of its kind, and for this compilation, interesting to the layman no less than to engineers, credit is due to the exposition congress. Programmes for the other ten sections of the congress are in course of preparation.

Subscriptions are being received daily by local organizations which will act as hosts for this great body, a large proportion of these being from foreign bodies and foreign engineers. The most noted experts of the world in

all departments of engineering work are availing themselves of this opportunity to pass through the canal en route.

PERSONAL.

C. J. GIBSON has received the appointment of town engineer of Bowmanville, Ont.

D. F. McLEOD, former city engineer of New Glasgow, N.S., has become city manager of Lakefield, Fla.

R. C. HARRIS has received the appointment of resident engineer for the Alberta Division of the C.P.R., with office at Calgary.

R. L. HAYCOCK is in temporary charge of the Civic Waterworks and Sewerage Department at Ottawa, in succession to A. N. Beer.

J. D. EVANS, recently chief engineer of the Central Ontario Railway, has been appointed division engineer of the Ottawa Division of the C.N.R.

T. J. BROWN has been appointed a resident engineer and bridge and building master for the C.P.R. company, his office centre to be Cranbrook, Alta.

T. S. LOWE, road foreman of engines for the C.N.R. at Limoilou, Que., has been promoted to master mechanic of the Lake St. John Division, with office at Limoilou.

T. C. HUDSON, formerly master mechanic of the C.N.R. Company at Joliette, Que., has been appointed division master mechanic of the Quebec Grand Division of that system, with office at Joliette.

R. L. DOBBIN, formerly resident engineer on the Moose Jaw water supply scheme during the construction period of 2 years, has been selected to fill the position of waterworks superintendent for the Utilities Commission, Peterborough, Ont.

ARTHUR J. HILLS was appointed in August, general superintendent of the Ontario Grand Division of the Canadian Northern Ontario Railway system, with headquarters at Toronto. Mr. Hills is now in charge of operation, maintenance of way and motive power. He was a graduate of the University of Toronto in 1899.

R. W. McCONNELL, for many years a member of the geological survey staff of the Dominion Government, has been appointed to succeed R. W. Brock, recently resigned, in the office of Director of the geological Survey and Deputy Minister of Mines. Since the resignation of Mr. Brock, Mr. McConnell has been occupying the position of Acting Deputy Minister of Mines.

GEORGE COLLINS, from 1906 general manager and secretary of the Central Ontario Railway, and also from 1903 a director of the same road, has been appointed recently superintendent of the Ottawa division of the Canadian Northern Railway, with headquarters at Trenton, Ont. The former system was taken over this year by the C.N.R., and from 1882 up to that time, Mr. Collins has risen in continuous service with the Central Ontario system.

WILLIAM C. TOMKINS, who received in August the appointment of assistant to the vice-president of the Grand Trunk and Grand Trunk Pacific Railway companies, and who succeeded in that office Martin M. Reynolds, deceased in June, 1914, has been connected with the staff of the G.T.R. system since 1885. Following upon his first position as auditor of pay-rolls came the office of general manager. The next promotion was to the immediate staff of the president, where he became in 1908 secretary to the late Mr. Reynolds, vice-president in charge of finance and accounting. Mr. Tomkins received his recent appointment on August 1, 1914.

B. B. KELLIHER has resigned from his position as chief engineer of the G.T.P. Railway system, due to ill-health. For 30 years Mr. Kelliher has been engaged in railway construction, and has achieved the rank of one of the foremost mountain engineers of his generation; for the last 10 years, he has been actively engaged upon the construction of the G.T.P. railroad; and for 9 years of this latter period, he has been engineer in charge of this great engineering scheme. Mr. Kelliher was a native of Ireland and a student of Dublin University. After serving as an apprentice to a civil engineer in Dublin and being engaged on the surveys for the Mitchellstown and Fermoy and the Galway and Clifton roads, he went to the United States. From 1886 to 1890 he was employed with the Union Pacific Railway; and from 1890 to 1896, was assistant engineer of the Northern Pacific Road on the Cascade and Pacific Divisions. After further experience as division engineer of the Oregon Short Line, he was chosen for the difficult task of locating a line through the mountains of Colorado from Denver to Salt Lake City for the Denver, Northwestern and Pacific Railway, and joined the Grand Trunk Pacific staff on the completion of this work as division engineer at Winnipeg.

OBITUARY.

Mr. John Middleton, a member of a C.N.R. survey party, met death near Lytton, B.C., where he was killed by falling a distance of 70 feet from a ledge of rock.

The death occurred recently of Murdock Lloyd of Toronto, a mining engineer employed at the Tough Oaks Mines, Swastika, Ont. Mr. Lloyd was fatally injured in a boiler explosion.

McGILL GRADUATES AND THE WAR SITUATION.

The following letter has been sent to every McGill graduate:—

At a time like the present, when the destiny of the Empire is at stake, McGill University and its graduates should come forward and do everything in their power to help the common cause. The individual graduate probably does not fully realize the influence the graduates as a whole have in Canadian affairs. Over 5,000 educated men, holding important positions all over the Dominion and elsewhere, are a tremendous power and influence, particularly if their efforts are concentrated on certain fixed objects.

It was felt by the Executive of the Graduates' Society and by the Committee in charge of the Reunion, which it had been proposed to hold in the fall of 1915, that in the present crisis in the Empire something should be done; and it was decided to write a letter to every graduate, asking him to use all his influence towards patriotic ends.

In order to make our influence felt in a definite way it was thought that a fund should be started to which EVERY graduate of the university would contribute. The contribution of each individual would be for the nominal amount of one dollar, which would represent his patriotic vote and the signification of his intention to do everything possible to assist Canada in the responsibility and duty created by the war.

The vote of the McGill graduates will be deposited in cash form to the credit of the Canadian National Patriotic Fund.

You are, therefore, invited to send your cheque, or to enclose one dollar in some other form, to the Treasurer of the fund, Geo. C. McDonald, 179 St. James Street, Montreal.

An immediate response is necessary if this action is to have all the effect that is hoped for from it.

For the Executive,
JOHN L. TODD President.
WILLIAM STEWART. Secretary.

NEW ENGLAND WATERWORKS CONVENTION PROGRAM.

Of particular interest on the program which has been arranged for the thirty-third annual convention of the New England Waterworks Association, to be held at Boston, Mass., from September 15th to September 18th, will be the report by Chairman George C. Whipple, of the committee on statistics of filter operation. This will be the first of its kind in the history of waterworks conventions in America. Other papers of interest will be those read by Frank A. McInnes and Clarence Goldsmith, of Boston, on lessons to be learned from the great Salem fire.

At the "superintendents' sessions" there will be papers by many eminent men of foremost authority on the operation of waterworks plants; while additional committee reports will be given by Frank A. McInnes on "Standard Specifications for Cast-Iron Pipe," by Allen Hazen on "Meter Rates," and by Frederic P. Stearns on "Low Water Yields."

SECOND INTERNATIONAL CONGRESS OF MUNICIPAL EXECUTIVES, 1915.

At the First International Congress of Municipal Executives, London, Eng., it was resolved to grant the request of the American Commission of Municipal Executives, assembled by the Southern Commercial Congress, that the second assemblage of the Congress be held under the auspices of the commission at Washington, D.C., in September, 1915. Senator Duncan U. Fletcher of Florida, president of the Southern Commercial Congress, and chairman Clarence J. Owens of Maryland, managing director of the Southern Commercial Congress and director-general of the American Commission, will have charge of this second international congress, and have already commenced the arrangement of plans to make it the greatest convention of civic leaders municipal officials ever held.

JOINT CONVENTION.

A joint convention is to be held by the American Road Builders' Association and the American Highway Association in 1915, either at San Francisco or at Oakland, Cal., during the Panama-Pacific Exposition, the exact date not yet being determined.

RECENT ELECTION MADE BY THE INTERNATIONAL ASSOCIATION OF TESTING MATERIALS.

The council of the International Association of Testing Materials has elected as members of Commission No. 58 on "Standardization of Methods of Testing and Nomenclature of Road and Paving Materials," Prevost Hubbard, Assoc. Am. Soc. C.E., in charge of the division of roads and pavements for the Institute of Industrial Research, Washington, and lecturer in highway engineering chemistry at Columbia University, New York; and Arthur H. Blanchard, M. Am. Soc. C.E., consulting highway engineer, and professor in charge of the graduate course in highway engineering at Columbia University.

At the recent convention of the Canadian Union of Municipalities, which was held at Sherbrooke, Que., a resolution was unanimously adopted to the effect that Victoria, B.C., should be the centre at which the 1915 assembly of the union should convene.

INTERNATIONAL IRRIGATION CONGRESS.

The Twenty-first International Irrigation Congress will be held at Calgary, Alta., October 5th to 9th, 1914.

COMING MEETINGS.

NEW ENGLAND WATERWORKS ASSOCIATION.—Secretary, Willard Kent, Narragansett Pier, R.I. Annual convention to be held at Boston, Mass., September 15th to 18th.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

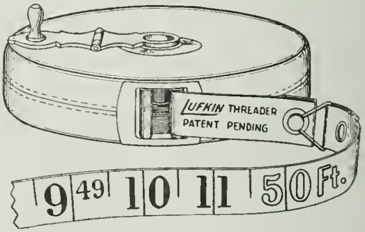
AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—Charles Carroll Brown, Secretary, Indianapolis, Ind. Meets at Somerset Hotel, Boston, Mass., October 21st, 22nd and 23rd.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

METALLIC TAPE "THREADER."

The Lufkin Rule Co. of Canada, Limited, Windsor, Ontario, has just put out a patented measuring tape attachment known as a Threader. It is a loop and stud arrangement, by means of which the tape, though securely fastened to the winding drum of the case when in use, can yet be readily detached from it and a new tape as readily attached, no manipulation of the case, case screw or drum being required to do this. Woven tapes are sometimes torn by accident or through long use often become soiled and worn in such a



way that they must be replaced while the case is yet in very fair condition. The case not receiving the same hard use as the tape line usually outwears it, and representing approximately half the value of the outfit it is of considerable importance that it be a simple matter for anyone to insert a new tape in the old case as often as necessary and thus get the fullest measure of use out of the case as well as the tape. Metallic tapes without cases are quite generally stocked by hardware houses, etc., and can always be easily obtained. The attaching is perfectly and easily accomplished by means of the Threader, which will hereafter be furnished with the company's metallic woven tapes without extra charge.

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

THE NATIONAL TRANSCONTINENTAL RAILWAY

GENERAL DESCRIPTION OF THE NATIONAL TRANSCONTINENTAL RAILWAY CONSTRUCTION, DETAILING THE METHOD OF SURVEYS EMPLOYED IN DETERMINING THE MOST DIRECT AND FEASIBLE ROUTE—STAFF ORGANIZATION, ETC.

By DUNCAN MacPHERSON,

Assistant to the Chairman in Charge of Operation, Transcontinental Railway Commission.

An act respecting the construction of a National Transcontinental Railway was assented to by the Dominion Parliament on the 24th October, 1903, which provided for the construction of a line to be operated as a common railway highway across the Dominion of Canada, from ocean to ocean, and wholly within Canadian territory.

This line was, by the act, divided into two distinct parts; the Eastern Division, from Moncton to Winnipeg, to be constructed under a government commission, and the Western Division (extending from Winnipeg to the Pacific Ocean) to be constructed by the Grand Trunk Pacific Railway Company.

The act provides that the Eastern Division shall be built from the eastern terminus, at Moncton, through the central parts of the Province of New Brunswick, and through the Province of Quebec, by the shortest available line, to the City of Quebec; then westerly, through the northern part of the Provinces of Quebec and Ontario, and through the Province of Manitoba to the City of Winnipeg, according to such plans and specifications as may be determined, having due regard to directness, easy gradients and favorable curves.

The commissioners and the chief engineer were appointed by order-in-council August 20th, 1904, and met within a few days for organization. One of the first questions to determine was in regard to the survey work to be undertaken during the autumn and winter on that portion of territory not covered by the Grand Trunk Pacific Railway parties who were out east of Winnipeg, in the direction of, and nearly up to, Lake Abitibi. It was decided to form the territory between Moncton and near longitude 84° into four districts—"A," "B," "C," "D":—"A" from Moncton to the boundary between the Provinces of New Brunswick and Quebec, supposed to be about 290 miles; "B" from the boundary to Clear Lake, about 420 miles; "C" to the provincial boundary between Quebec and Ontario, about 300 miles; "D" to the longitude 84°, about 240 miles.

Soon after these four districts had been formed, the commissioners arranged to take over from the Grand Trunk Pacific the survey parties east of Winnipeg, with their supplies, plans, profiles, etc., and to organize two more districts, "E" and "F," thus covering the whole distance between Moncton and Winnipeg. District "E" extends about 255 miles westerly from the west boundary of "D" to a point about 30 miles west of Lake Nepigon. District "F" extends from this point to Winnipeg, about 385 miles.

The total distance from Moncton to Winnipeg was estimated to be about 1,900 miles, on what was assumed to be the most direct feasible route. The problem to be solved of definitely locating this most direct and feasible route was not an easy one, when it is remembered that, for more than half the distance, the line of general directness ran through an unsurveyed, unsettled and practically unknown region, cut up in all directions with a network of lakes and rivers, many of them not shown on any existing maps and, when so indicated, often found to be entirely misplaced. Our engineers had, therefore, in many cases, to make their own maps as the surveys proceeded and, in all cases, to correct and complete existing maps.

During the autumn of 1904 and the following spring, some 34 survey parties were equipped and sent out; and before the end of 1905 there were 45 parties in the field, consisting of about 18 men each, not counting a large number of men engaged in transporting supplies by canoe and packing in summer and by dog train in winter.

The early survey parties of 1904 were supplied on the time-honored "flour, pork and beans" food basis, and as a result of extreme cold and lack of variety in food, some of them suffered severely from scurvy.

The food schedule was revised on a liberal basis in 1905, with a plentiful assortment of soup, vegetables, jam, etc., with the result that not only was scurvy no longer heard of, but the men being so well supplied with wholesome food worked with much more energy and cheerfulness, showing that seemingly luxurious food proved a real economy.

Each survey party had an engineer in charge, transitman, leveller, topographer, draughtsman, rodman, picketman and 2 chainmen, cook and eight or nine axemen and packers. Each party was given certain governing points to connect and instructed to thoroughly exhaust the possibilities for the most favorable and reasonable direct line between these points. Barometric explorations and compass lines were followed by preliminary lines run with transit, and plans were plotted with 10-ft. contours on a scale of 400 ft. per inch. With these plans and profiles on same scale, projected locations were made on the most favorable lines and afterwards actually run on the ground

and called a first location. These plans and profiles were plotted in the field, and tracings, with reports, sent to headquarters monthly. These reports were carefully gone over by the chief and assistant chief engineers, necessary changes suggested, and instructions issued accordingly. Whenever the head of a party completed what he considered the best possible first location, the engineer in charge was changed and another man given a chance to improve the line by making his best attempt at a revised location. The original head of a party, or a third man, was given a chance to still further revise for a final location. In this way it was found that a healthy rivalry was established and good results obtained. Revision of location is, however, never considered as finished until construction work is well under way; and it is often found, after the line is cleared, that slight changes will effect a very considerable saving. An equation table giving definite values for savings in distance, curvature, rise and fall, etc., was furnished all parties in the field, so that when the estimated cost of construction of any two or more lines was had, the better one to adopt from all points of view could be at once determined.

Maximum Curves.—The maximum curve used is 6° (Rad. 955 ft.) and is only used sparingly where the topographical conditions prohibit an easier radius with reasonable cost. All curves of 1° (Rad. 5,730 ft.) and sharper are connected to their tangents with easy spirals.

The maximum grades decided upon are, so far as the writer is aware, the easiest on any transcontinental line in America, being on tangents of 0.4% = 21.1 feet per mile adverse to the major or eastbound traffic, and 0.6% = 31.68 feet per mile against the comparatively minor westbound traffic. These maximum grades are used sparingly and only for the purpose of avoiding heavy work. On curves, the grades are reduced 0.04 ft. per degree in the index of the curve, so that, on the maximum curve of 6°, the maximum eastbound grade would be 0.4 minus $6 \times 0.04 = 0.16\%$ or 8.44 ft. per mile.

All curves of 1° and over are spiralled at both ends. Vertical curves are used at all intersections of grades. The width of embankments at sub-grade is 16 ft. for banks 16 ft. or less in height; the width of embankments for greater heights, 18 ft. Earth excavations are 22 ft. wide at sub-grade; rock excavations, 20 ft. wide at sub-grade. Slopes of earth embankments are 1½ to 1; rock, 1 to 1. Slopes of excavations are: earth, 1½ to 1; loose rock, 1 to 1; solid rock, ¼ to 1. The depth of ballast is 18 in. between rail base and sub-grade, or 11 in. below the under side of tie 7 in. thick.

The whole line between Moncton and Winnipeg, with the slight exception of short approaches to the Quebec Bridge on 1% grades, was definitely located with the above-mentioned very easy maximum grade; but at one point in New Brunswick, at mileage 146 from Moncton, it was found that, by the insertion of about 12½ miles of 1.1% grade adverse to eastbound traffic, a saving would be made of 17.2 miles in distance, nearly two million dollars in construction, and one and a quarter million dollars in capitalized operating value.

At another point in Quebec, near mileage 286 from Moncton, a similar grade about 10 miles long adverse to westbound traffic was found to effect a saving of 18.8 miles in distance, about half a million in construction, and over three-quarters of a million dollars in capitalized operating value. These possible temporary grades were adopted with the corresponding saving in distance and cost. If the future traffic of the road justifies the expense, these two short lengths of standard grade can be built at any time.

The proviso for directness of alignment proved a very wise precaution; as, in the Province of New Brunswick especially, the people inhabiting the fertile, well settled St. John River Valley very naturally desired to secure the advantage which would accrue to their section of country by the construction of a transcontinental railway. The fact that this would unnecessarily lengthen the line by 29 miles, a most important factor on a through route, did not appeal to them as strongly as to the inhabitants of the more western provinces anxious to secure the best possible outlets for the rapidly increasing volume of freight from the great wheat field of the west. Fortunately, our engineers were able to prove that the direct line would not only be much shorter and effect a great saving in operation, but also that the total cost of construction would be very considerably less. An additional factor in favor of the direct line was the opening up of new territory not hitherto possessing railway facilities; whereas, the St. John Valley is already served by the Canadian Pacific, and to some extent by the Intercolonial Railway.

The surveys being well advanced for some distance east of Winnipeg and west of Quebec, tenders were called, closing on the 12th March, 1906, for 150 miles of line from the north side of the St. Lawrence at Cap Rouge, westward, and for a steel viaduct 3,000 ft. long, 150 ft. high, across the Cap Rouge Valley; also for 245 miles from near Winnipeg to Peninsula Crossing, near the proposed junction with the Fort William branch of the Grand Trunk Pacific Railway. This branch line had been under construction for some time; and the intention was, as soon as it and the portion of the main line between the junction and Winnipeg were completed, to start operating between Fort William, Winnipeg and the west, thus giving another outlet to the Great Lakes from the western wheat fields.

The summer of 1906 was a busy one in railroad construction all over the continent of North America, the result being that good men were almost impossible to obtain, so that progress was not as fast as was anticipated on the two first main contracts let. The financial depression in 1907 proved, in some ways, a blessing in disguise to railway contractors; as only roads which were strong financially were able to proceed with any new construction; also, men were more plentiful. From time to time as the final location was completed on different sections, new contracts were let until, on October 29, 1908, the last contracts were let on Districts "D" and "E". In the summer of 1908, 21,000 men were at work on the various contracts between Moncton and Winnipeg.

The originally estimated distance of 1,900 miles between these points had been reduced gradually by repeated revisions of location at various points to a distance of 1,804.8 miles. This distance is 261 miles less than the shortest distance over any other combined railway between Moncton and Winnipeg. The distance between Winnipeg and Quebec City over the Transcontinental Railway, will be 1,351 miles, which is 215 miles shorter than the shortest existing line, and the grades are so much more favorable that engines of equal capacity could haul nearly twice the load on the former line than they could on the latter.

Transportation of grain by water has always been much cheaper than by rail, but the latter has been slowly and surely cheapening until at the present time, when the easy gradients and tremendously powerful locomotives of modern lines will make a combination of land difficult to excel, or peradventure, to equal on water.

The distance from Winnipeg to Quebec, via rail to Fort William, and lake, canal and St. Lawrence River to

Quebec, is 1,771 miles, involving five trans-shipments of wheat. The distance on the Transcontinental Railway will be 1,351 miles, and, as the maximum eastbound grade is 21.12 feet per mile, compensated for curvature, a heavy modern locomotive is capable of hauling on this grade a gross load behind the tender of 4,290 tons. Assuming the tare 33⅓% of gross load, the net paying load would be 2,860 tons, equal to 95,333 bushels of wheat in one train. If we assume the earnings of such trains to be $4.40 per train mile (the average earnings of the Canadian Pacific Railway freight train miles for 1913 were $2.99 for an average of 440 tons per train), we find the cost per bushel over the 1,351 miles between Winnipeg and Quebec to be 4.25 cents. The lowest rate that the writer is aware of having been in force from Fort William to Montreal, via the lake, canal and St. Lawrence River, a distance of 1,216 miles, was 4 cents per bushel in 1908. This four cents per bushel for 1,216 miles would be equivalent to 4.44 cents for 1,351 miles, so that at 4.40 per train mile, the engines above referred to could haul grain on the Transcontinental eastbound from Winnipeg to Quebec for 0.19 cents per bushel cheaper than the cheapest existing water route could haul it the same distance, and 10.86 cents per bushel cheaper than the present combined rail and water rates between the two points in question. In brief, at about one-quarter the present rail and water rate. It would appear that the days of the absolute supremacy of water transportation were in danger of at least a partial eclipse.

The comparative values of Transcontinental Railway and existing lines between Winnipeg and Quebec would be as follows:

From Winnipeg to nearest Atlantic seaport (Quebec) via Transcontinental Railway, is 1,351 miles (allowing 6 miles from north end of bridge to city) or 215 miles shorter than the shortest existing railway. Assuming the operation of only 6 daily trains each way, and the cost of a train mile $1.50, this shortening in distance alone is worth $35,312,500 in operating value capitalized at 4%, without taking into account the enormously increased earning value of the whole line due to its extremely low grades; but the maximum eastbound grades on Transcontinental being 0.4%, and westbound 0.6%, as against 1% on existing lines, not only can freight trains of about twice the capacity be hauled on former, as compared with the latter, but with the shorter distance they would make the trip in about 12 hours less time. Omitting consideration of this saving in time, which is in itself of considerable value, the operating values of the N.T.R. and existing lines can be fairly compared as follows:

Yearly cost of operating 20 daily trains on existing lines over 1,566 miles = 1,566 × 2 × 10 × 365 × $1.50	$ 17,147,700
Yearly cost on Transcontinental, 1,351 miles, is based on 12 daily trains, because they can haul the tonnage of 20 trains on existing lines = 1,351 × 2 × 6 × 365 × $1.50	8,876,070
Yearly saving in operation by N.T. Railway.	$ 8,271,630
Capitalized at 4%	$206,790,750

This $206,790,750 is only the increased earning value of the Transcontinental Railway between Winnipeg and Quebec over a line with 1% grades 215 miles longer.

As the whole line from Winnipeg to Moncton is expected to cost $161,300,000, of which about $40,000,000 was expended east of Quebec and $121,300,000 west of Quebec, it would appear, therefore, that even with moderate traffic the Transcontinental is capable of earning good interest on its enormous cost.

Owing to the comparative inaccessibility of parts of the line, the last 300 miles of it were not actively under construction until the end of 1910; but by that time it was covered with workmen, rock drills, steam shovels, and all the necessaries of modern railway construction.

In order to keep check on the rate of progress of the work, the writer introduced on this line percentage forms of reports, being modifications and extensions of somewhat similar forms in use on the Canadian Pacific Railway. This form is returned monthly by the division engineers, through the district engineers; and it is then graphically plotted on a diagram which shows at a glance, not only the percentage done during the month on grading, ballasting, and all the other items of construction, but also shows the percentage done to date under each of these headings and the percentage done of the whole work in each main contract. This form of report has been found invaluable as an aid in answering requests for information from the House of Commons when in session, and for compiling our annual reports.

Our engineering organization consisted of a chief engineer, assistant chief engineer, bridge engineer, district engineers—each in charge of a district from 250 to 400 miles long—division engineers—each in charge of from 40 to 50 miles—and resident engineers—each in charge of 10 to 15 miles.

The final connection of track between Moncton and Winnipeg (except for Quebec Bridge) was made in November, 1913, and the car ferry for bridging this gap, capable of carrying 27 loaded freight cars, or a passenger train, has already arrived at Quebec.

The completion of ballasting, buildings, etc., has been pushed vigorously this season, so that it is confidently expected to have the whole line ready for transporting this season's wheat crop in October, 1914.

NEW FOREIGN TRADE COMMENCING IN AMERICA.

Gleaned from the press and from consular offices, the following items of a few of the immediate needs of China, South America and Europe should aid American manufacturers. A consular report from Rome, Italy, states that owing to all steel material for the ordnance of the ships under construction for the Italian navy being tied up in France or Germany, the navy is looking to the United States to furnish the material; and investigations have already been made among the American steel plants. One hundred and fifty thousand tons of steel are wanted. A telegram from the American minister at Caracas, Venezuela states that cement is needed in that country.

The export department of the United States Steel Corporation has received a contract for 100 miles of 80-lb. steel rails to be shipped to South America. At present Shanghai, China, is experiencing a building boom and the demand for building materials is constantly increasing, according to a consular report. At Hankow, China, there is an opportunity for the establishment of an American firm carrying a full-sized stock of building materials.

Small orders for the export of fabricated steel and machinery are already being received by American manufacturers as a direct result of the effect of the European war on industry in England and Germany. Inquiries are coming to hand at a rate that bids fair to act as a forerunner of the anticipated development of export trade, not only with South America, Africa and Australia, but with England and with Scandinavian and Mediterranean countries.

DESIGN OF NEW AND RELIEF SEWERS.

In several previous issues (August 27th and September 3rd) of *The Canadian Engineer* articles appeared dealing with special phases of the new sewerage plan for the City of Cincinnati. The sewerage investigations formed the subject of a very complete report recently issued. Another portion of it that contains an abundance of information for sewerage and municipal engineers is based on that portion of the work in connection with the design of new and relief sewers, which is chosen as the subject of this article. This work was under the direction of Mr. F. J. Van Hook, from whose report we present the following:

A critical study of the existing sewerage system of Cincinnati was made with a view to recommending such improvements as would provide relief in districts subject to flooding in times of storm, and such new sewers as may be required for districts not provided with sewerage facilities. In the design for the new sewers recommended the combined system of sewerage was employed. Since the quantity of house sewage is relatively very small, as compared with the storm water-flow, it is evident that the problem presented is one of storm sewer design.

Rainfall and Run-Off.—Before taking up the detailed studies for sewerage improvements, analyses were made of the several factors controlling the determination of the amount of surface drainage for which provision should be made in the design of storm sewers. The factors considered are as follows: (1) Intensity of rate of rainfall. (2) Relation between rainfall and run-off, or the proportion of rainfall which immediately reaches the sewers. (3) Extent and shape of the area to be drained. (4) Surface slopes.

Many attempts have been made to establish relations between these factors and to express them in formulæ. As there appeared to be no method which had been regularly and continuously used in Cincinnati for the determination of the amount of storm drainage for which sewers and drains should provide, a review was made of the more commonly accepted methods and formulæ to ascertain if any one of these was applicable to local conditions.

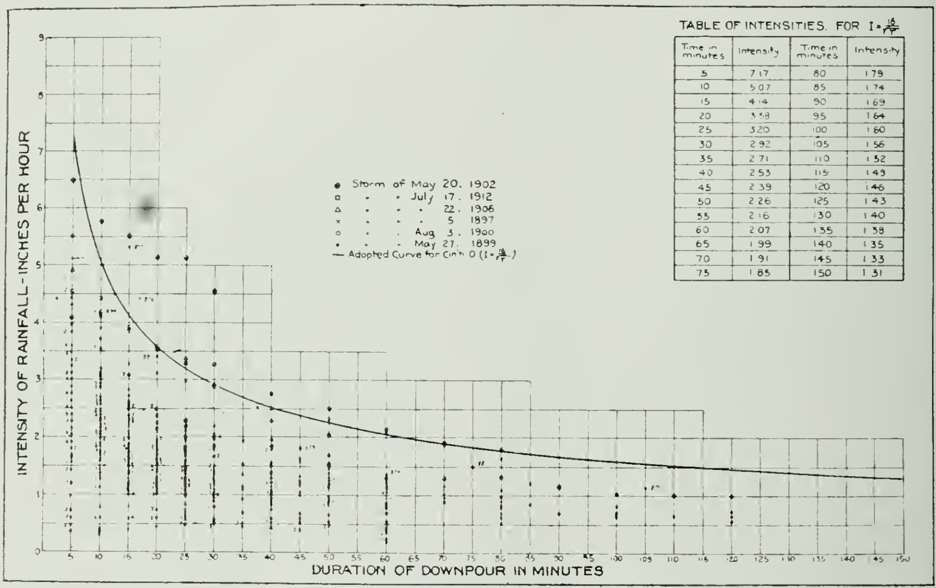
Table I.—Rates of Precipitation Which Fix Lower Limit of Excessive Precipitation in Storms Since 1904.

Period (minutes).	Rate (inches).	Period (minutes).	Rate (inches).
5	0.25	40	0.60
10	0.30	45	0.65
15	0.35	50	0.70
20	0.40	60	0.75
25	0.45	80	0.80
30	0.50	100	0.90
35	0.55	120	1.00

Most of the run-off formulæ are based on conditions existing in the particular city or locality for which they were derived and it is, therefore, evident that these should not be used excepting under similar conditions. Also, some formulæ are made dependent upon an adopted maximum rate of rainfall which is kept constant. On the other hand, the use of the so-called "rational" method of analysis through the introduction of the element of time permits of a varying rate of rainfall immediately dependent upon the area, shape and slope of the territory to be drained.

Also, on account of the unusual topographic features prevailing in Cincinnati, producing numerous small drainage areas with comparatively steep surface slopes in the outlying districts and flat slopes in the older portions of the city, it is important that the proper rainfall intensity and run-off for short periods of time should be accurately determined.

In view of these facts, it was concluded to adopt the "rational" method in determining the amount of storm



Time in minutes	Intensity	Time in minutes	Intensity
5	7.17	80	1.79
10	5.07	85	1.74
15	4.14	90	1.69
20	3.58	95	1.64
25	3.20	100	1.60
30	2.92	105	1.56
35	2.71	110	1.52
40	2.53	115	1.49
45	2.39	120	1.46
50	2.26	125	1.43
55	2.16	130	1.40
60	2.07	135	1.38
65	1.99	140	1.35
70	1.91	145	1.33
75	1.85	150	1.31

Fig. 1.—Relation Between Intensity and Duration of Rainfall, Cincinnati, 1871 to 1912.

drainage for which provision should be made. This formula may be expressed as follows:

$$Q = A\,C\,I$$

in which,

Q = the discharge in cubic feet per second.
A = the area drained in acres.
C = the ratio of run-off to rainfall.
I = the intensity or rate of rainfall during the period of concentration.

The procedure in this method of analysis is as follows:

(1) The time is first approximated by observing the surface or sewer slopes, estimating the sizes of pipe necessary and, assuming that they run full, determining the velocities. The time necessary for flow from the remote portions of the drainage area under consideration can then be calculated.

(2) With the time factor approximated, the intensity or rate of rainfall is determined from the rainfall intensity curve or equation.

(3) The run-off coefficient C, or reduction factor, is then determined by estimating the probable future increase in the percentage of impervious area.

(4) Having determined the rate of rainfall and the run-off coefficient, the discharge may be calculated and the sizes and grades of sewers determined in the usual manner. A closer estimate can then be made of the time factor and, if found necessary, a second calculation made of the sizes and grades.

Intensity or Rate of Rainfall.—The use of the "rational" method of analysis requires a thorough study of the local rainfall records for the purpose of determining a rainfall intensity curve which shall define the limit of excessive storms for which provision should be made in the design of storm sewers. By means of this curve the rate of rainfall can be determined for any period of time.

Rainfall Records.—Rainfall records for Cincinnati have been kept by the U.S. Weather Bureau from 1871 to date. Through the courtesy of the local forecaster of the weather bureau, these records have been examined and data relating to significant storms taken from them and made available for use as the basis of the rainfall studies.

The U.S. Weather Bureau published in 1912 the total monthly rainfall for each year from 1871 to 1912 inclusive, together with the total annual precipitation and the mean precipitation for each month, and for each year. These data were available but were not of particular use in the rainfall studies made in connection with the sewerage problem.

Unpublished Data Furnished by U.S. Weather Bureau.—(1) The records of heavy rainfalls having a total precipitation of 1.5 ins. or more, in 24 hours, or having a rate of 1 in. per hour for shorter periods, with extracts from the daily journal, from 1871 to 1897, were tabulated.

(2) The hourly amounts of precipitation during the storm of march 12 and 13, 1907, during which 7.19 ins. of rain fell during 48 consecutive hours were tabulated. While this was an exceptionally heavy rainfall extending over a long period of time, it did not give the very high intensities which make it of great significance in the problem of sewer design.

(3) The accumulated amounts of excessive precipitation from July 1, 1897, to July 31, 1912, for short periods of time from 5 minutes to 120 minutes were tabulated. From 1897 to 1904 the amounts were tabulated for each 5 minutes for storms in which the rate of precipitation equalled or exceeded 0.25 in. in any 5 minutes or 0.75 in. in 1 hour. After 1904 the amounts are tabulated for all storms during which the rates of precipitation equalled or exceeded in any period those given in Table I.

The data mentioned in the preceding paragraph were compiled from the charts taken from the automatic recording rain gauge at Cincinnati. These are the storms which form the most reliable basis for studies of intensity of precipitation and, while the older records furnish some valuable data the chief reliance must be placed on the records of the last 15 years.

Re-Arrangement of Data Furnished by Weather Bureau.—The table mentioned under paragraph 3, above, gives the amount of accumulated rainfall by periods ranging from 5 to 120 minutes, from the beginning to the end of excessive precipitation but does not give the maximum rainfall for each length of period indicated. A table was

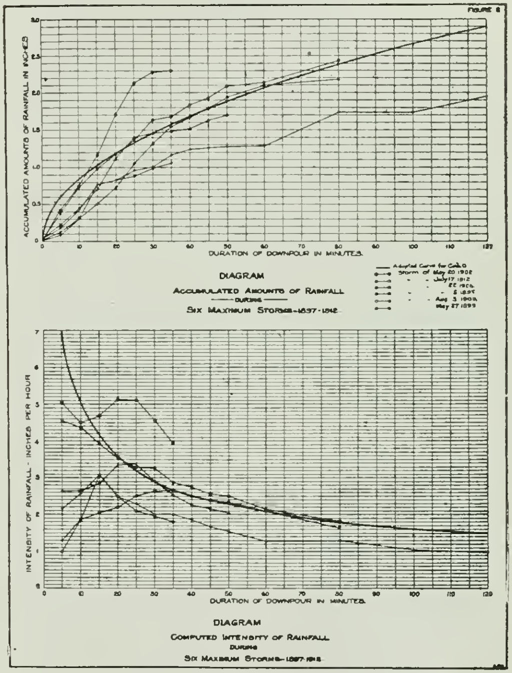


Fig. 2.

prepared to give the maximum precipitation for periods of from 5 to 120 minutes' duration. In this table the precipitation given for any specified period was the maximum amount falling during a period of such duration. For example, during the storm of September 13, 1910, the maximum quantity of precipitation during any 10 minutes was 0.41 in., whereas the amount which had fallen at the end of the first 10 minutes of excessive precipitation was but 0.21 in., and the former figure does not necessarily include the latter.

The intensity of precipitation was calculated for short periods of from 5 to 120 minutes for each of the significant storms, the result of said calculations being tabulated. These calculations are based upon the maximum quantity of precipitation during the period specified, as indicated by the data in the tabulation mentioned in paragraph 3. The intensity tabulation includes data re-

lating to 93 storms occurring from July 5, 1897, to July 17, 1912. These data form the basis of the studies which have been made to determine the rate of rainfall for which provision should be made in designing sewers and upon which the rainfall curve hereinafter described has been based.

An examination of all records from May 31, 1871, to July 17, 1912, indicates that there have been 63 storms during which the intensity for some period of time was equal to or in excess of 1 in. per hour, and which produced a total rainfall of at least 0.5 in. during the stated period. The data relating to these storms are compiled in a table, entitled "Intensity of Precipitation During Excessive Storms at Cincinnati," and are arranged in order of descending intensities.

In another table entitled "Excessive Rainfall at Cincinnati," there have been compiled the data relating to all storms of excessive total rainfall or excessive intensity, arranged by months. This table indicates that there have been 92 storms since 1871 when the total rainfall amounted to or exceeded 2 ins., or, where the intensity amounted to or exceeded 1 in. per hour for a period in which the precipitation was 0.5 in. or more. There are given in this table the total precipitation for the whole storm, as well as the amount of precipitation, duration and intensity of precipitation during the period of excessive rate of rainfall.

Diagram of Intensity and Duration of Precipitation.—On Fig. 1 the rate of precipitation of each of the excessive storms for periods of from 5 to 150 minutes has been plotted as has also a curve which marks approximately the upper limit of all storms, except that of May 20, 1902, which was of extreme intensity. It is unfortunate that records showing the rates of precipitation are not available for a period of more than 15 years, but the fact that there have been during this time four storms in which the intensity was practically that shown by the curve, indicates that such storms may occur at intervals of from 3 to 5 years. It has been deemed wise to use in the design of the storm sewers, a curve, represented by $i = \frac{16}{T^{0.6}}$ to include these storms, in which i = intensity of precipitation and T = duration of period under consideration. It has not, however, been deemed wise to include the extreme storm of May 20, 1902, which, based on present records, is not likely to occur oftener than once in 15 years and probably will recur at even greater intervals.

This curve is higher than the curves which have been adopted in several other places, but appears to be fully warranted by the rainfall data accumulated in Cincinnati since 1871 and particularly in view of the rainfall data secured by means of the automatic recording rain gauge of the U.S. Weather Bureau during the last 15 years.

The topography of Cincinnati is such that the time of concentration in most of the sewers is very short, this making that part of the curve dealing with intensities for periods of from 5 to 30 minutes rather more important than that part dealing with intensities of periods greater than 30 minutes.

The intensities indicated by the curve have not been exceeded materially except by one storm, that of May 20, 1902. The storm of July 17, 1912, slightly exceeded the intensity indicated by the curve but the excess lies well within the limits of unavoidable errors.

In Fig. 2 the rainfall records for six maximum storms from 1897-1912 have been platted on two diagrams, the upper diagram showing the accumulated amounts and the lower diagram the actual intensity of precipitation for the successive periods of time. For purposes of comparison, the curve adopted for use in designing sewers has been shown on these diagrams.

Ratio of Run-Off to Rainfall.—Having determined upon the intensity or rate of rainfall for which provision should be made, the next factor of importance is the determination of the proportion of the rainfall which immediately reaches the sewers in any section of the city. This proportion of the ratio of run-off to rainfall is relatively difficult of determination, not only for present conditions but also for future development. Some of the factors which influence its determination are: the extent of improvement and development within the area, the surface slopes, character of the soil, frequency of storm inlets as well as the capacity of the tributary or lateral sewers to carry off the storm water.

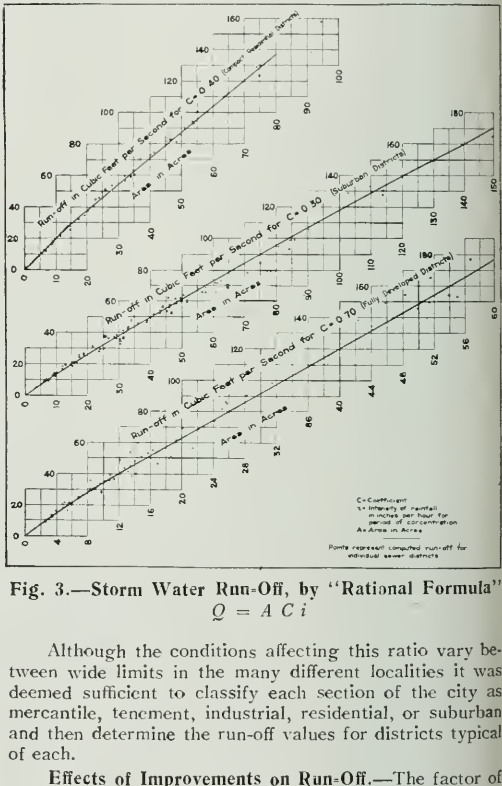

Fig. 3.—Storm Water Run-Off, by "Rational Formula"
$Q = A\ C\ i$

Although the conditions affecting this ratio vary between wide limits in the many different localities it was deemed sufficient to classify each section of the city as mercantile, tenement, industrial, residential, or suburban and then determine the run-off values for districts typical of each.

Effects of Improvements on Run-Off.—The factor of greatest importance is the extent to which each of these districts is improved and developed by buildings and pavements. To furnish the data bearing on this point surveys were made in the following districts which were selected as representing typical conditions:

(1) Mercantile district. (Walnut Street Sewer.)

(2) Tenement district. (Densely populated, Clark Street Sewer.)

(3) Combined industrial and densely populated district. (Bader Street Sewer.)

(4) Residential districts. (Walnut Hills, Bloody Run Sewer.)

In each of these districts the area covered by roofs, pavements, walks, yards, lawns, and the undeveloped ter-

ritory were ascertained and to these different classes of surfaces run-off values* were applied and a final value determined upon for that district. The nature of the results obtained by these surveys and computations are shown in Tables II. to V.

Sewer Gaugings.—In addition to analyses of the surfaces of these selected typical districts, and the determination of the proportions of pervious and impervious areas, gauging stations were established in the sewers draining these districts, for the purpose of furnishing data which will serve both as a check on the method of analysis used and the relation between the rate of rainfall and the storm flow in the sewer.

To gauge the storm flows in the mercantile district an automatic clock-recording sewer gauge was placed in a side chamber of a sewer in that district. This gauge registers on a chart the depth of water flowing in the sewer during the progress of a storm. At the same time records of the rainfall are obtained by the government rain gauge located on the postoffice building, which lies within the area drained by this sewer. For the residential district a similar sewer gauge was placed in a side chamber of a sewer in that district. In order to obtain the rainfall records within this drainage area, an automatic tipping bucket rain gauge of the Frieze type was installed by the city.

The storm flow in the Clark Street Sewer, in the tenement district, is measured by means of a gauge of the maximum or flood-flow type, consisting of a staff with small bottles attached on either side which are filled as the water rises in the sewer, the highest bottle filled registering the maximum depth of flow. Other gauges of the same type were set at manholes in six other sewers.

These gauges have been maintained since June 1, 1913, but the records obtained thus far have been too meager to warrant any deductions, especially since the storms of the last five months have been of very moderate intensity and of short duration. To obtain conclusive results from storm flow gaugings it is necessary that they be extended over a long period of time in order that a sufficient number of records of storms of great intensities and sufficiently long duration may be secured. Such records will be of the greatest importance in the design of storm sewers for Cincinnati, and it is therefore to be hoped that these gaugings may be continued for several years. Fig. 4 shows details of one form of gauging chamber.

Run-Off Diagram.—Before the analyses of the improvements in typical districts were completed designs were in progress for new and relief sewers in the various parts of the city. In these designs the rational method was used and the following coefficients were adopted for the determination of the amount of run-off to be provided for:

C = .30 for suburban districts where little future development may be expected.

C = .40 for residential districts.

C = .70 for densely populated and completely developed tenement and small block districts.

The amounts of run-off which were determined in the course of the numerous designs have been plotted and curves projected by the use of which run-off quantities can be determined directly for any area in question without otherwise laborious computation work. These curves, shown on Fig. 3, have been used for the later preliminary studies. For completely developed commercial districts higher coefficients should be used.

Method of Study.—With the completion of these preliminary studies, and decision as to method of design, the preparation of plans for new and relief sewers was at once started, the problems generally recognized as most urgent being attacked first.

Data Available.—The complaints received were used as an index to the localities or districts in most urgent need of relief sewerage. For the study of these districts it was necessary to have at hand the records of existing sewers, as well as the proper portions of the topographic map. In so far as possible the two branches of the Division of Sewerage Investigations which were carrying on

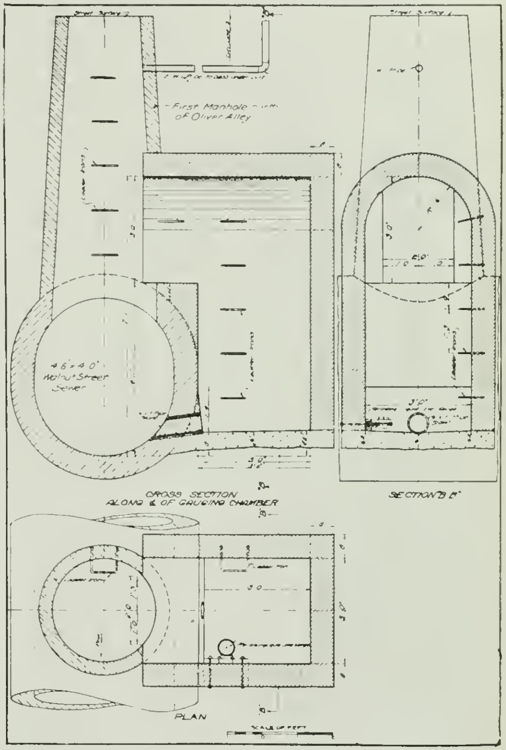

Fig. 4.—Details of Typical Gauging Chamber.

these surveys, directed their efforts in such a way as to secure the necessary data as soon as possible. But the fact that such data were not at once available in the various parts of the city requiring sewerage plans has been a handicap to the progress made in these relief investigations.

Procedure.—To determine the cause of cellar floodings or other defective drainage and to recommend the most suitable relief measures, necessitated an exhaustive study not only of the sewers in the immediate vicinity of the floodings but in the adjacent territory as well, inasmuch as it was often necessary to divert portions of the drainage into adjacent sewer systems. For this purpose all existing sewers and inlets were plotted on the portion of the topographic map covering the district under investigation. The district was then subdivided to such an extent that the drainage to each inlet could be determined.

The data were then tabulated in a manner which indicates at a glance at what points the existing sewer is of insufficient capacity, as well as the sizes and grades necessary for the proposed relief sewer. To supplement these studies a house-to-house canvass was then made to determine the extent of the territory affected by defective sewerage as well as to serve as a guide in the recommendation for the proposed relief.

The flooding of cellars by backwater from sewers, and other causes of defective sewerage have been traced to one or more of the following causes:

(1) The improper use of sanitary systems of sewers by the connection of roof leaders and street inlets.

(2) Inadequate provision for storm drainage in sewers intended to receive it.

(3) Defective construction of combined sewers.

The problem of providing relief for such conditions was, therefore, somewhat different from the design of new sewerage, inasmuch as it is obvious that the existing sewers should be used to their fullest extent. In some cases sufficient relief could be obtained by replacing the local sewer with one of larger capacity, in others it was necessary to cut off and divert portions of the drainage into adjacent systems, while in some extreme cases it was found necessary either to reconstruct the sewer throughout its entire length to the outlet, or to provide an addi-

Table II.—Run-Off from Improved Areas in Typical Commercial District.

Area: 30.4 acres.

Character of District: Commercial. Area covered by office buildings, stores and other business houses. No undeveloped area.

Soil: Sand and gravel.

Character of improvement.	Area in sq. ft.	Per cent. of total area.	Estimated degree of imperviousness.	Equivalent impervious area, sq. ft.	Per cent. total area impervious.

Impervious coefficient for district, 69.9%.

tional storm sewer. The latter alternative, however, was rarely possible, as it is generally necessary to place the proposed sewer at the same depth as the existing sewer in order to intercept the tributary or lateral sewers.

Studies for relief sewers were carried to a point where it was possible to recommend the best and most economical methods of relief, as well as to prepare preliminary plans, estimates and reports.

Table IV.—Run-Off from Improved Areas in Typical Combined Tenement and Industrial Districts.

Area: 35.6 acres.
Density: 55 persons per acre.
Character of District: Tenement and industrial.
Soil: Clay and sand to gravel.

Character of improvement.	Area in sq. ft.	Per cent. of total area.	Estimated degree of imperviousness.	Equivalent impervious area, sq. ft.	Per cent. total area impervious.

Impervious coefficient for district, 35.9%.

Hickory is the strongest Canadian wood. When properly seasoned a hickory column will support a weight of 12 tons per square inch cross-section, which is considerably more than what could be borne by a pillar of cast iron or steel of the same length and weight.

The mineral production of Ontario in 1913 had a total value of $53,207,311, the largest yet recorded in any year. Of this $37,507,935 was of metallic, and $15,699,376 of non-metallic substances. The increase over the output for 1912 was $4,865,699, or more than 10 per cent.

FINISHING TEMPERATURES AND PROPERTIES OF RAILS.

THE U.S. Bureau of Standards has carried on an investigation into the manufacture of steel rails. The main objects of it were to determine, from measurements taken in representative rail mills, the present American practice regarding the temperatures at which rails are rolled; to demonstrate the ease and accuracy with which such temperatures may be measured; to find out what the "shrinkage clause" in rail specifications really means; and finally to determine for rail steels some of the physical properties, particularly those of interest in manufacture and some of which, it would seem, are not sufficiently well known as yet. Among these last are the expansion, melting ranges, critical ranges and temperature distribution throughout a rail section on cooling.

Table 1—Summary of Ingot Temperatures at Blooming Mill.

Mill.	Number of ingots observed.	Average temp. C.	Average time in blooming mill, seconds.	Remarks.
A	20	1140±10	120±25	Excessive time in pits.
	19	1082±16	121±16	In pits 1 hr. 35 min. to 2 hrs.
B	30	1102±12	91±7	Two heats.
C	29	1087±17	71±3	Two heats.
D	43	1118±15	37±2.3	Seven heats.

In the spring of 1913, observations were taken of ingot and finishng temperatures of rails in four representative mills, designated as A, B, C, D. Temperatures were taken with the Holborn-Kurlbaum type of Morse optical pyrometer.

In Table 1 is given a summary of the temperatures of ingots as measured at the blooming mill during rolling for rails, and in Table 2 a summary of finishing temperatures of rails.

Table 3 illustrates with what uniformity of temperature it is possible to carry out the rolling of rails in practice. The letters refer to the position of the rail in the ingot. It is evident that a uniformity of ±10 deg. C. may be maintained.

Table 2—Summary of Rail Finishing Temperatures.

Mill.	A			B	C	D
Location of station	Hot saw			Hot saw.	Cooling bed No. 1.	Just before hot saws.

				Mean A, B, C, D,	B & E	
				939±9	920±7	
				Mean E, F, G, H,	C & F	
				928±9	904±8	

An inspection of the tables shows that there is practical uniformity among the several mills for the rolling temperatures of ingots for steel rails, the range being from 1,080 deg. C. (1,975 deg. F.) to 1,140 deg. C. (2,085 deg. F.). With the exception of the Bessemer rails of Mill D, rolled at an average temperature of 1,047 deg. C. (1,917 deg. F.), there is no very considerable difference among the finishing temperatures of the rails as observed at the hot saws for the several mills, the range being about 880 deg. C. (1,615 deg. F.) to 990 deg. C. (1,815 deg. F.); or, in other words, the four mills all finished their rails to within 50 deg. C. of 935 deg. C. (1,715 deg. F.) on the average, excepting the Bessemer rails of Mill D. This temperature of 935 deg. C. is 270 deg. C. (520 deg. F.) above the mean value, 665 deg. C. (1,230 deg. F.) of the critical ranges of these rail steels. Concerning the distribution of temperatures within the head of a cooling rail, it is shown that the centre of the head is some 50 deg. C. (120 deg. F.) to 60 deg. C. hotter than the optical pyrometer reading at 935 deg. C.; therefore the centre of the head is finished, on the average, at about 325 deg. C. (615 deg. F.) above the critical range for 100-lb. sections.

The tables of finishing temperatures show several other facts of interest. For example, it is evident that it is a possible and easy operation to determine accurately the temperature of each rail length in succession as it arrives at the hot saw. (See Table 3.) From the measurements at Mill A, the relative temperatures of rails differing in weight of section, rolled from ingots having closely the same weights and temperatures, are shown. Thus the average of the finishing temperatures of the top rails (A and D or A and C) for 100, 90 and 75 lb. sections were, respectively, 988 deg., 976 deg. and 924 deg., and similarly for the others.

Chemical analyses and microphotographic examinations were also made and the mechanical properties determined for a number of samples of rail the rolling of which had been observed. From a comparison of these few observations, there appears to be not a sufficient degree of correlation to warrant associating very specifically any of the characteristics defined by these three methods of examination, either with the temperatures of rolling here observed or with each other.

The following thermal properties of these rail steels were determined in the laboratory: The critical range on heating is located (maximum) to within 7 deg. C. of 732 deg. C. (1,350 deg. F.) for the ten samples of O. H. and Bessemer steels examined. On cooling, the critical range lies between the limits 680 deg. C. (1,256 deg. F.) and 650 deg. C. (1,202 deg. F.). The melting or freezing range for rail steel extends from about 1,470 deg. C. (2,680 deg. F.) to nearly the melting point of iron located at 1,530 deg. C. (2,786 deg. F.).

The expansion for O. H. and Bessemer steels is not the same. Above 800 deg. C. (1,470 deg. F.) the expansion for both increases linearly with temperature and the linear coefficient per degree Centigrade has the following mean values from 0 deg. to 1,000 deg. C.; (1) For Bessemer steel (carbon .40 to .50 per cent.) = 0.0000146, (2) for open hearth steel (carbon .65 to .70 per cent.) = 0.0000156.

The average composition of the Bessemer steel was carbon = 0.40 to 0.50 and manganese = 0.76 to 0.93; of the open hearth steel, carbon = 0.66 to 0.70 and manganese = 0.66 to 0.72.

In 1909 the American Society for testing Materials limited the shrinkage allowance on 100 lb. sections to 6¾ in. in 33 ft., or to an equivalent of 1,947 deg. F. (1,064 deg. C.) for O.H. and 2,055 deg. F. (1,124 deg. C.) for Bessemer rails. This specification is still in force.

* This line represents the mean degree of temperature of above table.

A rail of 100 lb. section in cooling freely in air from a uniform temperature of 1,070 deg. C. (1,960 deg. F.) reaches its recalescence point at 670 deg. C. (1,238 deg. F.) in about 8 min. 30 sec. The maximum difference in temperature between the centre and outside of the head during this cooling is about 85 deg. C. at 1,000 deg. C. (1,832 deg. F.), drops to 55 deg. at 900 deg. C. and to 30 deg. at 800 deg. C., becoming 0 deg. again at 670 deg. C.

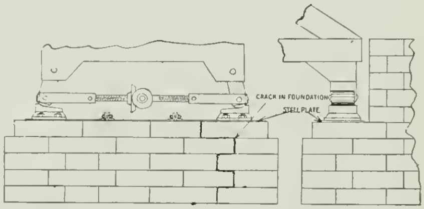
A comparison of the shrinkage clause in American rail specifications (for example, those of the A.S.T.M.) with the expansion of rail steel shows that this clause permits finishing rails at 1,120 deg. C. (2,045 deg. F.), or 450 deg. C. (840 deg. F.) above the critical range of rail steel, and above the temperature at which many ingots for rails are actually rolled in practice and well above the practice of the rail mills for finishing temperatures, as shown in Table 2. Such a shrinkage clause, therefore, does not serve the avowed purpose of limiting the finishing temperatures to a value slightly above the critical range.

In conclusion, it should be emphasized that the various series of observations recorded in this investigation are of but a preliminary nature and do not pretend to solve the question of the relations between temperature of rolling and the properties of rails. It would seem desirable to make a much more complete and comprehensive study of the various matters mentioned and of related questions than has hitherto been attempted, and on a scale commensurate with the importance to the community of the problem of sound rails.

BRIDGE REPAIR ON C.P.R.

By J. G. Koppel,
Electrical Superintendent of Bridges, Sault Ste. Marie, Ontario, Canada.

On the end piece of a swing bridge crossing the Ste. Marie Ship Canal at Soo, Ontario, a repair was recently made in a very efficient manner. The bridge is 407 feet in length, over which runs a single track for the Canadian Pacific railroad trains. The swinging and the end piece shoe-jacks operate by electric motors from a centre cabin elevated over the track. From time to time it was found that the bridge tended to tilt to one side, especially the south end, which is on a curve,



BRIDGE REPAIR ON THE CANADIAN PACIFIC.

and finally a serious crack developed in the masonry which grew worse every day, and in order to keep the bridge safe we had to devise some kind of relief or safeguard to prevent a total rupture.

Arrangements had to be made to make the necessary repairs without interrupting the running of the trains on the track, and at the same time not to interfere with boats passing through the canal. The accompanying drawing shows the crack in the masonry which amounted to fifteen-sixteenths of an inch, and also shows how the repairs were accomplished. A one-half inch steel plate was made in three sections, and drilled to fit on the jack-shoe bolts, and one jack-shoe at a time was removed and the plate laid in place and the jack-shoe replaced. When both plates were secured in position, then the centre plate was put in and the bolts screwed down, and when all were in tension the masonry was drawn into its original position, while a mixture of cement was poured into the crack, which made a very good job, as the foundation is now apparently as good as could be desired, and safer than the original structure, as nothing short of an earthquake could move the steel plate that we added to the structure.

Not only so, but it is evident at a glance that a new idea has been added to structures of this particular kind. Masonry under direct vertical pressure is always reliable, but under slightly horizontal pressure of an intermittent kind, such as is caused by the oscillation of a heavy locomotive and attached train rounding a curve the tendency of the masonry to crack or dislocate is very great, and a reinforcing plate should be used.

POSSIBLE FAULTS IN OUR METHODS OF TEACHING.

By I. F. Morrison,
Lecturer in Structural Engineering, University of Alberta.

It is the chief function of any engineer, young or old, to solve problems, and to obtain, not only a solution, but the best solution considered from all points of view. Such a best solution requires a sound knowledge of the fundamental principles of the physical, chemical and mathematical sciences and some understanding of business methods, economics, law and many other important fields. At present it is not possible to deal with these latter requirements as extensively as seems desirable in our engineering courses within the limited amount of time allowed. The young engineer must pick these up for himself; and there is no reason why he should not do so if he has had the proper training in other fields and has learned to study effectively. The fundamental principles and their application to problems, coupled with a training in actual methods of study, seem to be the important qualities to be desired in an engineering graduate.

One of the outstanding faults of the present-day engineering student is his dependence on problems and on text-books. Such dependence is a habit due to poor training, which in turn is fostered by the improper use of text-books and the assignment of poorly chosen problems. The first is due to the habits acquired by the student during an early part of his school training; while the latter is wholly due to the teacher in his engineering courses. Without doubt, problem-work is highly desirable. It is an efficient, practical method of applying practice in the use of fundamentals. The tendency, however, is to bury the fundamentals in problems with the resulting loss of independence on the part of the student. The childhood propensity to imitate and to follow seems to persist in the minds of many engineering students even until the time of graduation. Problem-work should retard rather than promote such a growing dependence and can be used effectively in overcoming the difficulty.

No doubt the modern methods of our public school education systems are in part responsible for this condition; and for that reason alone, an inimical influence should be brought to bear upon the student by the engineering college tending towards independency of thought and ability. For this, quality and not quantity in most cases should be required in problem-work. Drill is for those who are followers, not for leaders. The engineering college should aim to effect the transition of its newly accepted students from dependent to independent thinkers, from followers to leaders with intuition and initiative.

A problem which requires an indirect solution is of greater value than several which may be quickly solved by a formula. The following problem is taken from one of the most recent text-books on applied mechanics, and is preceded in that book by an illustrative problem in which the statement is made "Apply the formula," referring to the well-known formula $F = Ma$. A force of four pounds causes a certain mass to move from rest through 18 feet in 3 seconds. Find the mass. According to the worked example which precedes it, the student applies the formula; which is a very common type and is applied in quantity. Eventually the student learns, not that the force produces an acceleration inversely proportional to the mass or an equivalent fact, but that simply $F = Ma$.

Consider the other type of problem which demands something more than a mechanical application. An iron ball, starting from rest, rolls down an inclined plane 10.2 feet long in 4.8 seconds. What is the inclination of the plane with the vertical? The solution is indirect and requires a careful consideration of the forces which act to cause the ball to roll down the plane.

The first problem, while not quite direct, demands but little reasoning. At this point the student has already learned the formula $s = \frac{1}{2}at^2$, and is now also dependent on the fact that $F = Ma$ is the ultimate solution of his problem. Such an exercise is nearly worthless, unless the student needs practice in multiplication. Many problems of this sort will make the student dependent on a formula for the solution of any problem so that ultimately his ability to solve problems will be limited to doing those which he has seen done elsewhere, or for which he can find similar cases already worked in his text-book.

To be of the greatest value, problems should demand the applications of principles and common sense rather than formulæ. They should be interesting and practical. The ability to understand new problems and to obtain the best solution for each is the ultimate aim. This can be accomplished only by independency in thought and ability.

Objections have been raised to the present method of usage of symbolic formulæ. Everyone seems to agree that such formulæ should be thought of in terms of English words and that they should be so taught; but few seem to realize that the problem-work is perhaps partly responsible for the objectionable conditions. Most students naturally follow the line of least resistance where it is made evident. "Apply the formula." A short symbolic formula is not only attractive from this point of view but is soon recognized as an easy means to an end. Problems which give merely a drill in the use of symbolic formulæ and therefore require only a mechanical operation, might well be avoided. The benefits derived from them cannot be greater than the effort applied to them

Symbolic formulæ have their place: their role is important, but their importance is secondary. We should hardly think of teaching shorthand to children who have not yet learned to read and write in the ordinary way. Much less would we think of mixing reading, writing and shorthand together, when taught. Then, why should we seek to start a subject in elementary mechanics with notations immediately followed with formulæ? Perhaps it would be well to avoid formulæ entirely for a while and to allow the use of them to be developed naturally by the student. It would be interesting to watch the development of symbols and formulæ in an elementary class. The writer believes that each student would eventually evolve some system of notation and make up his own symbolic formulæ. This would be putting the formulæ in their proper relation to the subject: it would give the proper weight to their importance.

However, the ability to translate a derived formula is of great importance. This point must not be overlooked; and the translation of formulæ which have been derived should be insisted upon. Students will see the value of writing the statement of some physical law with single letters more readily than they will observe the complete meaning of a derived formula. Nevertheless, if they have been the promoters of their own formulæ originally, this difficulty should not persist.

Efficiency, like economy, is sometimes false. Both must be developed along natural lines. It is not economy to set an unskilled workman to work with a valuable machine; nor is it efficiency to require an untrained student to use a symbolic formula. After all, formulæ are merely the result of a natural method developed to obtain efficacy.

STEEL TOWER TRANSMISSION LINES

A STUDY ON THE LOCATION AND CONSTRUCTION OF HYDRO-ELECTRIC POWER TRANSMISSION LINES AND DISCUSSION OF PRESENT EXPERIMENTS BEING CONDUCTED RELATIVE TO THEIR OPERATION.

By ALBERT B. CUDEBEC,

Constructing Engineer, Utah Power and Light Company, Salt Lake City, Utah.

At first glance it might seem that transmission line location and construction falls within the field of the electrical engineer. However, it is likely that the civil engineer is a more successful locator and construction man, while a combination of electrical and civil engineering experience are the ideal requirements for a new and growing branch, soon to become known as "Transmission Engineering."

Hydro-electric power development may be classified into three operations: Generation, Transmission and Distribution.

Of the three divisions, transmission is the weakest link, and is receiving an unusual amount of study and experiment at this time.

Large water-powers are frequently located in isolated districts many miles from the power market. Scarcely two decades past, many large water-powers were not available for commercial purposes, chiefly because this art of transmission was as yet not sufficiently perfected.

Transformers were in their embryo stage and direct current almost universally used.

With the coming of modern transformers and alternating current, most water-powers were brought within commercial operating distances of a possible market.

Electrical designers have been successful in the development of reliable generators and transformers, while the solving of low-tension distribution problems has kept the pace, but the transmission link still gives cause for grave concern.

Continuity of power is absolutely essential to obtain and hold the business and good-will of the consumer, and severe penalty clauses in power contracts for interruption are the rule rather than exception.

Only a few years ago voltages of 11,000 were the average, while the more daring engineers were attempting transmission at 44,000 volts. To-day many systems are operating at pressures between 130,000 and 150,000 volts.

The location and construction of lines carrying these lower voltages were comparatively simple matters. The distances covered were short, and conductors, insulators and poles were cheap in comparison with the modern high-voltage steel tower construction.

Franchises along public highways were easily obtained, and when found advisable to cross privately owned property, the right to set a few poles could be secured at a nominal cost. The securing of a profile was needless, and the construction foreman usually chose the pole locations by inspection, while little or no attention was paid to elimination of angles.

With the rapid advance in the art of transmission, the steel tower has displaced the wood pole for high voltages. One good example of this quick change occurred under the writer's observation. An expensive wood pole line carrying a single 60,000-volt circuit, which was completed for service a little over four years ago, was pulled down during the past summer season and replaced with a double-circuit 110,000-volt steel tower line. The rule is, however, to retain the old lines and, if desirable, parallel them with a new line, the old one being kept for emergencies in case of break in the new line.

Lines carrying moderate loads, together with line pressures limited to 60,000 volts, are still supported upon poles. Pin-type insulators are still used, but the suspension insulator is very rapidly displacing the old type, even at these moderate voltages.

Steel tower lines are of two distinct types:—

(1) The rigid towers, capable of resisting horizontal stresses in all directions.

(2) The flexible type, whose function is to support the conductor only and will not resist horizontal stresses parallel to the direction of the line.

If a flexible type is used, it is necessary to specify that a rigid tower be placed about every mile to take the strains in conductor after sagging.

As the flexible tower is not commonly used, we will refer only to the rigid or square-base tower hereafter.

A modern tower line, carrying current at pressures between 130,000 and 150,000 volts, will cost from $10,000 to $14,000 per mile, and its location demands as careful study as the location of a railroad. It is an old adage that successful railroad locators are born and not made, and it seems probable that this term will soon apply to transmission locators. The characteristics necessary for a successful locator are: (1) A thorough knowledge of the factors which affect the first cost as well as subsequent operation. (2) A keen sense of observation so that physical facts are quickly noted and all advantages taken.

The essential difference between railroad and transmission line location is the elimination of a necessary limiting grade. Public highways, villages and telephone lines are to be avoided, but primarily a minimum distance between terminals is the goal sought by all locators.

A minimum number of angles is also desired, as every angle means a heavier tower with a "dead-end" and "strain-point," which are expensive.

When the pressure on an overhead transmission system exceeds a certain critical value, depending upon the spacing, diameter and elevation of the wires, there will appear on the surface of the conductors a halo-like glow, to which the name of "corona" has been given. Apart from its luminous effect, the appearance of the corona is accompanied by a certain loss of power, which becomes serious very quickly after the critical point is passed. If the electrical designer has specified wire and spacing which is near the corona limit at the average elevation of the line the loss rapidly increases with the elevation and is proportional to the length of the line passing over the high elevations.

* The Cornell Civil Engineer.

There are other phenomena due to corona which are purely electrical, which are of no interest to the locator, but lie within the sphere of the electrical designer.

The effect of altitude being so important, transmission lines which pass over mountain ranges must be kept in as low passes as possible, but if high points are unavoidable, the length of line over these points should be kept a minimum.

Tower lines are cheaper if located across rolling hills and valleys, where longer spans and fewer towers per mile are obtainable than in level country.

Where reliable U.S.G.S. sheets are not available, it is preferable to first run a preliminary line, then project the location. When the located line is being staked out, a careful classification of the ground crossed should be taken. This should include swamps, rock out-crops, class of timber, cultivated ground, etc.

At the same time a line of accurate levels should be run which will show, along the centre line, all breaks in ground of a foot or more. All transverse slopes of more than 10° should be recorded.

As soon as the detailed profile has been completed, tower locations can be made in the office. The method of locating towers which has proven to be the most practical is the one described in the "Electrical World" under date of September 11th, 1911, by Mr. J. M. Viehe.

On all high-voltage lines which are supported by suspension type insulators, it is necessary to carefully compute the relation between length of span and corresponding sag between the range of temperature which may be expected to occur in the district through which the line is passing.

During extremely cold weather, an uplift upon a suspension insulator will cut down the clearance between conductor and the towers which might cause "flashovers," and if the uplift is serious, would cause mechanical failure of the crossarm.

All towers of the rigid type are ordinarily designed to withstand great strain in a horizontal direction, but are not supposed to resist any great amount of upward pull. It is, therefore, necessary to place the towers in such a position that no great upward pull will be exerted.

The office procedure for properly locating towers is first to make certain assumptions for loading, i.e., assume a maximum wind pressure added to the weight of the conductor itself; then to the sum of these two must be added the weight of an arbitrary thickness of sleet which may be expected to accumulate upon the conductor at times. Several conditions are investigated for sag and tension, as sleet and ice, with a sudden drop in temperature, or a combination of any of these assumptions.

Assuming that the copper conductor will take the form of a catenary between supports, the sag for any length of span can be readily computed. A certain minimum clearance from the ground is specified, depending upon the character of country through which the line is passing. A templet representing conditions at maximum temperature is then prepared, using the same scale as the plotted profile.

After the adjacent tower locations have been made, it is necessary to test these locations for cold weather conditions. This test is applied by the use of a similar templet, which is drawn to scale, and shows the position of conductors as they will exist at minimum temperatures If the contraction of the copper is sufficient to lift the conductor above the intervening tower, it will be necessary to change the length of span on either side until a position is found where no uplift to insulators will occur and at the same time keep within the minimum prescribed clearance during maximum temperatures.

A great number of combinations will occur while studying the proper location for transmission line towers, and the most economical points for locations are often the result of several days' study.

Owing to the fact that interruption to service are not unusual from line troubles, it is best to build duplicate lines if feasible to finance the construction. If a duplicate line is authorized, it is better to construct it upon separate supports located over a different route in order to avoid the chance of destructive storms putting both lines out of commission at the same time. Separate routes for transmission lines, will, of course, increase the cost of patrolling and right-of-way, which is in turn offset by more continuous service.

All terminals of a modern power distribution system must be kept in constant telephone communication. In fact, the telephone is as necessary to the modern power system as is the telegraph and block signal to the operation of a modern railroad. Statistics show that interruptions and troubles with the average operating telephone system are more frequent and cause more worry to the operating superintendent than does the main transmission line. It frequently happens that when a break in the transmission line occurs, the telephone line will also be out of commission. This is more likely to occur if the telephone line is strung upon the same supports as the main conductor. It is, therefore, advisable to build a separate telephone line of modern construction at a sufficient distance from the transmission line to avoid the chance of crossing with the main conductors.

Five years ago transmission line towers were averaging from 2,000 to 3,000 lbs. each, while to-day towers of 5,000, 7,000 and 12,000 lbs. in weight are not infrequent. The average heavy tower when erected will cost from $700 to $1,000, and it is, therefore, good business to study the line very carefully, indeed, before finally specifying locations.

As soon as all tower locations have been made, a field party should stake these towers out upon the ground, and this is where the best of judgment must be exercised. It is frequently found that the locations as selected in the office will place the tower directly upon a pile of rocks, or in wet ground, etc. By moving the tower a short distance in either direction, these natural difficulties may be avoided. At the same time, it must be borne in mind that a slight change in tower locations will very materially alter the position of the conductors with reference to the ground, as the amount of sag changes rapidly with changes in span length. The field man must, therefore, be thoroughly acquainted with the technical detail of the scheme by which towers are located, and must be equipped with a celluloid templet in the field and adjust the small changes in location so that all requirements are fulfilled.

If there are several different types of towers, which may be used, such as different heights, weights and side-hill extensions, etc., it is possible for the field men to change the office selection of a tower with a 10 or 20 ft extension to one with a 4 ft., 6 ft. or 8 ft. side-hill extension, thereby saving expensive excavation and at the same time reducing the amount of steel.

The location of all towers having been made, the line is now ready for construction. The procedure of construction is as follows:—

(1) Clearing line of all timber, including "Danger" timber outside of the right-of-way proper. (2) Excavation for footings. (3) Distribution of stubs and tower steel. (4) Placing of stubs in concrete or earth and backfilling

same. (5) Assembling towers, including hanging of insulators or crossarms and distribution of small hardware for stringing purposes. (6) Erection of towers. (7) Stringing of conductor. (8) Cleaning-up crew.

In order that the construction men may be supplied with the best information possible, it has been found economical to condense all the information regarding location, types of towers, numbers of insulators, etc., into a pamphlet, which is furnished to each general foreman. It is also found of great assistance to the man in charge of material distribution, to be furnished with a sheet showing the railroad stations from which material must be hauled, and which will include the number and types of towers shipped to each station.

Whenever the supporting ground is poor or ground water is known to stay continuously in the holes which are excavated for stubs, it is always good policy to concrete the stubs and protect the channels which connect to the towers with a concrete collar, but if the ground is good, firm, dry earth, concreting is not necessary except for angle and dead-end towers. If the line to be constructed specifies towers which range from 3,000 to 3,500 lbs. it is cheaper to leave the holes open and bolt the stubs to the towers after erection, no templet being necessary to hold the stubs in place. On the other hand, with heavy towers, ranging from 5,000 to 12,000 lbs. and upward, it is better to set and backfill all stubs previous to the erection of towers by means of a steel or wood templet.

Common labor is all that is necessary for the entire construction program, including stringing of conductor, but it has been noted that within the last ten years labor unions have been insisting that union steel workers shall be specified for assembling and erection, and that union linemen must be used for stringing conductor. This is entirely unnecessary as far as results of the work are concerned, as it only takes a few weeks to train men to assemble and erect towers, and string conductor. In fact, it has been found that skilled steel workers and linemen have to be trained to this class of work in the same manner as common labor.

There are several methods of erection of towers, but the writer prefers the "A" frame method. A crew of 8 men will assemble on the average of from 2 to 3 towers per day and a crew of 15 men will erect from 8 to 16 towers daily if the ground is not too rough.

The conductor used upon modern heavy transmission lines will run from 150,000 to 300,000 c.m.; 250,000 c.m. conductor weighs about ¾ lb. per lineal foot. The tackle and grips necessary to pull this conductor must be unusually heavy. The conductor comes from the manufacturer in ½ mile or mile reels, weighing from 4,000 to 6,000 lbs each, and these reels are usually mounted upon some simple standard. An eccentric reel has been found very convenient. The conductor is pulled out by teams and passed through especially designed wooden snatch-blocks, the sheave for which is preferably lignum vitae.

The splice between two pieces of heavy conductor must be very carefully made. Copper splicing sleeves are now universally used with which to twist them into position.

It is very necessary to protect hard-drawn copper from being injured at the surface, and every precaution is taken to keep the conductor from being scored by rocks or being struck by any object which will crack the surface. The conductor is usually sagged and tied in at every mile. The pull necessary to properly sag the conductor depends upon the temperature. This stress is measured by the use of a dynamometer, but it is preferable to check the sag by sighting from one tower to the next to avoid trouble in case the dynamometer should get out of repair.

An average crew of 12 men will string from one to two miles of conductor per day, consisting of 6 copper wires and 2⅜ inch steel ground wires. The entire organization necessary to construct a line 135 miles long of 250,000 c.m. conductor during a period of seven months, is approximately as follows:—

1—Superintendent	2—Clerks
1—Assistant Superintendent	2—Stenographer

TOTAL AVERAGE FORCE—600 Men
100 Teams

The advance in the art of transmission has been great in the last ten years, and as yet no stable conditions seem to have arrived. It, therefore, seems doubtful to the writer that it is advisable at this time to spend so much capital in constructing heavy steel tower lines which may be obsolete within six or eight years. The life of modern towers, if properly erected and inspected, will average from 30 to 50 years. We believe that until the present rapid advance in the art of transmission has more nearly reached a standard, it would be better to construct with the idea in view of re-building in ten years. On the contrary, it is claimed that the investing public would not be interested in financing temporary construction, but will cheerfully invest in projects calling for permanent construction.

The length of span between towers is usually not limited by the strength of the conductor itself, but rather by the horizontal spacing necessary to avoid crossing due to side-swaying. Whenever spans of unusual length are necessary, copper-clad steel conductor is specified This has practically all of the strength of a high-grade steel cable, coupled with the conductivity of copper. By pulling this conductor to a much higher tension than ordinary hard-drawn copper, sufficient horizontal clearance between conductors can be secured and still retain towers using standard clearance.

During the past year or so, some transmission engineers are attacking the policy of increasing the weights of towers and extending the lengths of spans, claiming this policy to be false economy. At a recent convention of the American Institute of Electrical Engineers, held at Vancouver, B.C., a very spirited discussion took place over the question as to whether it would not be better to reduce the length of spans rather than increase them.

The Provincial Government of British Columbia is erecting two new pumping stations on the dyked lands and adjoining the Pitt River. One of these stations is to be located on the Maple Ridge side and the other on the lower Coquitlam side of the river. These new plants have been necessitated by the growing utilization of these dyke lands. In the last two years a number of industries have been located on the Coquitlam side, and these required considerable land drainage pumping during the summer freshet season.

SURGE TANK PROBLEMS V.

CONTINUATION OF ANALYSIS OF SPILLWAY EFFECT — STUDY OF SURGE TANK WITH VARIABLE CROSS-SECTION — APPROXIMATE FORMULA FOR SURGE TANKS WITH CONSTANT CROSS-SECTION.

By PROF. FRANZ PRASIL.

Authorized Translation by E. R. Weinmann and D. R. Cooper, Hydraulic Engineers, New York City.

Investigation of the Influence of $h = u.v^2$.

Finally, a study may be added which permits a comparison between the results of the assumption already made (that $h = n.v$), and the results obtained if we use the usual formula $h = u.v^2 = u^1.\frac{Lv^2}{P.2g}$ where the friction coefficient u^1 is again assumed as constant (P = hydraulic radius of the conduit). With this condition it is necessary to use the first original equation (15) in which we must, according to the direction of the flow in the conduit, be careful to use the right sign for h. If this makes the investigation somewhat complicated, it may be said that the differential equation, which we obtain introducing the value of v in the continuity equation (17) is not only of the second (i.e., higher) order, but also of the second degree, so that difficulties occur in the determination of the general integral. This is especially the case if in the equation mentioned $q > o$ and variable.

Therefore, in the following we consider only for comparative purposes the case of a sudden shut-down of Q and for the phase of the first surge. In order to get more generality, we first consider the surge tank section as variable with the height, which means that it is assumed as a given function of z. The motion equation is then:

$$\frac{L\,dv}{g\,dt} + z + h = o. \qquad - \quad - \qquad (15\text{ A}).$$

The equation of continuity is:

$$a.v = A.s \qquad - \quad - \quad - \qquad (17\text{ B})$$

If we multiply equation 15 A with $a.v.dt$, it follows, considering equation (17 B)

$$\frac{L.a}{g}\,v.dv + zA\,s\,dt + h.A.s.dt = o \qquad (90)$$

$A.s\,dt = A.dz = dV$ represents the change of the water volume V in the time dt. It also represents, with given surge tank dimensions as function of z or with reference to the graphical demonstration appearing further on, the function of a variable x where $z = x - h_1$ and where V is measured positive up from that level which lies below $n - n$. That is, for $z = -h_1$ or $x = o$; $V = o$.

With $h = \frac{u^1\,L\,v^2}{P.2g}$ and $h_1 = \frac{u^1\,L\,v_2^2}{P.2g}$ and multiplying (90) with $\frac{2g}{La}$ we get

$$d(v)^2 + [\frac{2g}{L.a}\,.\,x + \frac{u^1}{P.a}(v^2 - v_2^2)]\,dV = o$$

If we say $v^2 = y$ $\quad v_2^2 = y_2$ $\quad \frac{2g}{L.a} = a_1\ \frac{u^1}{P.a} = \frac{1}{a_2}$ the total differential equation follows:

$dy + [a_1 x + \frac{1}{a_2}(y - y_2)]\,dV = o$ which integration can be done introducing the integrating factor $\mu = e^{\frac{V}{a_2}}$

$$y - y_2 = -a_1 e^{-\frac{V}{a_2}} \int_0^V x\,e^{\frac{V}{a_2}}\,dV$$ and introducing the values for y, a_1, a_2.

$$v^2 = v_2^2 - \frac{2g}{L.a}\,e^{-\frac{u^1V}{P.a}} \int_0^V x\,e^{+\frac{u^1V}{P.a}}\,.\,dV \qquad (91)$$

With help of this equation v may be found as a function of V and x, because by given relation of the volume V to x and vice versâ, in formula (91) $\int_0^V x\,e^{+\frac{u^1V}{P.a}}.dV$ may be determined by means of quadrature even if $V = F(x)$ is given only by a curve. The method is illustrated by the diagram shown in Fig. 12. The relation of the volume V to x is shown by a curve, the abscissæ of which represent the values of V and the ordinates the values of x. The construction of the x curve $I - I$ may be accomplished, based on the given dimensions of the surge tank. $V = o$ corresponds, as said before, to the operating level for a flow of Q_1 cubic feet per second. With the same abscissæ, we construct a curve II — II, the ordinates of which are given by the values $e^{+\frac{u^1V}{P.a}}$ and another curve III — III with the ordinates $x.e^{\frac{u^1V}{P.a}}$ and then the integral curve IV — IV. If we construct a further curve V — V, the ordinates of which we get if we multiply the ordinate values of the integral curve by $\frac{2g}{L.a}\,e^{\frac{u^1V}{P.a}}$ and if we construct at the distance (v_2^2) a

line parallel to the axis of abscissæ we then see that the difference of the ordinates between the (v_2^2) line and the curve V — V gives the values of v^2. Naturally, we must select suitable scales for all curves, that is to say, for their ordinates. The scale for the last curve is naturally the same as for (v_2^2). The intersection of the last curve with the parallel (v_2^2) determines the ordinate which gives the value of V on the axis of abscissæ, for which $v = o$, that is, when the highest water elevation occurs. The corresponding ordinate of the x curve gives the height of the highest elevation above the operating level.

If A is constant: $V = A.x$ and equation 91 becomes

$$v^2 = v_2^2 - \frac{2\,g.A}{L.a} . e^{-u^1 \frac{A.x}{P.a}} \int_0^x x\, e^{u^1 \frac{A\,x}{P.a}} dx$$

If we introduce $\frac{2\,g}{L} . \frac{A}{a} = \frac{1}{B^2}$; $u^1 \frac{A}{P.a} = \frac{1}{D}$ we get

$$v^2 = v_2^2 - \frac{e^{-\frac{x}{D}}}{B^2} \int_0^x x\, e^{\frac{x}{D}} .dx$$

$$v^2 = v_2^2 + \frac{D^2}{B^2} \left(1 - \frac{x}{D} - e^{-\frac{x}{D}}\right) \qquad (92)$$

And for the computation of the maximum value X of x ($v = o$)

$$\frac{v_2^2 . B^2}{D^2} + 1 = \frac{X}{D} + e^{-\frac{X}{D}} \qquad (93)$$

The results here obtained may now be used for comparative purposes with the results of the example of case (A).

$v_2 = 6.63$ feet per sec. $\qquad \frac{v_2^2}{2\,g} = .68$ feet

$h_1 = 9.6 \text{ feet} = \frac{u^1}{P} . 9050.0.68$

$\frac{u^1}{P} = \frac{1}{641} \qquad \frac{1}{D} = \frac{u^1}{P} . \frac{A}{a} = \frac{1}{9.6}$

$\frac{1}{B^2} = \frac{2\,g\,A}{L.a} = \frac{1}{2.094} \qquad B = 1.447$ sec.

$$\frac{v_2^2\, B^2}{D^2} + 1 = \left(\frac{6.63^2 \times 1.447^2}{9.6^2}\right) + 1 = 2.00$$

Therefore

$$\frac{X}{D} + e^{-\frac{X}{D}} = 2.00$$

$$\frac{X}{D} = 1.86 \qquad X = 17.81 \text{ feet}$$

In case (A), where we assume the same conditions with $h_1 = n.v$ in which $n = 1.445$ seconds, we got z max $= 6.55'$ and therefore the highest elevation above the initial level z max $+ h_1 = 6.55 + 9.6 = 16.15'$. This

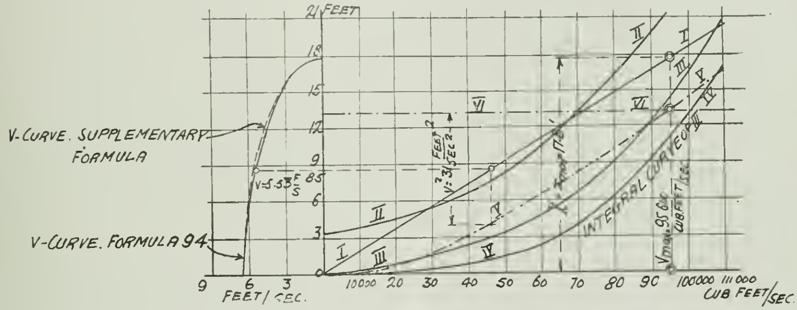

Fig. 12.

value is smaller than the value which we computed for X by 1.66 feet, and it is necessary for us to correct the formulæ obtained under the assumption that $h = n.v$, in order to get as near as possible to the new results. For this purpose, we assume that for the expression of the elevation x above the initial level the formula

$$\left.\begin{aligned} x &= h_1 + z = h_1 + R.e^{-\frac{t}{2\,T_0}} \sin\left(\beta + \frac{t}{T_1}\right) \\ \frac{dx}{dt} &= s = \frac{R}{T}.e^{-\frac{t}{2\,T_0}} \sin\left(2\gamma - \beta - \frac{t}{T_1}\right) \end{aligned}\right\} \qquad (94)$$

with $tg\,\gamma = \frac{2\,T_0}{T_1}$ and $\frac{1}{T^2} = \frac{1}{T_1^2} + \frac{1}{(2\,T_0)^2}$

and therefore

$$\frac{d^2x}{dt^2} = -\frac{R}{T^2}\, e^{-\frac{t}{2\,T_0}} \sin\left(2\gamma - \beta - \frac{t}{T_1}\right) \qquad (95)$$

should be used, where the values R and β are again to be determined from the initial conditions, that is to say, where $t = o$, $x = o$ and $z = h_1$, $\frac{dx}{dt} = c_1$, but the values

T_0 and T and T_1 must be determined, not as before from the given dimension, but from the condition that X becomes the maximum value of the elevation above the initial elevation, that is, for $x = X$ the derivative $\frac{dx}{dt}$ must become zero, and as before for $x = o$, the second derivative $\frac{d^2x}{dt^2}$ becomes zero. From the latter condition follows:

$2\gamma - \beta = 180^\circ = \pi$ therefore $\gamma - \beta = 180 - \gamma$

$\beta = 2\gamma - 180^\circ$ and for $t = o$ we get

$$o = h_1 - R \cdot \sin 2\gamma$$

$$c_1 = \frac{R}{2T_0} \sin\gamma \sqrt{\left(\frac{2T_0}{T_1}\right)^2 + 1}$$

because $\frac{1}{T} = \frac{1}{2T_0}\sqrt{\left(\frac{2T_0}{T_1}\right)^2 + 1}$. See equation (38).

The time t_x when $x = x_{max} = X$ ($\frac{dx}{dt} = o$) is computed from

$$\frac{t_x}{T_1} = \gamma - \beta = \pi - \gamma. \quad \text{Therefore}$$

$$X = h_1 + R e^{-\frac{T_1}{2T_0} \cdot \frac{t_x}{T_1}} \sin(\beta + \gamma - \beta)$$

and, as $\frac{T_1}{2T_0} = ctg\,\gamma$

$$X = h_1 + R e^{-(\pi - \gamma)\, ctg\,\gamma} \cdot \sin\gamma \quad (96)$$

and we can first determine γ with

$$R = \frac{h_1}{\sin 2\gamma}; \quad \cos\gamma \cdot e^{+(\pi-\gamma)\, cotg\,\gamma} = \frac{1}{2\left(\frac{X}{h_1} - 1\right)}$$

Is γ with this equation computed, we have for the other values

$$R = \frac{h_1}{\sin 2\gamma}; \quad 2T_0 = \frac{R}{c_1}\sqrt{tg^2\gamma + 1} = \frac{R}{C_1 . \cos\gamma};$$

$$T_1 = \frac{2T_0}{tg\,\gamma}; \quad \frac{1}{T} = \sqrt{\frac{1}{(2T_0)^2} + \frac{1}{T_1^2}}.$$

These values may then be introduced in the formulas for

$$x \text{ and } \frac{dx}{dt} = s \quad - \quad - \quad - \quad (94)$$

If the movement so determined must be similar to that which occurs if $h = u^1 \frac{L}{P} \cdot \frac{v^2}{2g}$, then the velocities $v = s\frac{A}{a}$, which we get for the same elevation x in both cases, must have the same values. If these values are not exactly equal, but if we get approximately equal values it depends on the degree of approximation desired whether we use the supplementary formula (92) or not.

In order to investigate this case, we proceed to compute the example.

With $X = 17.81$ feet $h_1 = 9.6$ feet we get

$$\cos\gamma\, e^{+(\pi - \gamma)\, cotg\,\gamma} = \frac{1}{2\left(\frac{X}{h_1} - 1\right)} = .581 \quad \gamma = 71^\circ\, 50'$$

$$\beta = 2\gamma - 180^\circ = -36^\circ\, 20'; \quad tg\,\gamma = \frac{2T_0}{T_1} = 3.047;$$

$$R = \frac{h_1}{\sin 2\gamma} = 16.2 \text{ feet with } c_1 = 0.098 \frac{\text{feet}}{\text{sec.}}$$

$$2T_0 = \frac{R}{c_1} \sin\gamma \sqrt{tg^2\gamma + 1} = \frac{R}{c_1} tg\,\gamma = 500 \text{ sec.}$$

$T_1 = 164.3$ sec. $T = 155.9$ sec. t_x $(x = X) = 310$ sec.

$$\text{and therefore } x = 9.6 + 16.2\, e^{-\frac{t}{500}} \sin\left(\frac{t}{164.3} - 36^\circ\right)$$

$$s = \frac{16.2}{155.9} e^{-\frac{t}{500}} \sin\left(71^\circ\, 50' + \frac{t}{164.3}\right); \quad v = \frac{s . A}{a} = s \times \frac{5380}{80}$$

With these formulæ, we may compute the relative values of x, s and v for the different values of t. From the supplementary formula (92)

$$v^2 = v_2^2 + \frac{D^2}{B^2}\left(1 - \frac{x}{D} - e^{-\frac{x}{D}}\right) \quad - \quad (92)$$

we may compute the values of v for the same values of x or they may be determined graphically from Fig. 12. They correspond to the assumption that $h = u^1 \frac{L}{P} \cdot \frac{v^2}{2g}$ and we get the following table of values:

t Sec.	o	50	100	150	200	250	300	310
x feet	0	4 06	9.21	12 9	15 7	17.4	17.8	17.81
s feet / sec.	.098	.092	.082	.0623	.0425	.023	.00328	.00

and from that

v feet / sec.	6.63	6.25	5.49	4.23	2.92	1.51	.20	.00

But from Formula (92)

v feet / sec.	6.63	6.3	5.38	4.05	2.83	1.35	.066	.00

If we plot in the rectangular co-ordinate system (Fig. 12) the two values of v as ordinates with the values of x

as corresponding abscissæ, then we see from the curves thus obtained that we may use the supplementary formula with sufficient accuracy for the determination of the movement. If we compare the values of T_0 and T as they have been found for both assumptions of h, that is to say, for T_0 the values 194.5 and 250.0 and for T the values 137.5 and 155.9, then we see that the second value of T_0 is 1.28 times as large as the first, the second value of T is $1.13 = \sqrt{1.28}$ times as large as its first value. The first values have been found from the formulæ $T_0 = \frac{L}{n.g}$ and $T = \sqrt{\frac{L}{g} . \frac{A}{a}}$ and from this we see the importance of the supplementary formula (92). It is evolved from the principal equation 15 if we introduce instead of L, a distance L^* which is 28% larger than L (provided that the value n is the same according to the relation $h_1 = n.v_1$) then with the distance L^*, we compute the values T and T_0. It is evident that with the introduction of the formula of resistance $h_1 = n.v$, the influence of the friction has been introduced in the equation as too large. We have, therefore, assumed in the supplementary formula the working capacity and, therefore, also the mass of the conduit volume, larger than they really are, but obtained the right value of the elevation through the supplementary formula. The friction height which corresponds to the elevation $X = 17.81$ feet can be obtained by computing the work balance, according to the former scheme, if we introduce the actual length of the conduit.

G becomes $5,380 \times 17.81 = 2,994$ tons;

$$y_1 = \tfrac{1}{2}\, 17.81 = 8.9 \text{ feet.}$$

USEFUL WORK IN FEET TONS		USED WORK	
15.800	KINETIC ENERGY OF CONDUIT VOLUME		
28,740	POTENTIAL ENERGY OF G = 2994t FOR h = 9·6		
	LIFTING WORK OF 2990t FOR 8·9'	26.650	TOTAL
TOTAL 44.540	FRICTION WORK	17,890	44,540

The total friction work of 17,900 foot-tons corresponds, therefore, to an average friction height with respect to the weight of the water of

$$h_{\text{average}} = \frac{17{,}900}{2{,}994} = .60\, h_1$$

For case (A) we found $h_{\text{average}} = .755\, h_1$ as the average value which corresponds to an elevation of only 16.75 feet actually. The maximum elevation above the initial level will be larger than 16.75 feet and smaller than 17.81 feet, therefore, $0.60\, h_1 < h_{\text{average}} < .755\, h_1$. The true value will be apparent if observation results in constructions of larger dimensions than can be obtained. We may remark also that the above determined values of T and T_0 in the supplementary formula are only correct for the first surge from $x = o$ to $x = X$. We may carry the mathematical investigation further and find the values for the drop from the first maximum elevation to the first minimum level. Other values for T and T_0 must be introduced, which correspond to smaller values of L^*. This repeats itself for the further phases of increase and decrease until finally L^* becomes nearly equal to L. This corresponds to the decrease of the velocity fluctuations during the movement and also with the decrease of the influence of friction.

Conclusions.

We may summarize our results as follows:

1. If the conduit ends in a pond, from which the penstock goes directly to the turbine, and if the area of the pond surface $A > 150.m.a$ where a = the conduit area in square feet and m the number of miles conduit length: we need not expect any periodical fluctuations of the outflow, even if the outflow varies during the observed time. If $A < 150\ m\ a$ as is the case with artificial surge tanks, such periodical fluctuations may occur.

2. The maximum elevation above the initial level (operation level for full outflow) has approximately the same ratio for a short time for a sudden as well as for a gradual close of the whole outflow.

3. The value of the maximum elevation above the initial level may best be computed by means of the work balance, where for the average friction height 0.7 of the value of that height h_1 must be introduced, which corresponds to the drop of the water surface in the surge tank below the level of the water surface before the conduit for full outflow.

4. The extent of drop below the static level for full opening is approximately equal to the rise above computed.

5. For the determination of the oscillations during and after completed shut-down, we may use for a fair degree of approximation the formulæ, computations and demonstration methods which correspond to the analysis above developed on the theory of damped oscillations. The values of T and T_0 and therefore also T_1 may be determined if investigating the maximum elevations, as shown in our last study.

6. For operation, which results in a periodical variation of the outflow, resonance features may occur.

7. The maximum elevations may be decreased by construction of spillways in the surge tank or in the conduit.

The theory furnishes a good explanation concerning the manner and the relative value of the operations close enough for most practical purposes. But a high degree of accuracy will be accomplished only where experiments furnish much more exact values for friction in conduits under different conditions.

Appendix A—Surge Tank With Variable Cross-section.

Assuming a quadratical relation between friction-head and conduit velocity the following relation was obtained. (See Formula 91.)

$$v^2 = v_2^2 - \frac{2g}{L.a}\, e^{-\frac{u^1 V}{P.a}} \int_0^V x\, e^{+\frac{u^1 V}{P.a}}\, dV \qquad (91)$$

The maximum surge is obtained by making $v^2 = o$ and solving the latter equation for X. The previously described graphical method may be applied without further comment to surge tanks of variable cross-section with the exception that the X curve is no longer a linear function of V. For this reason and because of complex integration due to the insertion of a complicated function the graphical method is more appropriate than the analytical.

In the following example this method is applied to a surge tank, circular in section, which has a sectional area of 5,380 sq. ft. at the operating level, as was assumed before. However, in this case the sectional area increases in direct proportion to the height in such a ratio that at a height of 19.7 ft. the sectional area is 6,450 sq.

ft. (See Fig. 14.) All other data for the problem is the same as assumed in the main article.

L = 9,050 ft.
a = 80 sq. ft.
p = 32.8 ft.
Q = 530 cu. ft. per sec.
v_2 = 6.63 ft. per sec.
P = 2.44
h_1 = 9.6 ft.
u' = .0038

$$\frac{u'}{P.a} = \frac{1}{51{,}300} = \frac{1}{a_2}$$

$$6.63^2 = 44.0 = \frac{64.4}{9050.80} e^{-\frac{V}{51{,}300}} \int_0^V x\, e^{+\frac{V}{51{,}300}} dV$$

With this graphical method (Fig. 13) a maximum surge of only 17.0 ft. is obtained, whereas in the former example, with a surge tank of a constant sectional area

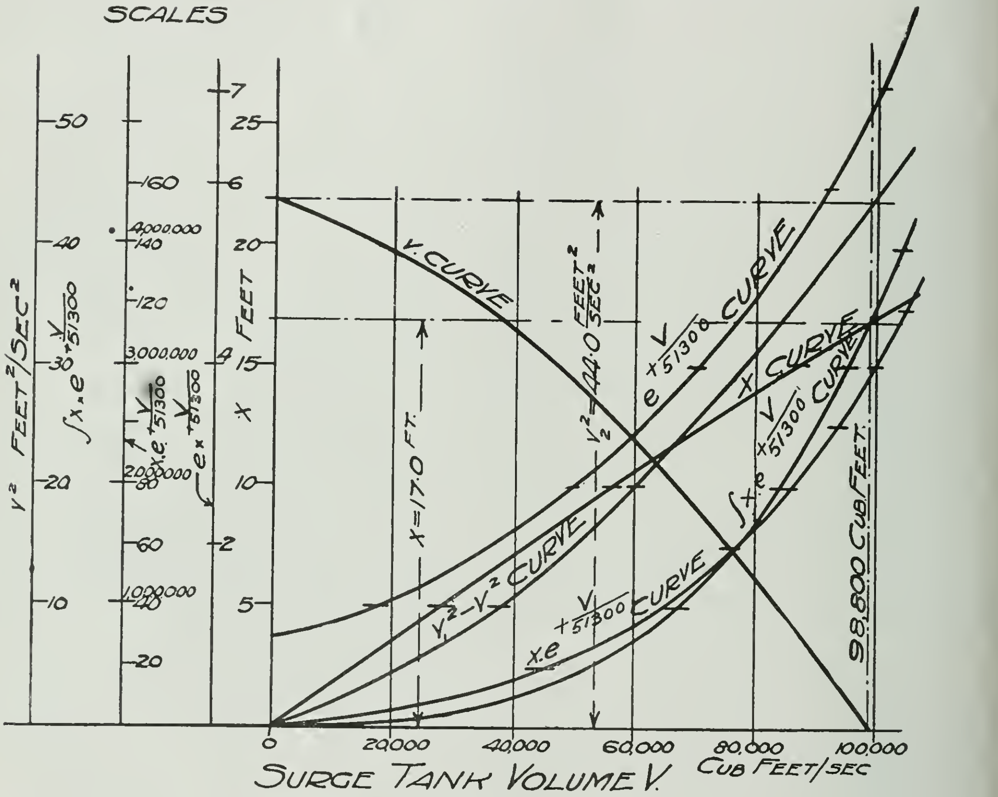

Fig. 13.

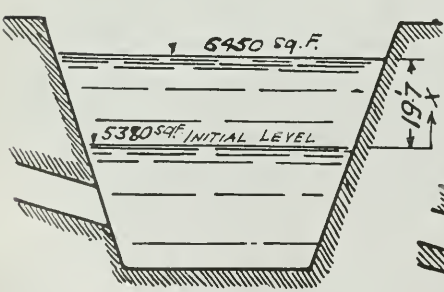

Fig. 14.

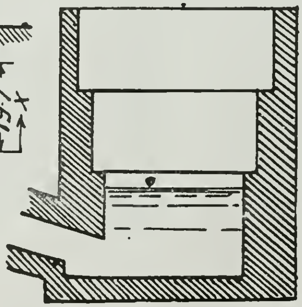

Fig. 15.

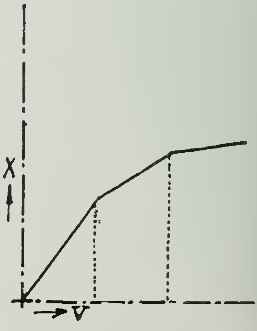

Fig. 16.

of 5,380 sq. ft. a surge of 17.8 ft. resulted. But the volume of water lifted is, in this case, somewhat greater, that is, 98,800 cu. ft., as compared to but 95,600 cu. ft. in the former case.

In the same easy way the graphical method may be applied to a surge tank in which the cross-section varies irregularly with the height. For instance, as the Albula plant of the city of Zurich. (Fig. 15.) In this a break occurs at the points on the x curve where the ratio between sectional area and height changes. (See Fig. 16.)

Appendix B—Simplified and Approximate Formula for the Determination of Surge Tanks With Constant Cross-Section.

By A. Strickler.

The designing engineer must often consider several solutions for one problem and from these select the best for the actual work. For these preliminary investigations he is in need of a simple slide-rule formula. In the following such a formula will be derived for the required area of a surge tank with given maximum surge.

As initial formula, equation 51 may be used for a sud-

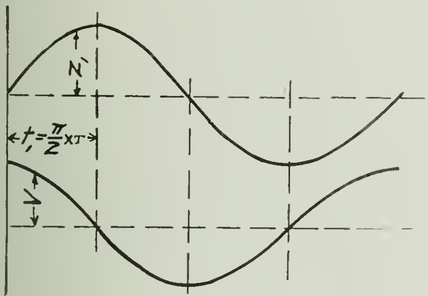

Fig. 17.

den full shut-down.

$$\frac{M \cdot v_1^2}{2} + G \cdot h_1 = G \cdot y_1 + A^1 \qquad (51)$$

The notation being the same as before, the average friction head in the surge tank for the first surge may be called h_a. Equation 51 can now be written:

$$-\frac{w.a.L}{2g} \cdot v_1^2 + G\left(\frac{y_{max}}{2} - h_1\right) + G \cdot h_a = o$$

$$-\frac{a.L.v_1^2}{2g} + \frac{A.y^2_{max}}{2} - A.y_{max}.h_1 + A.y_{max}.h_a = o \qquad (51a)$$

since $h = \frac{u^1.L}{P.2g} \cdot v_1^2$; $\quad h_a = \frac{1}{t_1}\int_0^{t_1} h.dt$

$$= \frac{1}{t_1}\int_0^{t_1} \frac{u^1.L\,v_1^2}{P.2g}.dt \qquad (51b)$$

t_1 = time from the beginning of the surge to the moment of maximum elevation. In order to integrate equation 51b, v must be known as function of t. The simplifying assumption is now made that the first part of the v curve is a regular cosine curve. This would be true if the water level fluctuations were an undamped harmonic of the form

$z = C \,.\, \sin\left(\frac{t}{T}\right)$ (see Fig. 17).

Making the above assumption

$$v = \frac{s.A}{a} = \frac{A}{a}.\frac{dz}{dt} = \frac{A}{a}.\frac{C}{T}.\cos\left(\frac{t}{T}\right)$$

and also $\quad v_1 = \frac{A}{a}.\frac{C}{T}.\cos\frac{o}{T} = \frac{A}{a}.\frac{C}{T}$

$$v = v_1 \cos\frac{t}{T}; \qquad h = h_1 \,.\, \cos^2\left(\frac{t}{T}\right)$$

Substituting these values in equation (51b) there results:

$$h_a = \frac{1}{t_1}\int_0^{t_1} h_1 \,.\, \cos^2\left(\frac{t}{T}\right) dt = \frac{h_1}{\frac{\pi}{2}T}\int_0^{\frac{\pi}{2}T} \cos^2\left(\frac{t}{T}\right) dt \qquad (51c)$$

$$= \frac{h_1}{\frac{\pi}{2}.T} \times \frac{\pi.T}{4} = \frac{h_1}{2} \qquad \therefore \qquad h_a = \frac{h_1}{2}.$$

The average friction head in the tank for the time up to the maximum surge is therefore equal, under the above mentioned assumption, to half the friction head which exists in the conduit during operation. This value of h_a introduced into equation 51a (work balance) gives:

$$-\frac{a.L}{2g}.v_1^2 + \frac{A}{2}.y^2_{max} - A.y_{max}.h_1 + \frac{A.y_{max}.h_1}{2} = o$$

$$\text{or } A = a \,.\, \frac{\frac{L}{g}.v_1^2}{y_{max}\,(y_{max} - h_1)} = \frac{a\,\frac{L\,.\,v_1^2}{g}}{(z_{max} + h_1)\,z_{max}}$$

$$\therefore A = \frac{a.v_1^2}{2g}.\frac{2L}{(z_{max} + h_1)\,z_{max}}.$$

This formula gives results somewhat too large (1% to 3%) but is exact enough for preliminary computations.

Bibliography.

In the following the translators add a list of publications, dealing with the subject of surge tank regulation:

On the control of surges in water conduits. By W. F. Durand. A.S.M.E. Pamphlet No. 1353. Year 1912. Deals with surge tanks of the taper section type.

Speed regulation in hydro-electric plants. By Wm. F. Uhl. A.S.M.E. Pamphlet No. 1354. Year 1912. A survey of the methods used for the speed regulation of turbines.

The surge tank in water power plants. By R. D. Johnson. A.S.M.E. Pamphlet No. 1204. Year 1908. Contains the theory of the differential surge tank.

Wasserschlossprobleme. By Franz Prasil. Schweizerische Bauzeitung, Vol. 52, 1908. Authorized translation by E. R. Weinmann and D. R. Cooper. *The Canadian Engineer*, Vol. 27, 1914.

Druckschwankungen in Turbinenzuleitungsrohren. By A. Budau. Zeitschrift des oestreichischen Ingenieur- und Architektenvereins, year 1905. A mathematical analysis of pressure variation in pipe lines.

Beitrag zur Bemessung des Inhalts von Wasserschloessern. By Konrad Pressel. Schweizerische Bauzeitung, Vol. 53, 1909. A short study of the laws governing the water fluctuations in surge tanks.

Allgemeine Theorie ueber die veraenderliche Bewegung des Wassers in Leitungen. By Lorenzo Allievi and Robert Dubs. Berlin, 1909, Julius Springer. A mathematical analysis of the hydro-mechanic problems involved in pressure conduits.

Zur Theorie des Wasserschlosses bei selbsttaet'g geregelten Turbinenanlagen. By Dieter Thoma, Muenchen, 1910. R. Oldenburg. Containing an analysis of resonance phenomena.

Des effets de resonance, qui peuvent se produire pour les hautes chutes dans les coups de belier. By Comte de Sparre. La houille blanche, 1907. Investigates phenomena of resonance.

Die Kraftuebertragungsanlagen der Rurtalsperren-Gesellschaft. By Rasch and Bauwens. Zeitschrift des Vereins deutscher Ingenieure, pp. 609-611, year 1908. Gives an interesting account of resonance phenomena due to inadequate surge tank dimensions.

Unsteady water-flow in pipes. Water-ram. By I. P. Church. Cornell Civil-Engineer, year 1898.

Water hammer experiments. By M. R. Lott. Engineering Record, October, 1912.

The surge tank at San Francisquito power station No. 1, with discussions by R. D. Johnson, Roy Taylor and W. F. Durand. Engineering Record, years 1913 and 1914.

Versuche ueber Druckschwankungen in eisernen Rohrleitungen. By A. Strickler. Schweizerische Bauzeitung, Vol. 64, 1914, (Laboratory tests).

NOTE.

The article "Surge Tank Problems" will be issued at a later date in pamphlet form. A note will appear in *The Canadian Engineer* when ready for delivery.

PANAMA CANAL OPENED.

The United States War Department steamship "Ancon" has made the passage through the Panama Canal, and transit through the waterway is now officially open to the traffic of the world. The "Ancon" made its way from its berth at Cristobal to the end of deep water channel from the Atlantic to the Gatun Locks. It went through the locks, which have a lift of 85 feet, in 70 minutes. It continued through the waterway, from deep water on the Atlantic to deep water on the Pacific side, without incident.

Vessels drawing not more than 30 feet of water and up to 10,000 tons register may now make the passage. It will be possible to put some of the big American dreadnoughts through at any time.

Facts About the Canal.

Total length of canal, 50 miles.
Salt water, channel to Gatun Locks, 7 miles
Fresh water, Gatun Lake and Culebra Cut, 33 miles.
Fresh water, Pedro Miguel Lock to Miraflores Locks, 1½ miles.
Salt water, Miraflores Locks to Pacific, 8½ miles.
Width of channel, 300 to 1,000 feet.
Minimum depth, salt water, 40 feet.
Minimum depth, fresh water, 41½ feet.
Total angles in canal, 600d 51m.
Sharpest angle, Tabernilla, 67d 10m.
Work begun by Americans, May 4, 1904.
Number of men employed, average, 40,000.
Steam shovels employed, 101.
Locomotives employed, 307.
Drills employed, 4,572.
Railway cars employed, 4,572.
Dredges employed, 20.
Cranes, piledrivers, barges, tugs and miscellaneous machines employed, 263.
Total cost, $375,000,000.
First vessel through Gatun Locks, Sept. 26, 1913.
Water let into Culebra Cut, Oct. 1, 1913.
Gamboa dike blown up, Oct. 10, 1913.
First vessel through Miraflores Locks, Oct. 14, 1913.

Culebra Cut.

Length, 9 miles.
Width at bottom, 300 feet.
Width at top, ¼ to ½ mile.
Deepest excavation, 495 feet.
Average depth of excavation, 120 feet.
Excavated by French, 20,419,720 cubic yards.
American excavation, estimate, 89,794,493 cu. yds.
Added excavation, account of slides, about 22,000,000 cubic yards.
Day's record for one steam shovel, 4,823 cubic yards.
Largest slide, Culebra, 10,000,000 cubic yards.

Gatun Dam.

Length, 8,000 feet.
Width of base, 2,100 feet.
Width at water level, 400 feet.
Width at top, 100 feet.
Height, 115 feet.
Volume of rock and clay, 22,100,000 cubic yards.

Gatun Lake.

Area, 164 square miles.
Height of surface above sea level, 85 feet.
Water capacity, 183,000,000,000 cubic yards.
Area of watershed, 1,320 square miles.
Minimum depth, rainy season, 47 feet.
Minimum depth, dry season, 39 feet.

Gatun Locks.

Length over all, 3,500 feet.
Width over all, 350 feet.
Volume of concrete construction, 2,043,730 cu. yds.
Width of side walls at base, 52 feet.
Width of side walls at top, 8 feet.
Width of centre walls, 60 feet.
Height of walls, 81 feet.
Dimensions of lock chambers, 1,000 x 110 feet.
Depth of water in lower lock chambers, 40 feet.
Depth of water in upper lock chambers, 41½ feet.
Length of lock gate leaves, 65 feet.
Height of lock gate leaves, 47.4 to 82 feet.
Weight of largest gate, 1,483,700 pounds.

Editorial

DEPRESSION AND DUTY.

Governments and municipalities, corporations and individuals should strive at this time to remember the natural virtues—justice, prudence, temperance and fortitude. The theological virtues—faith, hope and charity—are equally important, but they will follow without effort if the natural virtues are exercised.

Justice demands that all men who are willing to work be given work.

Prudence requires careful avoidance of extravagance and equally careful avoidance of panic that might be caused by unnecessary retrenchments and false economies.

Temperance embodies rational self-control. It means the suppression of any tendency to thoughtless actions. It implies the calmness and patience that were never more essential in Canada's history than at present.

Fortitude calls for resolution and constancy. It is demanded when the evils of trade depression and war are encountered, if they are to be overcome and transformed into opportunities.

No men in Canada are able to recognize these broad principles of philosophy better than the technically trained and those whose experience has been in handling large numbers of men. Therefore the engineers and contractors have a duty that they should remember. They should be leaders in thought, leaders in action. No man in a community to-day should be bigger than its city engineer, for instance. And the engineers and contractors must direct public thought and action into sane, philosophical, business-like channels.

RAILROADS FAVOR GOOD HIGHWAYS.

Public roads are an indispensible part of the transportation system of Canada, supplementing the railroads and waterways. That this is well recognized by the railroad officials is evidenced by recent remarks made by President Harrison of the Southern Railway Company.

Speaking of the relation of the country highway to the railroad, Mr. Harrison said: "Whatever may be the final destination of the farm products, their first movement must be over the country road, and if the farmer is to receive the largest measure of benefit from good roads, the policy should be adopted of improving those highways which radiate from market towns and shipping stations and over which the farmers must haul their produce. The profit which will be earned by the farmer may depend largely upon the condition of the road from his farm to a shipping station. With good roads he can not only haul heavier loads in shorter time but, except as to perishable commodities, he can market his produce when prices are most favorable and can do his hauling when it is most convenient, and even when the ground is too wet for work in the fields.

"The manifold advantages of an improved highway in reducing the cost of drayage, facilitating social intercourse, promoting school and church attendance, expediting rural mail delivery, increasing the value of farm lands, and promoting agricultural development back from the railroads, are so great that they need but to be enumerated to present a convincing argument in favor of road improvement.

"Several years ago the Southern Railway Company, in conjunction with the United States Agricultural Department and State and local authorities, operated over its lines a good roads train, carrying machinery and lecturers, and building at central points object-lesson roads. This was accelerated in 1911 by the operation of another good roads train in co-operation with the United States Department of Agriculture and the American Highway Association."

CO-OPERATING WITH COMPETITORS.

Trade is rapidly becoming civilized. Corporations, like individuals, have learned that it pays to apply the Golden Rule. No better example of the benefits of proper association of interests could be found than the eleventh annual meeting of the National Paving Brick Manufacturers' Association at Buffalo last week.

The aim of brick manufacturers formerly was to advance as much as possible by individual effort, each plant jealously keeping its competitors in the dark regarding any improvements in machinery or methods, each engineer regarding his knowledge and his experiments as strictly private property.

The result was brick that was not dependable, not uniform, not standard. Co-operation, better ideas, and more liberal business policies have changed all this. Largely through the work of the association mentioned, paving brick has been brought up to a high standard and is being manufactured more efficiently and more economically.

Over two hundred and fifty brick manufacturers and guests, among whom were many municipal and highway engineers and road contractors, attended the meeting. The business sessions were completed on the first day, and the following two days, Thursday and Friday, were devoted to inspections of brick highways in and near Buffalo. There was a free exchange of ideas, both in regard to manufacturing processes and methods of construction. The relative advantages of bituminous and cement grout fillers; the necessity or otherwise of transverse expansion joints, and the best fillers to use if such joints are left in the pavement; the advisability or inadvisability of longitudinal expansion joints at each side of the road, and the advantages therefor of bituminous fillers and of creosoted wood strips—these and scores of other problems of great interest to highway engineers were discussed informally, and many of them practically settled by concensus of opinion.

The discussions were extremely valuable, because over half the men present were brick highway experts—men like "Bill" Perkins, formerly resident engineer at Buffalo for the New York State Highway Commission; Frank Dunn, of Dunn-Wire-Cut-Lug-Brick fame; Will P. Blair, the association's energetic secretary; and scores of other men who, like those mentioned, have built hundreds of miles of brick roads.

The meeting was by no means entirely one of self-admiration, however. It was realized that there is serious work still to be done by the association to perfect brick and methods of brick construction. For in-

stance, the announcement of the State Highway Commissioner of Illinois that he is building 82 miles of road—12 miles of brick and 70 miles of concrete—reminded the members of the association that there are engineers who believe that in building a brick road with cement filler, the bricks should be laid a mile apart.

LETTER TO THE EDITOR.

British Manufacturers Showing Courage.

Sir,—We want to ask you to help us and other British engineering manufacturers by putting a note in your journal explaining that we are keeping our shops going notwithstanding the war, and want all the orders we can get from Canada.

Everybody here appreciates the enormous help we are getting from Canada in men and food, but we want your readers to help to keep our industries alive, so that we can keep the wolf from the door. If Canadians will make a determined effort to send their orders to the old country instead of to the States, it will be invaluable.

Bear in mind that about 25 per cent. of our men are with the forces now and that the rest of us must earn their keep, for the firm has undertaken to pay half salaries and wages to all men who have joined, as well as to keep their places open, and most other firms are doing the same.

We cannot expect to give quite such good deliveries just now as usual, but that is exactly where we look to Canadian buyers to stretch a point.

Sydney (Australia) has set a good example. The corporation had placed an order for a 5,000 kw. turbo-generator with a German firm at a "dumped" price. They have cancelled that order and have placed the work with us at our price and, what is more, they are going to pay us instalments as work proceeds in our shops.

WILLANS & ROBINSON, Limited.

Rugby, England, August 31, 1914.

PERSONAL.

R. H. SPERLING has been appointed assistant to the chairman of the B.E. Electric Railway company, in London, Eng.

WM. C. ROWSE, B.Sc., M.E., has been appointed to the chair in the University of Manitoba, as professor of mechanical engineering. Professor Rowse is a graduate of Purdue University.

H. P. MAYBURY, M. Inst. C.E., in November of last year appointed to the office of Chief Engineer of the British Road Board, has been elected to the newly created position of Manager and Engineer.

M. A. WOODS, recently assistant chief engineer of the G.T.P. Railway system, has been appointed to the position of chief engineer, left vacant by the resignation of Mr. B. B. Kelliher. Mr. Woods' headquarters will be at Winnipeg, Man.

M. C. FLINT, formerly assistant engineer in the construction department of the C.P.R. company, and engaged on branch line and double-track construction, has been appointed resident engineer of district No. 4 of the Alberta division of the C.P.R. system. Mr. Flint's headquarters are at Edmonton, Alta.

JAMES A. MacGREGOR has been recently promoted by the C.P.R. company to a position as district superintendent on the company's Alberta division. Mr. MacGregor's headquarters are Edmonton, Alta. His last office with the railway staff was that of a relieving superintendent on various divisions of the system.

THOMAS ADAMS, the noted town planning expert of the British local government board, is being brought to Canada by the Conservation Commission to act in an advisory capacity. Mr. Adams will arrive in Canada early in October. He will collect information for the commission relative to various Canadian municipalities, and his services will be available to any of them.

L. E. ALLEN, Belleville, Ont., county engineer for Hastings; A. W. ELLSON FAWKES, Calgary, Alta., waterworks engineer; E. C. A. HANSON, Saskatoon, Sask., city electrical engineer; G. H. HATFIELD, St. John, N.B., road engineer; W. MURDOCH, St. John, N.B., city engineer; and G. D. WEAVER, Melfort, Sask., are Canadian names appearing on the most recently published list of members of the Institution of Municipal Engineers (Great Britain).

GEORGE W. COBURN, recently appointed a resident engineer for the C.P.R. company, and located at Brandon, Man., began service with the company in 1896, and since that year, has received the following promotions: from 1896-1900, roadsman and draughtsman at Farnham, Que.; 1901-1907, draughtsman and assistant district engineer, Souris and Brandon, Man., and Moose Jaw, Sask.; 1907-1914, district engineer and resident engineer, Souris and Brandon, Man.

OBITUARY.

The death occurred on August 30th in New York of William De Hertburn Washington, a prominent member of the American Road Builders' Association. He was a member of the American Society of Civil Engineers, and, at one time, was United States consul at London, Ont. Twenty years ago, he went to New York and became President of the Hydraulic Construction Co. Mr. Washington took a prominent part in the Third International Road Congress, held at London, Eng., in June of last year, and also in December at the Philadelphia convention of the American Road Builders' Association.

Word reached the Department of Railways and Canals, Ottawa, on September 10th, of the death caused by drowning on August 25th of James Wilson, an engineer in the employ of the government for the past two years on the Hudson Bay railway construction.

COMING MEETINGS.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—Charles Carroll Brown, Secretary, Indianapolis, Ind. Meets at Somerset Hotel, Boston, Mass., October 21st, 22nd and 23rd.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

A weekly paper for engineers and engineering-contractors

BRIDGE ACROSS THOMPSON RIVER, LYTTON, B.C.

A FEW ILLUSTRATIONS AND A SHORT DESCRIPTION OF THE CONSTRUCTION OF THE NEW BRIDGE COMPLETED IN JUNE, 1914, BY THE PROVINCIAL GOVERNMENT, AND SPANNING THE THOMPSON RIVER AT LYTTON, B.C.

IN August of last year, the government of British Columbia commenced the construction of a bridge, which was designed by E. A. Stone, M. Can. Soc. C.E., M. Inst. C.E., Consulting Engineer, Vancouver. The structure was erected under the supervision of J. E. Griffith, Deputy Minister and Chief Engineer of the Provincial Department of Public Works, and was completed in June, 1914. It crosses the Thompson River, just above the junction with the Fraser, at a site lying between that of the old government's wooden bridge and the crossing of the Canadian Northern Railway. Fig. 1 illustrates the former structure and also shows in contrast the old and new bridges. The superior excellence in the appearance of the latter is self-evident, as is also the added height of level, that of the new bridge being 40 feet above that of the old.

The contract for both the supply of the material for the sub-structure of the bridge as well as for the entire construction was awarded by the government to the Graff Construction Company. The material used was concrete, and of that 2,000 yards were required. This concrete rests on a rock foundation, which is dry at extreme low water; and was deposited by means of buckets suspended from a cable running across the river, as shown in the

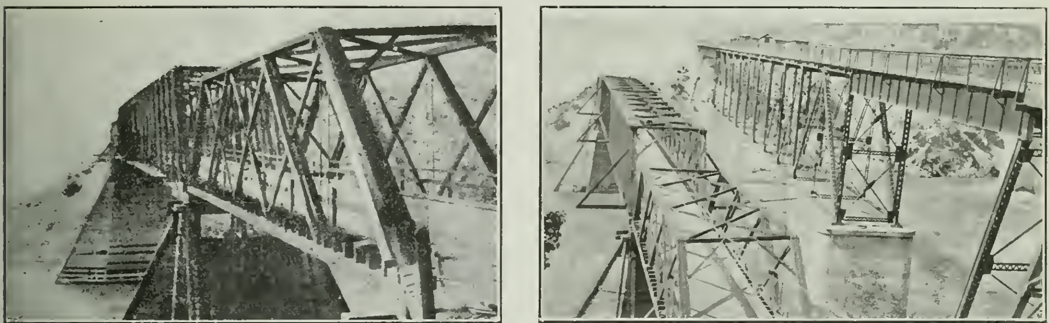

Fig. 1.—Old and New Bridges in Contrast.

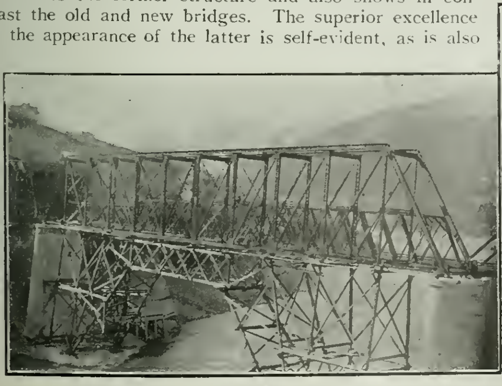

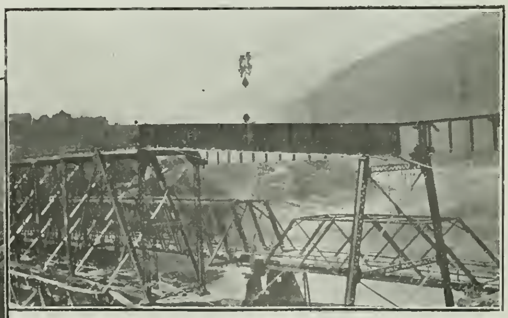

Fig. 2.—Falsework for Erection of 250-Foot Span. Plate Girder Span Being Placed by Cableway.

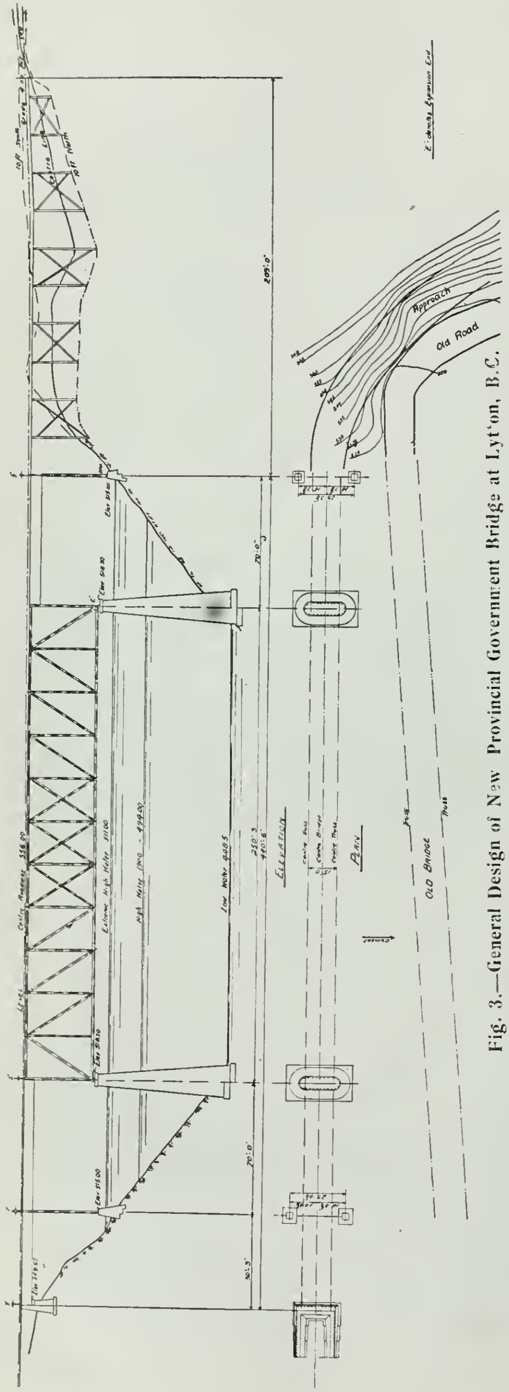

Fig. 3.—General Design of New Provincial Government Bridge at Lytton, B.C.

first and second sections of Fig. 5. The concrete was mixed to a consistency of 1 : 3 : 5, and, when completed, made a sub-structure of both satisfactory strength and very creditable appearance.

Fig. 3 shows the general plan of the new bridge as proposed and constructed; and Fig. 4, sections of the concrete abutments carrying the main truss span and of the trestle forming the approaches. As may be seen in the third section of Fig. 5, which indicates the progress made upon the south pier of the bridge by January 19, 1914, a timber trestle approach, 209 feet in length together with a similar length of grading, had to be built on the southeastern bank of the river. The concrete piers of the abutments which carry the main truss span of the bridge are 70 feet above low water, the distance of the resting surface of the truss above the extreme high-water level being 7½ feet. The large truss span resting upon these piers is 250 feet in length and 35 feet in depth (Figs. 1 and 2); while there are also two 70-foot plate girder spans, one on either side of the main section, and in addition a 50-foot plate girder span carried on steel

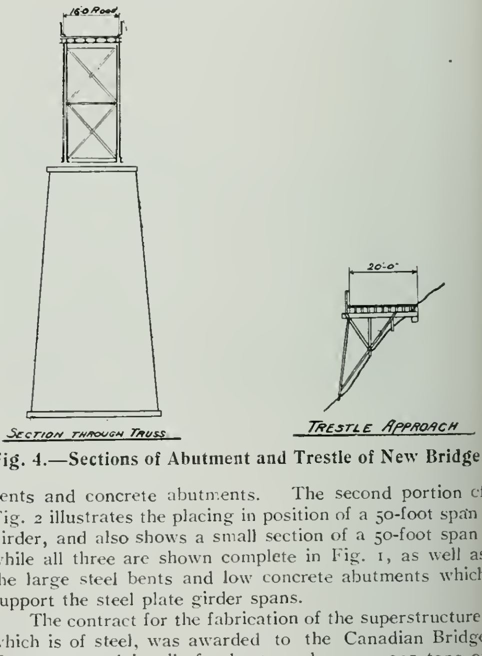

Fig. 4.—Sections of Abutment and Trestle of New Bridge.

bents and concrete abutments. The second portion of Fig. 2 illustrates the placing in position of a 50-foot span; girder, and also shows a small section of a 50-foot span; while all three are shown complete in Fig. 1, as well as the large steel bents and low concrete abutments which support the steel plate girder spans.

The contract for the fabrication of the superstructure, which is of steel, was awarded to the Canadian Bridge Company; and in all, for bents and spans, 215 tons of material were required. The bridge was so designed that the combined strength of the concrete and steel work would be capable of carrying a live load of 75 pounds to the square foot on the 250-foot truss and 100 pounds to the square foot on the 70- and 50-foot spans, together with a concentrated load of a 16-ton road roller.

The roadway of the bridge is 16 feet in width and has been constructed of 4-inch plank protected on either side by a 4-foot hand railing with posts 7 feet 7½ inches apart. The roadway plank is supported on 6-inch joists of varying depth, according to camber, on steel I-beam stringers, while a crowning, one inch thick, has been applied to the top of the floor.

By September 1, 1913, the Graff Construction Company, contractors for the bridge, had advanced to the

stage indicated in the first section of Fig. 5. The north abutment was in place; the cable-way erected, and the bucket had commenced the depositing of the concrete mixture for the formation of the piers; in October, this abutment was completed and the pedestals for the steel of the bridge work in progress in Fig. 2 were taken on April 15 and April 22, the former portion of the illustration showing the falsework used in the erection of the main span, perhaps the most interesting feature in connection with the building of the bridge, the falsework

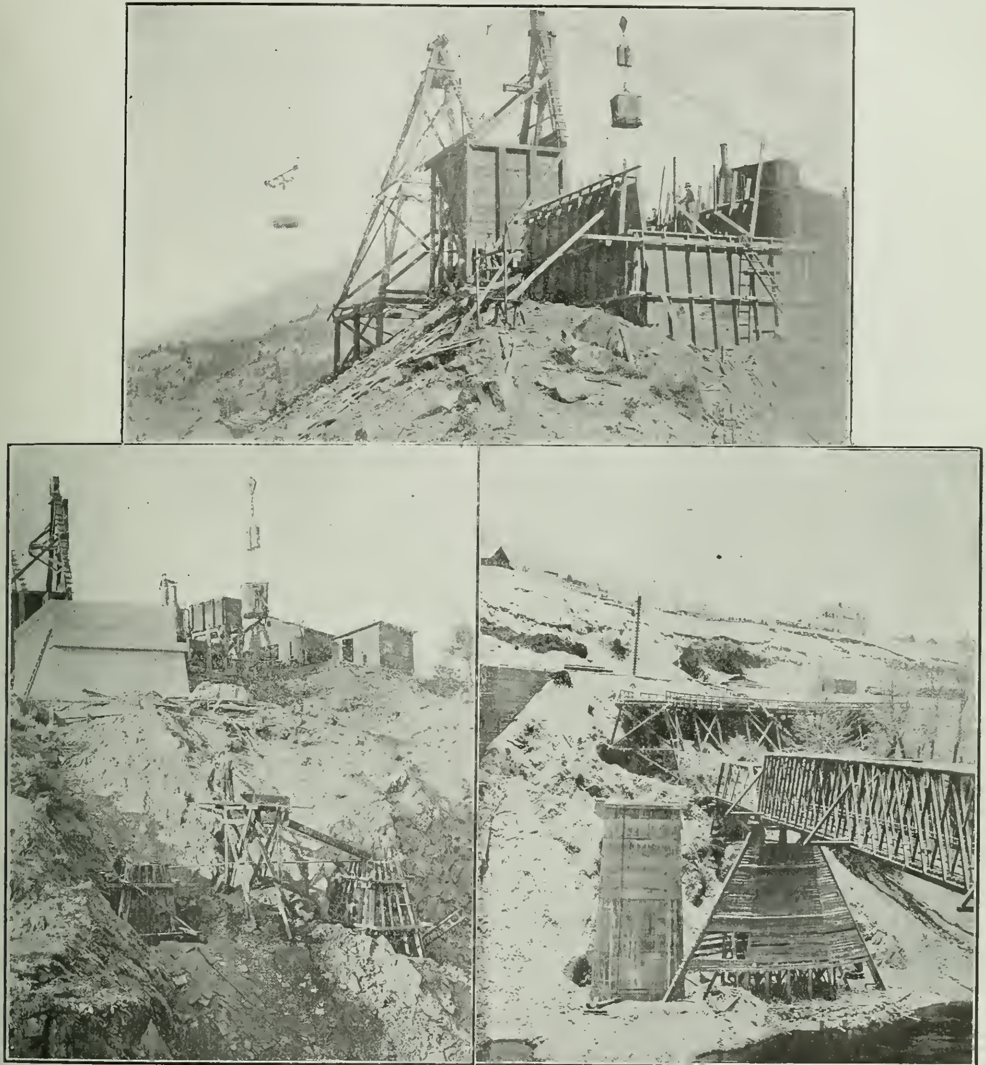

Fig. 5.—North Abutment in Place, Cableway and Bucket. North Abutment Completed and Pedestals of Steel Bent. South Pier and Timber Trestle Approach.

bent constructed, as shown in the second section of the same figure. The timber trestle approach on the south-eastern shore, shown in the distance in the third section, was completed early owing to the fact that the contractors were obliged to wait for lower water before commencing to build the main piers; and by January 19, 1914, the south pier had reached the stage of advancement also indicated in the last section of Fig. 5. The photographs extending from each shore and carrying a Howe truss in the centre; and the latter, descriptive of the erection of the steel superstructure, all of this being placed by means of a cableway. The structure was completed finally and opened for traffic in June, 1914.

Reference was made to the design of this bridge in *The Canadian Engineer* for July 17th, 1913.

OUTFALL SEWER CONSTRUCTION.*

By James Munce, M. Inst. C.E.,
Deputy City Surveyor, Belfast, Ireland.

In order to purify (where necessary) and dispose of sewage it must first be collected. The object of this paper is to ask engineers to take into consideration this particular section of their work, and leave for a little the chemists and bacteriologists to deal with the sewage itself which the engineers have collected for them in the place most convenient for getting rid of it, or of the effluent they leave us to dispose of.

As every portion of the country which is not a lake or marsh drains by gravitation to the sea, there is not except under very exceptional circumstances, any great genius displayed in designing a scheme entirely depending on pumps.

A town does not of necessity remove the natural watercourses, but there is no doubt the extension of buildings and streets with impervious surfaces sends the water more rapidly into the outlets, natural or artificial, provided for it. In fixing the sizes of sewers the sewage is the smallest item to be provided for, and the rainfall or surface water is the volume which needs most careful consideration.

The growth of the area within a reasonable period, and the increased use of water as the population increases, both in opulence and numbers, must not be forgotten. Many communities which a few years ago considered 25 gallons per head an ample supply now use 50 gallons. As sudden rainfalls often multiply the volume to be dealt with by 12 to 15, the positions of storm overflows and their possible effect on the streams or other outlets into which they discharge require careful study.

The problem in Belfast has been one of extreme difficulty. A large area of the city has been reclaimed from the sea, and many acres are so far below high-water level that they are only kept from daily flooding by the quay walls, which are 0.6 ft. above the highest recorded tide and 4 ft. above ordinary high water. Formerly the sewers all discharged into the harbor or into rivers which in turn discharge into it; they were protected by valves, and only discharged on the last half of the ebb tide. These have now been intercepted, and the area drained by them, and also the whole of the County Down portion of the city, 5,400 acres, form the low-level drainage area. It will be seen that as no storm overflows are available from the lower portion of this area except at and near the time of low water, storm pumps to relieve the sewers are unavoidable. The intercepting sewers extend for about 3 miles on the County Antrim side of the river, and rather more on County Down side, through lanes and streets made on the reclaimed areas; they have a fall of at least 2 ft. per mile, and on the portions nearest the river are almost entirely through alluvial deposits known locally as "sleetch," or in-filling of all kinds deposited inside the reclamation embankment.

The difficulty of construction in ordinary filling was of the usual kind met with in such material, and is not further referred to. The sleetch is a remarkable material; when dry it crumbles like fine sand; with a little moisture it swells and becomes like a soapy clay; with a quantity of water it has the consistency of soft dough.

The main outlet sewer was constructed for a mile in slob lands of sleetch, which are dry at low water, but covered from 2 ft. to 6 ft. at high water. As an example of the unstable nature of this sleetch, it may be mentioned that when the author was making the surveys for the scheme in 1886 he put a man out of a boat on the apparently firm bank of a channel to fix a pole; he sank so quickly in it that he was rescued with difficulty, yet when the work was being carried out this same bank proved one of the firmest places met with and most difficult to excavate.

When the scheme was laid before Parliament it provided for four cast-iron pipes, each 4 ft. in diameter, surrounded by concrete, as the outfall sewer into the sea, one-fifth of a mile in length.

The landowners on the lough side objected to the position of the outlet and opposed the Bill. The corporation directed their consulting engineer to meet the adviser of the opponents, both very eminent in their profession, and settle the matter amicably. They agreed to omit the iron pipes, and construct instead a wooden double trough 1 mile long under the slob, with its outlet in deep water. This chute, as it was termed, is constructed of pitch-pine, which was shipped at Galveston, already cut to the scantlings required and floated from the vessel direct to the work. The method of construction was as follows: Two rows of sheet piles were driven of a length sufficient to form a half-tide dam, and constituted the permanent outer sides. The range of tide is 8 ft. in Belfast. When a length of 100 ft. or so had been driven, a cross-dam was formed, and when the tide had fallen to the level of pile heads the dam was pumped out and the excavators had about six hours' work before the tide rose over the piles again. When a length had been excavated the centre piles were driven, and the construction of the woodwork completed. When a length was finished, the pile sides forming the half-tide dam were cut off and were sufficiently long to form the centre piles for another length. In due time the chute was completed. During the past twenty-five years it has cost a great deal to repair. Many remedies were proposed for it. Hundreds of tons of old concrete were placed on its top, and strong piles fixed to keep it in its place. It is still there, but is unsatisfactory. A ferro-concrete outlet sewer is now being constructed alongside it; when this has been completed the old wooden one will be abandoned.

Lessons to be drawn from the experience gained are that compromises made between rival consulting engineers in the short time available during the progress of a Bill before a Parliamentary Committee are not always satisfactory, and that the considered design of an engineer who knows local conditions should not lightly be set aside.

This new outlet sewer through the slob lands will be in progress for more than another year, and is well worth a visit by any who can afford the time.

The present city surveyor carried out the repairs to the 5,500,000 gallons storage tanks constructed on the slob in a very ingenious way. These tanks were leaking and cracked in the bottom and sides; to rebuild them would have probably cost £40,000, besides the terrible upset to the whole outfall of the sewers. He took one tank at a time and forced cement grout into the crevices and under the floor; altogether 1,120 tons of cement were used. It was mixed with an equal quantity of sand, and was put in under air pressure varying from 7 lbs. to 15 lbs. per square inch. The reservoir is now quite watertight.

Excavations recently made alongside it show that the grout found all the crevices in the foundation and followed them through the sleetch, even 4 ft. beyond the outer walls.

---

* From a paper read before the Blackpool (Eng.) Congress of the Royal Sanitary Institute.

The outfall sewer from junction of the high-level and low-level sewers at No. 1 pumping station to the outfall works is laid along the centre of an embankment about 150 ft. wide, formed of dredgings and sleetch lifted from the harbor during the previous twenty years. There is a timber pond on each side. When the sewer was commenced this embankment was comparatively dry, and the trench stood without timbering; those in charge were charmed, and for a week or two boasted of how cheaply the work was being constructed. Alas for their hopes! A few wet days changed all this, and sheet piling had to be adopted and left in for the entire length of the work to keep the sewer in line. Notwithstanding this precaution the arch cracked from end to end, and had to be made good before the sewer could be used. Some portions of it have spread, and had to be replaced recently. A road 50 ft. wide is now made along the embankment, and forms the approach to the outfall works.

As a relief to the main outfall sewer, and to make it available in times of storm for the increased volume flowing from the high-level area by gravitation, it was arranged to lay a 4-ft. diameter pumping main direct from No. 1 pumping station to the outfall works, a distance of about 1,000 yds.

Before deciding on the use of steel pipes careful examination was made of similar pipes which had been in use for some time as a sludge main from the tanks to the jetty where the steamer is loaded, and also of some others carrying the main outfall sewer under a sea channel; these proved to be in such good condition that the city surveyor had no hesitation in adopting similar pipes for this main.

They are 4-ft. diameter welded-steel pipes, 3/8 in. thick, with spigot and faucet joints. The material is in accordance with the British Standard Specification, and has a tensile strength of not less than 24 tons nor more than 30 tons per square inch, with an elongation of not less than 22 per cent. on a test bar 6 in. long. The pipes were raised to a temperature of 300 deg. to 350 deg. Fahr., and then dipped in a bath of Dr. Angus Smith's bituminous compound kept at a temperature 300 deg. Fahr. during the operation, after which they were covered with a wrapping of asphalted jute. They were then weighed, and the weight painted in white lead on the inside of the socket. When laid, the joints were caulked with gasken and 2½ in. of lead wool.

One decided advantage in the use of these pipes is the smaller number of joints to be made in bad ground, and the reduction of the volume of underground water which can enter such a pipe.

The amount of subsoil water which finds its way into trunk sewers, notwithstanding all attempts to make them impervious, is very large. Careful investigation in Boston proved that in pipes from 8-in to 36-in. diameter at least 40,000 gallons per mile per day got into the sewer, and it is estimated that on the average of large trunk sewers, 75,000 gallons per mile per day had to be provided for. These figures have, I believe, been adopted in the reports of the New York Sewage Commission. In waterlogged ground the figures would doubtless be greater.

On the other side of the harbor the subsoil is of an entirely different nature; sand is found in the lower portions, and red clay a little higher up. In the sand the tide rises and falls, evidently following some of the old channels of prehistoric days.

Some years ago, when a 5-ft. diameter sewer was being laid in a street 60 ft. wide, the trench was close-sheeted, and every precaution taken, as the contractor thought, to exclude water; yet he found it almost impossible to keep the trench dry enough to get in the concrete foundation, and claimed 50s. a lineal yard for an extra 6-in depth of excavation and concrete. (He was allowed 9s.)

An examination of an old survey of 1791, which lately came into the author's possession, shows that the site was at that date under the sea, and from other sources it is now discovered that the site was reclaimed about 1833.

Extensions of this sewer several miles in length were made through good ground, but one branch (about 1 mile), along what at one time was the margin of the lough, was nearly all the way through running sand. The contractor, however, put on very powerful pumps, and was able to keep the water out of the trench a sufficient time to enable the lower part to be built. Cracks appeared in buildings about ½ mile from the site; fortunately for him, his pumping operations were not suspected.

A relief sewer parallel to the main one referred to is now being constructed about 300 yds nearer the sea; although the ground is not good much of it being infilling the difficulty of construction is much less than in the case of the original sewer.

LOST PRESSURE IN GASEOUS EXPLOSIONS.

The following item has been abstracted from a paper read before the British Association for the Advancement of Science by Professor W. M. Thornton, D.Sc.,D., Eng:

When the maximum pressure of an explosion is calculated from the heat of combustion of the elements of the gaseous mixture, values are obtained which are in all cases about twice those found by experiment. The mean of a large number of "efficiencies of explosion" for different combustible gases approaches one-half. To account for this, four chief suggestions have been made: (1) That there is dissociation of the products of combustion; (2) that the specific heats are much higher at explosion temperatures; (3) that the products are rapidly cooled by radiation to the walls of the vessel; (4) that the combustion is not complete at the time of reaching the maximum pressure. None of these is in itself sufficient to account for all the loss of pressure. The suggestion is now made that it may be caused by the forces of cohesion which come suddenly into play at the moment of formation of a molecule, check the translational energy to which alone pressure and temperature are due, and raise for the moment the rotational energy of the combining bodies. It is shown that the ratio of the translational energy of two colliding and cohering bodies before and after collision is one-half, and this ratio is to be expected for the whole mixture.

The suggestion receives support from the form of the curve connecting efficiency of explosion and changed percentage of gas in the mixture. This efficiency can be shown to have the form $\mu = 1 - BN$, where B is a constant and N is the number of combustible units in unit volume. A combustible unit is defined as that group of one molecule of combustible gas and of oxygen atoms just sufficient for its complete combustion. At the upper limit N is zero, and the efficiency curve is triangular on a base coinciding with the limits of inflammability. Its mean height is therefore one-half of the maximum, and this agrees very fairly well with the observed values given by Clerk in the case of coal gas.

REFUSE DESTRUCTION.

By R. O. Wynne-Roberts,
Consulting Engineer, Regina, Sask.

[NOTE.—This very interesting paper was prepared by the author for presentation at the Convention of the Canadian Public Health Association, to have been held in Fort William two weeks ago, but which was cancelled owing to the European strife.—EDITOR].

ONE of the primary duties of a municipal authority is to dispose of the waste products of a city, quickly, hygienically and economically. Such duty, however, is a somewhat difficult one to carry out, sometimes. The satisfactory disposal of sewage, for example, has engaged the attention of specialists for many years, and it must be acknowledged that in a great number of places the efforts to efficiently treat sewage have more or less been failures, for a satisfactory effluent is to be found in only a few places. Yet, a solution must and will be found for this problem, and meanwhile communities are perforce to adopt the best available process.

In the matter of refuse disposal, the situation is somewhat dissimilar, for a large number of towns have surmounted the difficulties with good results.

The temptation is to dispose of the refuse by the easiest, even if it is not the most sanitary, means. Refuse tips are plentiful, but the modern tendency is to abolish such dumping grounds as are used without discrimination, and adopt some other method. It is somewhat late in the day of advanced sanitation for filth to be deposited on the outskirts of a city without care or consideration and thereby be an annoyance to the people who are dwelling in the neighborhood, if not create a menace to the public health.

Town refuse consists of such a heterogeneous mixture, it varies in every load, every day and in every place. In cooler climes there is a larger proportion of ashes, whilst in warmer latitudes vegetables and other refuse will be more pronounced. Refuse from towns in districts of high rainfall and humidity will probably be more moist and resistent to fire than in districts of low rainfall and humidity, in spite of the receptacles being usually covered.

The quantity of refuse produced per capita in Europe is less than in America and as a rule no division is made for the purpose of collection.

In America, town refuse is often divided into three main classes: garbage, which "consists of organic waste or residue of animal, fruit or vegetable matter, and any matter or substance used in the preparation, cooking, dealing or storage of meat, fowls, fruit or vegetables"; ashes, which "constitute waste due to the combustion of coal or other combustible material, from residences, manufactories or business places and consists of fine ash, clinker and unburned coal"; rubbish, which consists of discarded and useless waste matters from residences or places of business not classified as garbage or ashes, such as paper, straw, excelsior, rags, bottles, old clothes, shoes, tin cans and other like waste materials."[1] There are other refuse such as manure, street sweepings, dead animals, night soil, sludge, etc.

In America, the collection of town refuse is often made separately for each class named. Separate receptacles have to be provided and the contractors or the municipal authority make periodical calls to remove each class of refuse. Much depends upon the frequency of such collections, as to the cost of the work and the efficacy of this system. Daily removal by municipal forces will obviate practically all nuisance, and if rightly organized a combined collection can be as economically done, if not more so, than insisting on the wrapping of garbage in paper and the separate collection at less frequent intervals. It can be easily understood that the separation of garbage, ashes and rubbish entails the loyal support of the householders and the ordinary experience is that the simpler the duties imposed upon the householders and others, the more likely they are to be performed.

The common method of refuse disposal is by dumping it into depressions or pits or on waste land. Reference has already been made to this and it is therefore necessary only to state that progressive authorities are becoming more insistent that such a method is not desirable in well-goverened cities, unless due care is taken to cover the refuse with earth or other deodorant.

The disposal of garbage on pig farms is repugnant to the minds of all citizens having a high regard for the welfare of the people, and for the production of food by clean methods. It is stated that about 75 pigs are necessary to dispose of one ton of garbage daily.[2]

In Los Angeles, Cal., the garbage piggery was investigated by the Grand Jury. They reported that "the investigation of this Grand Jury shows that at the present time (March, 1912) there are located on the hog-ranch about 21,000 head of hogs; that the percentage of death of the hogs ranges from 40 to 65. We find, further, that the percentage of tubercular hogs on this ranch ranges from 10 to 20. Of this number two per cent. are condemned by the health officials, the other portion being placed on the market. We further find that cholera, strike, swine plague or swine fever is prevalent at the ranch at all times. In fact we find that at the present time this hog-ranch is quarantined for all purposes except for the purpose of slaughtering for food."[2]

It is palpably unnecessary to add to the foregoing indictment. The writer is unaware if this practice prevails in Canada.

It may be stated that a contractor has recently been awarded the contract for the disposal of the garbage of Los Angeles by means of a garbage reduction plant. The city is to receive 51 cents per ton for the garbage.[3]

Two cities in the United States own garbage reduction plants, namely, Columbus and Cleveland, Ohio. There are other cities where contractors have erected reduction plants to deal with the garbage of these cities.

This method was first introduced in Germany (where, curiously, it is not much used to-day) and later on it was introduced into the United States. It is similar to the plants installed in packing houses to dispose of the offal and to convert it into saleable by-products. Some of the reduction plants are operated on the "drying method," but the "cooking method" is stated to be the most satisfactory. The process consists of placing the garbage in steel digestor tanks, and when about 10 tons are so disposed of, the valves are closed and steam is admitted. After a few hours' cooking, the mixture is pressed to extract the free grease and the moisture. The solid matter is then dried and afterwards saturated with naphtha, gasoline or other solvents to dissolve the remaining grease. The solvent is recovered by distillation and the grease and tankage is sold to buyers, who refine the

[1] Report of the City Waste Commission of Chicago, 1914.

[2] Refuse Disposal in Small Cities and Towns, by Samuel A. Greeley, Illinois Society of Civil Engineers, 1913.

[3] Journal of Cleveland Engineering Society, March, 1914.

grease for various purposes, and the tankage is used for fertilizers.

Columbus is a city of about 185,000 inhabitants and the reduction plant has cost about $220,000. The sale of the grease and tankage brings more revenue than is sufficient to pay the cost of operation, plus the capital charges, as will be seel below:

Financial Statement for 1913.

1,095,594 lbs. of grease sold	$40,839.35
2,095 tons of tankage sold	14,223.31
Hides	1,247.39
Miscellaneous	489.73
Total receipts	$56,799.78
Total operating expenses	$39,560.25
Gross profit	$17,239.53
Allowing 4 per cent. interest and 20-year sinking fund	$16,292.00
Net profit	$ 947.53

The total quantity of garbage received was 20,710.74 tons, so the net profit amounted to about 4.57 cents per ton.

Garbage, however, is only one portion of town refuse and incidentally it may be mentioned that the householders in this large city, have to dispose of their refuse, other than garbage, by arranging with any one of the 140 private contractors.[4]

Columbus is now installing a Sterling destructor to cremate rubbish only. Natural gas is available and consequently the proportion of ashes is stated to be small.

Garbage reduction plants are capable of being operated with profit in cities of over 100,000 inhabitants. Mr. C. O. Bartlett, however, expresses the opinion that any small place producing one ton of garbage per day can be successfully treated in this manner.[3]

A full description of the reduction plant erected at Boston for the Boston Development and Sanitary Company, is to be found in the "Engineering Record" of May 10th, 1913, and of the Columbus plant in Mr. Irwin S. Osborn's report of January 1st, 1913, to which those interested in this process are referred for further particulars.

A number of towns in Britain have adopted the Lightning Dust Manipulator, for instance, Southwark, a large borough in London, Halfax, Hove and others. The process consists in pulverizing the raw refuse into manure. This is done by means of high-speed revolving hammers striking the refuse against the breaking block and a final disintegration effected by trituration between the hammers and the grinding plate. Southwark sells about 20,000 tons of manure annually. The manure is similar to black mold, and as the Southwark works are located in a populous part of London, and the plant has recently been extended, the process is practically inoffensive. Hove is one of the fashionable seaside resorts in South England and Halifax is a large commercial centre in Yorkshire.

The text of this paper is Refuse Destruction, and the remainder of the writer's observation will be confined to it.

For the sake of a clearer definition, furnaces operated at a temperature of about 1,500 degrees Fahr. or less, will be called incinerators, and those which have a working temperature of over 1,500 degrees will be called destructors. In America these furnaces are called low and high temperature incinerators respectively. It seems preferable to know what is referred to by a distinctive name, rather than by a qualifying term which is often omitted.

Fire is the oldest and best-known method of disposing of offensive rubbish. It has been adopted by all races and in all ages, with more or less satisfaction. Burying offensive matter is another ancient and effective way of getting rid of such matter.

The first engineer who successfully designed a furnace to effectually destroy town refuse by fire was Mr. Alfred Fryer, of Nottingham, England. This was in 1874. He built two such furnaces in Manchester in 1876 and these have been extended and improved and are still in use, which fact at least suggests that Fryer had evolved a scheme based on right principles.

This innovation, however, met with a hostile reception. The public prejudices against the adoption of such furnaces were so strong that it is surprising it survived.

Following Fryer, there were several aspirants who claimed to have designed furnaces superior to Fryer's, for example, Pickard's "Gommand," Wilkinson, of Birmingham; Healy, of Brighouse; Heard, of Paddington; Burton, of London; Stafford and Pearson, and others, but Fryer's furnace held its position. These, and some which were designed later on, were of the incinerator class—low temperature, slow burning, producing soft clinker and obnoxious gases. Mr. Charles Jones (Ealing) in 1885 introduced his "fume cremator" which was an ample proof that something was needed to improve the combustion.

Mr. William Horsfall, in 1887, brought out the first high temperature furnace, which improvement gave a new impetus to the process. Horsfall also improved the furnace by arranging for a front exhaust of gases, by which means all gases had to pass over the active grate before being discharged and by so doing the fume cremator was found to be unnecessary and was ultimately abandoned.

From 1887 to the present time many improvements have been introduced, such as steam jet blowers, forced air draft, regenerators or air pre-heaters, continuous grates, twin grates, mechanical feeders and clinkering, dust catchers, steam producers, and so on. To deal with each of these would entail a long paper, as each maker has devised certain features in connection with furnaces, etc. They will, therefore, be referred to collectively as far as possible.

Incinerators, then, are the survivors of the earliest types and destructors are the later developments.

Incinerators are furnaces capable only of slow combustion and require some form of drying-hearth or device for reducing the moisture contained in the refuse, prepatory to creation. Some incinerators are charged with large quantities of refuse at one operation, the result being the lowering of the temperature of the furnace, the prolonging of the period of cremation as the combustion is more often local than general, the passage of green gases and the production of soft clinker and little steam. An analyses of the gases and a record of the maximum and minimum temperatures in incinerators will doubtless show that the work done is not altogether satisfactory.

Experience has shown that with destructors the same as with other furnaces, the percentage of carbon dioxide, oxygen and carbon monoxide contained in the gases in the main flues, is in proportion to the completeness of the combustion of the fuel and the carefulness of firing and clinkering.

It is manifest that not even the best coal-fired furnace can produce satisfactory percentages of the above con-

[4] Report on Disposal of Refuse, Newark, N.J., 1912.

stituent gases of combustion unless the temperature of the furnace is uniformly maintained, the range of heat fluctuations kept as small as possible, the quantity of primary and secondary air supplied is controlled to satisfy as nearly as practicable the requirements of the fuel used, and that the fuel is charged in small and regular quantities. Although coal is not usually quite constant in its calorific quality, it is vastly more so than town refuse, and if care is needed in the case of coal-fired furnaces, it is reasonable to advocate somewhat similar care in the cremation of refuse, if scientific and sanitary results are to be achieved.

Many incinerators require coal or other fuel to assist in the combustion of refuse, although the proportion of combustible matter in such refuse approximates that contained in refuse in other places where, with destructors, no other fuel is required or used, and good clinker and power are produced.

Engineers have during the last century developed the design of coal furnaces for steam raising and countless other purposes. Different grades of coal require different types of grates, etc. It would not be expected that a grate designed to burn steam coal with the maximum of efficiency would produce good results if bark was consumed.

A prudent manufacturer who requires a furnace for any ordinary industrial purpose would ordinarily adopt one that has already proven efficient, and if for any special purpose which needed some experimentation, he would start where others had left off, (unless he had good reasons for doing otherwise) and so make use of whatever knowledge that was available.

Bearing in mind what has been achieved in many parts of the world with destructors, it would seem inadvisable to erect incinerators.

The more municipal engineers investigate this important problem, the more readily they will appreciate the necessity for the fullest consideration of the capabilities of various types of furnaces which it is contemplated to install.

There are several makers of destructors and incinerators on the market, and the writer does not propose to exploit any particular one. Each maker claims to have some features of superiority over others and doubtless some do possess certain advantageous qualities.

The original furnaces were top-fed and some are now being built on this plan, but in course of the last ten years or so back feed and front feed arrangements are found to answer rather better. Top feeding allows of mechanical labor-saving devices being used, but even then it entails more arduous labor to the men below in raking in the material by long rakes over the fires. Back feeding was introduced in 1891 and is claimed to be under better control, whilst front feeding means a better concentration of labor. Conditions will vary in different places and these must be taken into account when deciding the method of feeding.

Destructor furnaces require a strong draft in addition to the normal pull of the chimney, although, as one writer stated, since it has been demonstrated that incandescence can be maintained apart from the use of fans and regenerators, the question to be considered is whether it is good practice to run machines which absorb up to 15 per cent. of the total steam produced.[5] The steam jet is a simple, effective and economical blower, and the fan, being entirely mechanical, is more subject to wear and tear and liable to breakdowns and therefore should be in duplicate. The furnace pressure should be in balance, that is, the force of the blast under the furnace should be slightly in excess of the draw of the chimney, so as to render the intake of air at the doors during the time charging or clinkering takes place, as nearly nil as possible. The aim, nevertheless, of the furnacemen is to have these doors opened as few times as possible.

The advantage of either forms of blast does not appear to be very pronounced and to provide for all contingencies, the makers now usually include both in recent installations.

Pre-heating of the primary air is claimed to be of considerable value. The air, after being pre-heated, absorbs the moisture in the refuse most readily, and this is found to be done sufficiently quickly that refuse can be cremated without the intervention of a drying hearth. In ordinary steam boiler practice, pre-heated air is found to be of much value, for it increases the amount of water evaporated per hour. Brislee[6] gives an example of the advantage of pre-heated air. Two boilers were tested with the following results:

	Number one boiler. Cold air.	Hot air.
Weight of water evaporated, in pounds of water per hour	22,910	40,966
	Number two boiler. Cold air.	**Hot air.**
Weight of water evaporated, in pounds of water per hour	15,800	24,600

The increased evaporation was due to the extra heat brought into the furnace and the increased rate of combustion of fuel due to it.

In the case of the boiler No. 1 the evaporation was increased 79 per cent. and the No. 2 55.4 per cent.

Brislee points out that if air is heated before combustion is allowed to take place, then the heat in the air is added to the heat of combustion, and the quantity of heat available for raising the temperature of the products is therefore greater. In other words, conditions being equal in other respects, the pre-heating of air means economy of coal and the increased output of the boiler.

In destructors, however, regenerators do not constitute the only method of pre-heating of air. Regenerators consist of stacks of pipes, through which the hot gases pass out on their way to the chimney and around which the cold air passes into the furnaces. The sensible heat of the hot gases is partially imparted to the cold air and in this way the temperature of the air is increased from 200 to 300 degrees, or often more. This, of course, means the conservation of heat which would otherwise be lost in the chimney. Such regenerators offer some obstruction to the outgoing gases and to the incoming air, and to overcome this it is necessary to absorb some energy in driving fans. About 5 to 10 per cent. of the total steam produced from the refuse is thus utilized. Regenerators have in some instances been taken out for different reasons. It is easy to arrange for the primary air to be heated by passing it through flues built in the walls of the furnaces. This is being done in gasworks practice and has been found to be very effective. Indeed, such method of pre-heating air or an adaptation of the idea is provided in some destructors. Incidentally, the air required for the furnaces is taken from the vicinity of the refuse and by this means the building is ventilated.

[5] Surveyor, January 31st, 1913.

[6] Brislee. Introduction to Study of Fuel, 1912.

Continuous grates in one chamber are supplanting individual cells and grates and the advantage is evident. In the case of individual or single cells when refuse is charged into the furnace it has the tendency of lowering the temperature of that cell, and the effectual mixture and burning of the gases must take place in the combustion chamber. Whereas, in the case of the continuous grates, two or more grates are built side by side in one chamber with independent ash-pits beneath. When any refuse is charged onto any one of these grates, the cooled gases therefrom are mingled and burned in the furnace itself and no gree gases can escape into the combustion chamber without first passing over an incandescent body. Meldrum's Simplex Destructor was the first constructed on this principle and its usefulness was appreciated by other makers. Heenan and Froude, Horsfall, Fryer, Dawson and Manfield and other destructor builders now design some form of continuous, twin or series grates.

Mechanical stoking and clinkering and other forms of labor-saving devices are installed in a number of destructors. Boulnois and Brodie's charging trucks, Marten's charging apparatus, Horsfall's tub feed, Heenan and Froude's hydraulic feeder and others are examples of the methods most in use. Heenan and Froude's trough grate and hydraulic ram clinkering machine and Sterling's clinkering grate are installed in many plants. According to Mr. Fetherston's report[7] the arduous work of charging and clinkering at the Clifton (New York) destructor has been reduced by the use of the hydraulic ram charger and clinkerer and trough grate. The following figures are extracted from his report:

Comparison of Work Elements.—Official Tests.

Plant. Both in New York.	Cost per ton supervision and labor.	Pounds burned per furnace man per hour.	Pounds burned per sq. ft. per hour.	Per cent. of time furnace door open.
West New Brighton, 1908	$0.76	1,357	54.3	73.7
Clifton, 1913	0.41	3,330	144.2	5.1

Mr. Fetherston, however, expresses his opinion that some time must elapse before the complete economy of the mechanical devices is demonstrated.

Conveyors have been tried in several installations, but owing to the heterogeneous character of the refuse, they have not always been found to answer. The same remark applies to refuse elevators, etc. The three buckets and rake elevators in use at the Hackney destructor (London, England) capable of raising 10 to 12 tons per hour, are found to be very expensive to maintain and are liable to serious breakdowns.[8]

Hoppers or storage bins above the destructor furnaces are often found to be unsatisfactory, owing to the tendency of the refuse to bind and arch over the opening, and the bulky nature of the refuse often renders the hoppers inadequate in capacity, in which case some city authorities store the refuse in the carts or wagons and thus obviate creating of nuisance. In some cases the refuse in bins tends to ignite and cause an emission of noxious gases. In recently built destructors the hoppers are located behind or in front of the furnaces and are sufficiently large to hold one or more day's supply. Such a position is both cool and handy for hand-firing.

In the more recent developments of destructors the authorities have observed that it was possible to derive considerable steam power. The ordinary steam-producing capacity of destructors is calculated at one pound of steam for each pound of refuse burned, and as one horse-power may be based on 30 pounds of steam per hour, it will be seen that one ton (2,000 pounds) will, on the above basis, produce 67 horse-power, but a large quantity of steam is required for the plant itself, so that the net quantity of steam available for other purposes is less.

There are plenty of instances where the production of steam has exceeded one pound per pound of refuse.

Official tests made at the Clifton destructor in 1913 with a winter mixture of refuse gave a gross equivalent evaporation from and at 212 deg. Fahr. of 1.00 to 1.11 pounds at a pressure ranging from 117 to 126 lbs. per square inch, but at the West New Brighton destructor the results were 1.10 to 1.41 pounds of steam at a pressure of 130 to 137 lbs. per square inch. The production of steam during the year 1911 was 1.23 pounds per pound of refuse.[7]

In Milwaukee, the evaporation was 1.34 to 1.45 pounds and at Westmount, P.Q., from 1.48 to 2.11 pounds.[4] In Calgary, Alta., the average evaporation at tests was 1.13 pounds. In Darwen (England) the average evaporation during the year was 1.23 pounds, whilst on a test when burning unscreened refuse and slaughter-house refuse was 1.55 pounds of steam from and at 212 deg. Fahr. In Huddersfield (England) with one part of sewage sludge and two parts of refuse 1.4 pounds of steam were obtained.

A test was made in Rochdale (England) for the purpose of comparison. By using ordinary coal slack having a calorific value of about 12,500 B.t.u. 7.33 pounds of steam were produced from and at 212 deg. Fahr., as compared with 1.97 pounds from refuse.[9]

At Montgomery (Ala.) in 1911 the following test results were secured: 1.37 pounds of steam per pound of refuse; carbon dioxide in the waste gases, 11 per cent.; temperature in combustion chamber, 1,920 deg. Fahr. The refuse consisted of 25 per cent. ashes, 42 per cent. garbage, 13 per cent. rubbish, and 20 per cent. manure.

The steam produced by burning refuse is utilized for a variety of purposes, such as pumping sewage, or water, generating electricity, etc.

Part of the steam generated from refuse in London, Ont., is used for heating the Victoria Hospital, which is situated fifty feet away. In one city 72 million foot-pounds of energy is derived from every ton of refuse and used for pumping sewage. In Liverpool and Rotterdam, for example, the electric energy generated is used for street railway operation. In West New Brighton and Clifton plants, already referred to, a large quantity of steam is not utilized owing to the fact that the New York City charter prohibits its sale and consequently no revenue can be derived in this manner. This represents a loss of about $7,500 per annum. The quantity of refuse burned at each of these places is about 9,500 tons per year. In Westmount, P.Q., the destructor is an auxiliary enterprise operated in the same building as the municipal electric lighting plant, the steam generated by the cremation of the refuse being used in the production of electrical energy. Messrs. Hallock and Runyon, the engineers who were appointed to report on the disposal of refuse by the City of Newark,[4] stated that the total revenue in 1910 for electric lighting and destructor plants was $102,149.17, and the total cost of operation of the combined plant was $75,426.38, leaving a net profit of $26,722.79. The operating costs include all capital

[7] J. T. Fetherston, New York, February, 1914.
[8] Journal of Institution of Municipal and County Engineers, July, 1914.

[9] Refuse Disposal and Power Production, Goodrich.

charges and depreciation. The cost to the Health Department for the refuse destroyed was $9,449.06 for the year. The population of Westmount is about 16,000.

Other examples could be cited but the paper is already longer than was anticipated.

One incidental result of good steam production is the production of good clinker, which can be used for many purposes. Low temperature cremation results in soft clinker which is not only useless but objectionable, as it cannot be used and it often contains partially consumed organic matter. Clinker should be well fused and vitrified and this can only be produced by maintaining an uniformly high temperature in the furnace.

Good clinker is used for making pavement slabs, for sewage filtering media, brickmaking, crushed into sand and mixed with lime for mortar, etc.

Reference has already been made to steam production. In the earlier plants, the boilers were placed in the furnace directly over the fire, but it was found that the cooling effects of such boiler militated against the successful cremation of the refuse. The next step was to place the boiler between two cells and, although better results were obtained, the makers in later installations have located the boilers beyond the combustion chamber. By this means the maximum temperature is secured and the gases adequately combusted before coming into contact with any cooling surfaces. The figures quoted point to the possibility of developing considerable power by the high temperature cremation of refuse. If due attention is paid to the fundamental requisites of a destructor the cost of operating the same can be materially reduced by the sale or utilization of the steam and hard vitrified clinker produced.

In conclusion, the author has observed that some disappointment has, in places, been experienced owing to the makers' claims being exaggerated and impossible of realization. It would, of course, be folly to decry every new device, arrangement or design, until it has been put to a practical test, for that would be tantamount to placing an embargo on all legitimate developments, but experiments are costly and occasionally disturbing, as was recently found to be the case in a large plant in North America, whose designers received due publicity in engineering journals. The achievements that were going to be accomplished fell short and the works are now being improved.

The evolution of the destructor has been slow and expensive and the results of experience in all parts of the world has greatly assisted the makers in deciding upon the arrangements, capacity and construction best suited for the refuse produced in different places in different climes.

New York, Westmount or other destructors in the the east may not be quite suitable for western refuse, and doubtless this is the case. Each city has its own problem to solve and it, therefore, behooves that the authority contemplating the installation of a destructor or incinerator should take the fullest possible advantage of the experience of others under similar conditions and of the plant best suited to satisfy its own specific needs.

A Government wireless station will shortly be opened on Valentia Island, on the southwest coast of Ireland. It has been constructed by the wireless department of the Post Office, the installation being supplied by the Marconi Company. With a range of 500 miles, it is chiefly destined to keep Atlantic liners in touch with land two hours longer than is possible at present with the Crookhaven station.

THIRTY-THIRD CONVENTION, AMERICAN ELECTRIC RAILWAY ASSOCIATION.

The program for the 33rd Annual Convention of the American Electric Railway Association to be held at Atlantic City October 12th to 16th has been announced. The American Association proper and its four allied associations—Engineering, Accountants, Claims, and Transportation and Traffic—all hold sessions during the time of the convention. The programs are very elaborate. Over 73 committees are to report and papers are to be read on some very important subjects. The speakers before the American Association include Hon. Frank W. Stevens, former Chairman of the New York Second District, Public Service Commission; H. C. Donecker, Assistant General Manager, Public Service Railway Company, Newark, N.J.; Calvert Townley, Chairman of the Board of Directors, Lackawanna and Wyoming Valley Rapid Transit Company; Harry A. Bullock, Secretary, New York Municipal Railway Corporation, and R. B. Steams, Vice-President, The Milwaukee Electric Railway and Light Company.

Among the important reports to be made is one from the Committee on Public Relations, presenting a "Platform of Principles" covering what the committee believes to be the fundamentals of a lasting and proper adjustment of relations between the railways and the public.

The Accountants' Association is to consider the new classification of accounts which was prepared by the Interstate Commerce Commission in connection with one of the committees of the association, and will pass on a plan for an educational course for the accounting employees of electric railways. John R. Wildman, Professor of Accounting, New York University, H. S. Swift, treasurer, West Penn. Traction Company, J. F. Fogarty, secretary, North American Company, A. T. Smith, assistant chief, Division of Valuation, Interstate Commerce Commission, and Robert Sealey, North American Company, will deliver addresses.

The Engineering Association has a very large number of important matters to come before it, including the reports of its standing committees.

To the Claims' Association will be presented the report of its committee having in charge the formation of an accident prevention board, which it is intended will conduct a campaign for the prevention of accidents among the electric railways of the country.

Among the speakers before the Transportation and Traffic Association is N. W. Bolen, General Superintendent, Public Service Railway Company, Newark, N.J., who will talk on the Organization of a Transportation Department. This association will consider among other things a report of the committee dealing with the question of motor buses as auxiliary for electric railways.

The report of the Joint Committee on the Joint Use of Poles, made up of representatives from the American Electric Railway Association, National Electric Light Association, the American Institute of Electrical Engineers and the American Telephone and Telegraph Company will be considered by the American Association.

This committee has now been at work for two years in the preparation of a form of agreement and specifications covering the joint use of poles and the adoption of its report, it is believed, will mean much in the clearing up of obstructions in the streets of the cities of the country.

GUTTER CONSTRUCTION FOR STREETS AND ROADS.*

By T. Hugh Boorman, C.E.

HIGHWAY engineers and road specialists have always agreed that the pre-requisite for a good pavement is proper drainage and a substantial foundation for the wearing surface, and it is now generally conceded that we must have a waterproof surfacing even for country roads.

On a building's roof, we must pay the greatest attention to the gutter and afford the best method possible for the carrying off of the rain water to the outlets as efficiently and speedily as possible. Given the fact that we are to roof our roads with waterproofing material, does it not follow that we should apply similar precautions for road roofs?

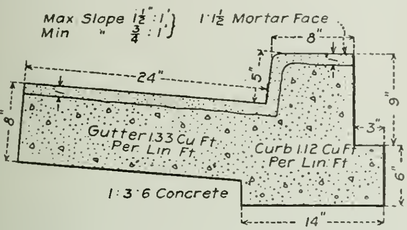

Fig. 1.—Standard Type of Combined Curb and Gutter.

In the June 10, 1914, issue of "Engineering and Contracting" is given the construction of concrete curb and gutter as adopted in Washington by the District Commissioners, under the supervision of Captain Mark Brooke, Engineer Corps, U.S.A.:

"**Concrete Curb and Gutter.**—In Fig. 1 is shown the standard type of combined curb and gutter in general use. It will be noted that the curb is unusually thick and the base therefor is quite broad. The method employed in laying is as follows:

"A trench is excavated and trimmed to a depth of at least 14 inches and a bed of bank gravel, free from excess clay or loam, spread to a depth of 6 inches and rammed. In making the curb, forms are placed and the mortar face formed by plastering on the inside before the curb concrete is laid. Curb and gutter is divided in 10-foot lengths, a clean cut joint being made either by use of a thin metal plate or with heavy paper. The face forms on the curb are removed within 24 hours and the surface troweled to a neat finish.

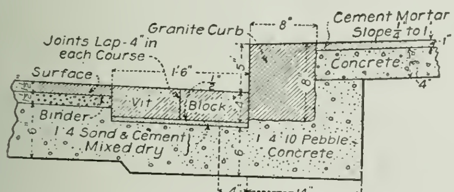

Fig. 2.—Granite Curb and Vitrified Brick Gutter.

"The specifications call for a high quality of sand and no stone over 2 inches in diameter. The mortar surface on gutters is placed immediately after laying concrete and thoroughly manipulated by troweling and beating with wooden battens so as to break any air cells and make the surfacing solid. Joints are filled with sand. A coating of dry cement and fine sand, 1:1 mix, containing thoroughly incorporated coloring matter, is floated on the surface. A jointing tool is used, cutting to a depth of ½ inch, and the exposed surface covered with sand for protection.

"**Granite Curb and Brick Gutters.**—The granite curb and vitrified block gutter is shown in Fig. 2. Granite curb is set in the following manner:

"A trench is excavated 18 inches wide and 15 inches below the top of the curb when set. One edge of this trench is 4 inches beyond the finished curb line toward the centre of the street. Five inches of 1:4:10 pebble concrete is placed in this trench and the curb set immediately, heavy mauls being used to bed it firmly. As soon as the curb is laid the trench on the sidewalk side is filled to within 5 inches of the top of the curb with concrete tamped in place. Excess concrete in front of the curb which will interfere with laying vitrified block gutters is removed and earth filled in behind the curb to prevent too rapid drying out of the concrete. No provision is made for longitudinal joints between the curb and the street surface base.

"In laying the gutter as soon as practicable after the concrete base has been laid, a dry mixture of sand and cement is spread to a thickness of not less than ½ inch as a bed for the paving blocks. The blocks are laid on edge joints, being broken so that each block has at least a 4-inch lap in every course. A plank is laid over several courses and a rammer used until the blocks reach a firm bed and present a uniform surface. After ramming, the gutter is grouted with a thin, easy flowing grout of neat cement."

On examination of the concrete gutter on the Chevy Chase experimental road sections in Washington and Maryland last month, I found several cracks, and venture the opinion that a prepared asphalt joint applied across the work every 25 feet would obviate this trouble at a very trifling expense. The work referred to, however, is in connection with broad avenues and streets having no business traffic; and what I wish to emphasize is the fact that in our city streets particularly our construction of gutters is generally poor, from the fact that stone blocks are used transversely, instead of longitudinally.

In England the gutters are laid longitudinally generally in the case of stone or wood blocks, with the inner two lines depressed about half an inch, so forming a natural curved gutter.

I have seen asphalt blocks on roads at Irvington, N.Y., so laid, and on the approaches to the North Philadelphia Depot of the Pennsylvania Railroad brick has been set in this way; on one side of the depot twelve courses of brick and on the other eight courses.

I contend that in all cases where other than a monolithic sheet pavement is used, the gutter should be paved with blocks, longitudinally laid, and with a natural curve. While realizing that innumerable varying surfaces, requiring different construction of gutters, call for exceptional work, I am submitting the following suggestions for consideration:

When practicable, all avenues and broad thoroughfares, other than in business sections, should have a Portland cement concrete curb and gutter, preferably strengthened and made more thoroughly waterproof by the addition of some of the improved dry or liquid compounds.

*From a paper read before the American Society of Engineers, Architects and Constructors, July 4, 1914.

For country and suburban roads, where cobblestones are obtainable, they should be laid from two to three feet in width, and after being placed should have poured in the interstices hot pure asphalt. Asphalt should be used which is of the best grade, free from coal tar or any of its products, and which will not volatilize more than one-half of one per cent. under a temperature of 300 degrees Fahrenheit for ten hours. The asphalt should not flow under 212 degrees Fahrenheit and should not brittle at 15 degrees below freezing, Fahrenheit, when spread thin on glass. In all cases of brick, stone, or wood blocks laid longitudinally along the line of curb and with joints broken, said joints should invariably be filled with asphalt cement of quality above described.

MUNICIPAL DEVELOPMENTS AT ASSINIBOIA, MANITOBA.

In *The Canadian Engineer* for September 3rd a description was given of the water and sewerage systems recently installed at Deer Lodge, in Assiniboia, a western suburb of Winnipeg. Since its publication we have been favored with some additional information respecting municipal improvements that have been made during the past several years in that locality. In this time over $410,000 have been expended in the municipality of Assiniboia for water supply and sewerage systems, and similar work to the extent of $500,000 is contemplated and in the process of design. During the past two years, also, pavement and bridge work has amounted to $215,000, construction work at the present time amounting to $170,000. Mr. G. W. Rogers is engineer for the municipality.

DECEMBER MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

At its annual meeting in New York December 1 to 4, the American Society of Mechanical Engineers will have a session on engineering metals and their application to methods of manufacture. Steels for construction and for tools, cast-irons and alloys of copper, tin and aluminum will be particularly investigated, with a view to bringing out as a matter of common knowledge the advances that have been made in these fields up to the present time. The session will be in charge of the sub-committee on iron and steel. A number of papers will be presented.

Another session that will be most interesting is that devoted to the general subject of engineering in connection with civic administration and public service. Papers on municipal engineering and related matters will be presented, among which are noted: "Utilization of Municipal Wastes," by Irwin S. Osborn, consulting engineer to the Department of Street Cleaning, Toronto, and other cities; "Training of Municipal Employees," by H. M. Waite, city manager, Dayton, Ohio; "The Cleaning of Filter Sands," by Sanford E. Thompson, consulting engineer, Newton Highlands, Mass.; "Controlling Factors in Municipal Engineering," by M. L. Cooke, director, Department of Public Works, Philadelphia, Pa.; "The Cleaning of Public Buildings," by W. H. Ball, Chief of the Bureau of City Property, Philadelphia, Pa.; "Municipal Colleges in Germany," by C. L. King, University of Pennsylvania, etc.

The usual sessions on machine shop press, railroads, etc., will be held. The above are mentioned in particular as being of special interest to our readers.

WAR AND ENGINEERING TRADE ABROAD.

The following interesting item on the effect of the war on European engineering trade was published in "Mechanical World" of August 28:

Of the several countries engaged in the present European conflict, it is tolerably evident that Great Britain stands to lose less by trade dislocation than any other. It is true that some of our manufacturing industries have been badly hit, but so far as the engineering trade is concerned a despondent view of the situation is by no means justified. Makers of textile machinery will probably be the worst sufferers, as the continent represents their chief outlet. But as regards general engineering the outlook is much more satisfactory. Certain branches are of course busily employed in meeting the demands of the naval and military authorities, and in these we have every reason to expect a continued period of activity. Makers of structural iron and steel should benefit by the elimination of Belgian and German competition, while, if machine-tool makers find the principal European markets closed against them, they have ample compensation in the absence of German competitors in our large home market. A further advantage we possess over continental competitors is that we are in a position to meet the requirements of colonial and neutral markets now that the western trade routes are open; and hence the present situation provides us with a unique opportunity of consolidating our position in such markets and extending our influence where possible.

The view is held in many quarters that our present trouble may be a blessing in disguise, if it only affords opportunities for recovering some of the industries which we have allowed Germany to filch from us. It is suggested that the refining of lead and other of the baser metals should again find a deal of employment in this country. Again, the manufacture of carbon twist-drills, which has drifted largely into German hands, should be recoverable if suitable plant he installed. This latter proviso is of course almost always a condition of success, and although it requires a considerable amount of courage to expend money under the present circumstances, it is tolerably obvious that those who do so will not have long to wait for their reward once the war cloud shows signs of lifting. Meanwhile, wise economy is to be commended; but the indiscriminate curtailing of business-getting organization, advertising, etc., savors of a penny-wise and pound-foolish policy, the results of which are bound to be the reverse of beneficial.

The building permits for the town of Welland during the month of August this year amounted to $13,625, which shows a decided decrease upon the amount for 1913 of $38,100. The building permits for the year to the end of August, total $314,018; and in 1913, the total shown was $356,996.

The following account has been published relative to building permits issued during the last month in the town of Galt: total estimated cost of permits issued during August, 1914, $92,500; total estimated amount for August, 1913, $40,565, showing an increase of $51,935. The increase is due to the permit which has recently been issued for the construction of an armory at a cost of $80,000.

The Bridle Belt Railway and Navigation Company propose to construct a $50,000,000 terminal project at Seattle, Wash., the initial unit of which is to be undertaken at once at a cost of $15,000,000. This first unit calls for the construction of two docks, each 4 stories high and 200 x 800 ft. These docks will connect with an 8-story building over Railroad Avenue, 500 x 500 ft., which in turn will connect with a 20-story 250 x 500 ft. hotel and office building facing on First Avenue. The hotel and office building will have a total depth below the First Avenue level of 10 stories, the ground floor of which will open on Railroad Avenue.

SUBTERRANEAN WATER AND THE CONSTRUCTION OF A CORE-WALL FOR AN EARTH DAM.

A SUMMARY taken from a letter by Mr. Harrison Souder, published in Proceedings of the American Society of Civil Engineers (Vol. XL., page 1569), deals with the Hinckston Run dam, built 13 years ago near Johnstown, Pa., showing the methods and the results of the employment of grout injection to close underlying rock strata against seepage under the dam. Despite the age of the work, the account is of great interest, for it was not until recently that any matter upon this early use of grout injection was published. Mr. Souder's report, as given in *Engineering and Contracting*, June 10, 1914, is reproduced in the following paragraphs.

The original Hinckston Run project called for an earth dam, 60 ft. high, to retain some 400,000,000 gals. of water, with a depth of 45 ft. at the breast. The intention was to build a dam with a clay core, but, as an unlimited quantity of cinder from the steel plant was available, it was decided, after the work was started, to use this as backing for the dam, in place of earth, and eventually to fill the whole valley below with this material, thus rendering the structure practically unbreakable. In view of this and the additional expense incurred in making the cut-off tight, the proposed height of the dam was increased to 80 ft., and later to 85 ft., above the original creek level. This gave a total maximum height above the bottom of the core-wall ditch of 112.8 ft., a depth of water at the breast of 73½ ft., and a capacity of 1,100,000,000 gals. The lake thus formed is 1¼ miles long. The watershed above the dam is 10.75 square miles.

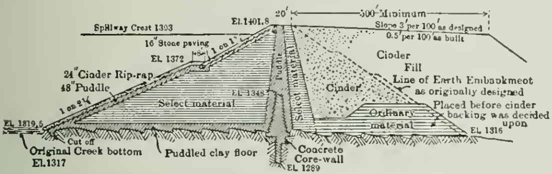

Fig. 1. Maximum Cross Section of Hinckston Run Dam.

The cross-section of the dam as built is shown by Fig. 1. The lower inner slope is 1 on 2¼, with 4 ft. of puddle and 24 ins. of cinder riprap. The slope above the berm is 1 on 1¾ with puddle lining diminishing to 2 ft. thick at the top. The facing is hand-laid stone paving. The puddle wall is 16 ft. thick at the top of the concrete core-wall, and diminishes to 4 ft. at the top of the dam.

When the core-wall ditch had been carried down to hard rock at what was thought to be the proper depth, some test holes were bored through the bottom to determine the character of the rock below. This disclosed a layer of hard sandstone a few feet down, with considerable water flowing below and above it. It was decided to deepen the ditch considerably, in order to get below any rock strata that might come to the surface within the flooded area, and to substitute a concrete core-wall for the clay one originally proposed.

An air compressor plant was installed. This was a 14 x 18-in. Ingersoll-Sergeant machine capable of driving two rock drills and six pneumatic rammers. These rammers were used in tamping concrete and also in puddling clay in such places as could not be covered by a 10-ton steam roller which was also supplied at this time in place of the 3-ton horse roller in use.

The finished ditch averaged in depth 25 ft. below the grubbed surface in the valley, but reached 50 ft. at the ends. The shale was excavated with picks, but the harder rock was loosened with light charges of dynamite, care being taken not to shatter the foundation or open up the seams. The advisability of cutting off the underflow to as great a depth as possible was realized, and it was determined to remove the shale down to the sandstone and try to cut off the flow below by forcing in cement grout under air pressure.

Grout Injection.—Drill holes, 2 ins. in diameter and from 10 to 16 ft. deep, were drilled through the rock, averaging about one hole per linear foot across the valley. Iron pipes, 2 ins. in diameter, 18 ins. long, and threaded on one end, were cemented into these holes. Portland cement grout was poured into them and then air at a pressure of from 30 to 60 lbs. was applied. The first holes were approximately 6 ft. apart. They were drilled generally 10 ft. below bed-rock.

Fig. 2 is a sketch of the first contrivance or receiver devised for applying the grout. It was a cylinder, 8 ins. in diameter and 6 ft. long. A screw flange was provided at top and bottom, and a steel head-plate was bolted to each end, with rubber gasket packing. The top bolt holes were open to allow quick removal of the lid. A 2-in. pipe with plug cocks was provided at the top and bottom. With a short hose, the cylinder was coupled to the pipes in the holes. The cylinder was filled with grout; the valve was opened; the grout ran into the drill holes; and the air pressure was then applied at the top. The contrivance was mounted on a truck running on a track in the bottom of the ditch. After trial it proved to be too slow and cumbersome, and another method was devised and operated satisfactorily. Fig. 3 is a sketch of this final arrangement. The method of grouting was as follows: A 1-in. pipe, long enough to reach to the bottom of the hole, was

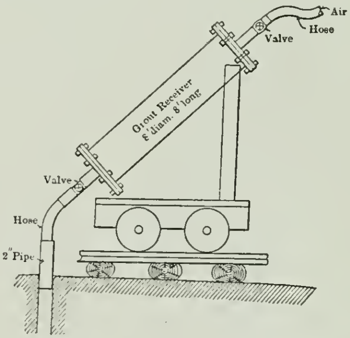

Fig. 2. Grouting Device Tried and Abandoned

inserted and air was applied to blow out water and dirt. Then a tee and the pipe, *C*, were attached to the tube in the drill hole with a sleeve union, as shown. The cock, *A*, was closed, the cock, *B*, was opened, and air was applied, thus forcing the water out of the hole and into the crevices and near-by drill holes; meanwhile, the pipe, *C*, was filled with grout, and the air hose was connected at the top. Then *B* was closed, *A* was opened, and air was gradually applied at the top of *C*, forcing the grout down into the crevices. The pipe was refilled about every 10 minutes until the hole would take no more. The apparatus was then removed and a cap was screwed on the

tube in the grouted hole. After a given length of ditch was grouted in this way, and sufficient time had elapsed to allow the grout to set, test holes were bored within the grouted area and the process was continued until there was no indication of water flow below the bottom. The greater part of the bottom was grouted successfully in this way, but, as explained later, the grouting scheme was abandoned where the core-wall ditch entered the side-hills.

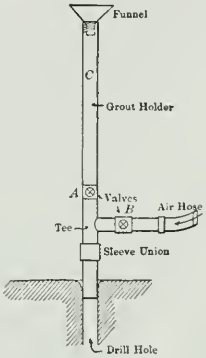

Fig. 3. Grouting Device Employed.

Handling Flow from Seams.—At the east end three large vertical open crevices were uncovered. The flow from these was so considerable that it was necessary to put in a force pump with a 4-in. suction and a 3-in. discharge, in order to keep the ditch clear. As the grouting method, after continued trials, did not give satisfaction at this end, it was decided to take up the bottom until the principal water strata were reached. This was done, and concrete was placed in the ditch, all the walls being plastered first with a rich cement mortar worked in with trowels. Two coats of plaster were applied on the north or reservoir side and one on the south side. The suction pipe of the pump was built in concrete, and carried up with the wall. The strong flow of water in this section of the ditch made it difficult to place the concrete for the core-wall without having the cement washed out before it set.

At first, the method indicated in the sketch, Fig. 4, was tried, namely, a line of 1-in. sheeting was placed as

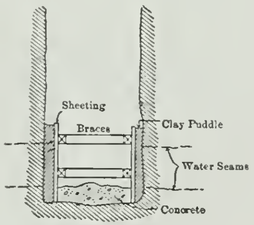

Fig. 4. First Method of Handling Water in Core-Wall Ditch.

shown, and clay was rammed between the sheeting and the rock to stop the water flow. Concrete was placed between the sheeting which was raised gradually as the concrete was carried up. This did not prove wholly satisfactory, and the method of piping the water directly to the sump was adopted, as shown in Fig. 5. This proved successful. Where there was too great a flow of water, plastering could not be done, but considerable neat cement was dumped in along the walls with the concrete and well worked in. After the concrete was well set, the pipes were plugged and the flow of water was shut off. As the concrete was carried up, the water came out of the ditch walls higher up, showing that the underflow had been intercepted. The core-wall ditch was extended well into the hills on each side of the valley, and test holes were bored for water, none being found because, after a certain distance, the rock became hard and massive and free from seams. At the west end of the ditch, there was as much trouble with water. It would seem that the underflow of the whole valley was concentrated at this point, the rest of the ditch having been grouted and the flow cut off.

The drill-hole grouting method failed in the west side of the valley, as in the east, and here the bottom was also taken out, down to the water strata, and the water fought inch by inch by piping it from the streams to the sump, as before described, and the ditch was completely filled with concrete.

The proportion for the concrete in the core-wall was 1 : 2 : 5, generally; but, at the bottom, it was much richer in cement, which was not spared in efforts to make a tight job. Near the crevices a proportion of 1 : 1 : 2½ was used. These proportions had to be varied, also, to suit the sizes of the stone supplied, which varied from ½ in. at times to 3 in. The top section of the wall was made of 1 : 3 : 6 and 1 : 3 : 7 cinder concrete. The concrete was mixed in a machine of the continuous-mixer type, consisting of a long square revolving box with a helix at the back. The

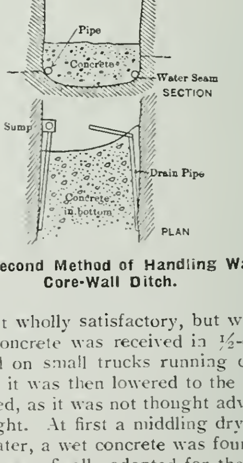

Fig. 5. Second Method of Handling Water in Core-Wall Ditch.

machine was not wholly satisfactory, but was the best to be had. The concrete was received in ½-cu. yd. dump buckets, carried on small trucks running on light track to the derricks; it was then lowered to the bottom of the ditch and dumped, as it was not thought advisable to drop it from any height. At first a middling dry concrete was required, but, later, a wet concrete was found to give the best results and was finally adopted for the remainder of the work.

After the core-wall reached above the surface the faces received two coats of plaster, one inside against the wood forms and another after the forms were removed. For the upper part of the wall, the plaster coat on the down-stream side was omitted; and, on the up-stream side, a cement wash applied with a brush was substituted for the second coat of plaster. Where sections of the wall joined, bonding grooves were provided.

The concrete core-wall contained 10,840 cu. yds. and required 13,166 bbls. of cement, or an average of 1.21 bbls. per cubic yard. The grouting and plastering took 2,078 bbls. of cement, in addition. The exact quantity of cement used in grout alone is not known.

SOME TUNNELING COSTS.

THE United States Bureau of Mines has made exhaustive investigation into the subject of mine tunneling, and, in the course of the work, found that data respecting tunneling costs were remarkably scarce. The Bureau thereupon undertook to gather the available data, which have been published in a recent bulletin from which the following statistics have been complied:—

LOS ANGELES AQUEDUCT.

Little Lake Division, Tunnels 1 to 10A.

Location: Inyo County, Cal.

Purpose: Water supply, power and irrigation.

Cross-section: Straight walls, arched roof, dished bottom.

Size: 7 feet 10 inches wide by 8 feet 5 inches wide.

Type of power: Electric power purchased at a nominal cost per kilowatt-hour from a hydraulic plant constructed and owned by the aqueduct.

Ventilators: Pressure blowers.

Size of ventilating pipe: 12 inches.

Drills: Pneumatic hammer, usually 2 in each heading.

Mounting of drills: Horizontal bar.

Number of holes per round: Usually 14 to 16.

Average depth of round: 6 to 10 feet.

Number of drillers and helpers per shift: 2 drillers and 2 helpers.

Number of drill shifts per day: Usually 1, but sometimes 2.

Explosive: 40 per cent. gelatine dynamite, with some 20 per cent. and some 60 per cent. Ammonia dynamite also tried.

Number of muckers per shift: Usually 5.

Number of mucking shifts per day: Usually 1, but 2 when 2 drill shifts were employed.

Type haulage: Tunnels 1 to 3-N, mules; tunnels 3-S, to 10A-N, electric; tunnel 10A-S, mules.

Wages: Drillers and helpers $3, muckers, $2.50, blacksmiths $4, helpers $2.50, motormen $2.75, dumpmen $2.50.

Tunnel 1B-S, Length 1,341 Feet.

(Through medium-hard granite at an average speed of 225 feet per month.)

	Cost per foot of tunnel.
Excavation	$ 9.15
Engineering	.18
Adit proportion	.28
Permanent equipment (estimated)	2.35
Timbering (857 feet)	1.02
	$12.98

In this tunnel, as in all of the tunnels of this division and of the Grapevine division, the cost of excavation includes the wages of shift foremen, drillers, helpers, muckers, motormen or mule drivers, dumpmen, blacksmiths and helpers, machinists, electricians (part), and power engineers; also the cost of powder, fuse caps, candles, light globes, machine oil, blacksmith supplies and fuel, and machinists' supplies, and the cost of power and of repairs for power, haulage, compressor, and ventilating machinery.

"Engineering" includes the cost of giving line and grade, etc.

"Adit proportion" is a proportionate charge per foot of tunnel to defray the cost of an adit from the surface to the tunnel line.

"Permanent equipment" costs were not segregated for each tunnel, but were compiled for the whole division, so the charge represents a proportionate charge per foot for the entire division cost, without salvage, of trolley and light lines, including freight and cost of installation; pressure air lines with freight and installation; ventilation lines with freight and installation; water lines with freight and installation; mine locomotives and cars, picks, shovels, drills and drill sharpeners, with repairs for the last four items.

Tunnel 2, Length 1,739 Feet.

(Through medium-hard but very wet granite at an average speed of 170 feet per month.)

	Cost per foot of tunnel.
Excavation	$ 8.81
Engineering	.19
Adit proportion	.34
Permanent equipment	2.35
Timbering (1,590 feet)	3.28
	$14.97

Tunnel 2-A, Length 1,322 Feet.

(Through medium-hard granite at an average speed of 150 feet per month.)

	Cost per foot of tunnel.
Excavation	$ 8.05
Engineering	.16
Adit proportion	.34
Permanent equipment	2.35
Timbering (1,322 feet)	2.51
	$13.41

Tunnel 3-N for 1,148 Feet.

(Through medium-hard granite at an average speed of 150 feet per month.)

	Cost per foot of tunnel.
Excavation	$10.10
Engineering	.23
Adit proportion	.51
Permanent equipment	2.35
Timbering (956 feet)	2.44

Grapevine Division Tunnels.

Location: Kern County, Cal.

Purpose: Water supply, power and irrigation.

Cross-section: Straight walls, arched rod, dished bottom.

Size: 7 feet 10 inches wide by 8 feet 5 inches high.

Type of power: Electric power purchased from aqueduct plant.

Ventilators: Pressure blowers.

Size of ventilation pipe: 12 inches.

Drills: Pneumatic hammer, usually 2 in each heading.

Mounting of drills: Horizontal bar.

Number of holes per round: Usually 18 to 20.

Average depth of round: 6 to 8 feet.

Number of drillers and helpers per shift: 2 drillers and 2 helpers.

Number of drill shifts per day: Usually 2.

Explosive: 40 per cent. ammonia dynamite, but 60 per cent. and 75 per cent. gelatine dynamite were employed in hard ground.

Number of muckers per shift: 4 or 5.

Number of mucking shifts per day: Usually 2.

Type of haulage: Electric after the first 400 to 500 feet.

Wages: Drillers and helpers $3, muckers $2.50, blacksmiths $4, helpers $2.50, motormen $2.75, dumpmen $2.50.

Tunnel 12, Length 4,900 Feet.

(Through hard granite at an average speed of 185 feet per month.)

	Cost per foot of tunnel.
Excavation	$22.10
Engineering	.32
Permanent equipment	2.35
Timbering (90 feet)	.08
	$24.75

Tunnel 13 for 1,525 Feet.

(Through hard granite at an average speed of 130 feet per month.)

	Cost per foot of tunnel.
Excavation	$20.60
Engineering	.10
Permanent equipment	2.25
Adit proportion	.37

Permanent equipment	2.25
Timbering (163 feet)	1.90
	$25.45

ELIZABETH DIVISION, ELIZABETH LAKE TUNNEL.

Location: Los Angeles County, Cal.

Purpose: Water supply, power and irrigation.

Cross-section: Rectangular, with arched roof.

Size: 12 by 12 feet.

Length: 26,870 feet.

Type of power: Electric power purchased from aqueduct plant.

Ventilator: Pressure blower.

Size of ventilating pipe: 18 inches.

Drills: Pneumatic hammer, 3 in the south heading and 2 in the north.

Mounting of drills: Horizontal bar.

Number of holes per round: 25 in the south heading, 16 in the north heading.

Average depth of round: 8 to 10 feet.

Number of drillers and helpers per shift: 2 drillers and 2 helpers at the north end, 3 drillers and 3 helpers at the south end.

Number of drill shifts per day: 3.

Explosive: 40 per cent. and 60 per cent. gelatine dynamite.

Number of muckers per shift: 6.

Number of mucking shifts per day: 3.

Type of haulage: Electric.

Wages: Drillers and helpers \$3, muckers \$2.50, blacksmiths \$4, helpers \$2.50, motormen \$2.75, dumpmen \$2.50.

Maximum progress in any calendar month: 604 feet, April, 1910.

Average monthly progress per heading: 350 feet per month.

North Heading, Elizabeth Lake Tunnel.

(Through altered granite, requiring much timbering, 13,370 feet.)

	Cost per foot of tunnel.
Drilling and blasting	\$11.25
Mucking and tramming	11.70
Engineering and superintendence	1.27
Drainage	.45
Ventilation	.22
Light and power	5.55
Timbering (13,031 feet)	8.48
Cost of auxiliary shaft	.93
Permanent equipment (full charge, no salvage; estimated)	3.70
	\$43.55

South Heading, Elizabeth Lake Tunnel.

(Through medium-hard to hard granite, requiring but little timbering, 13,500 feet.)

	Cost per foot of tunnel.
Drilling and blasting	\$14.65
Mucking and tramming	11.10
Engineering and superintendence	.86
Drainage	.17
Ventilation	.41
Light and power	4.93
Permanent equipment (without salvage; estimated)	3.70
Timbering (3,424 feet)	2.19
	\$38.01

Lucania Tunnel.

Location: Idaho Springs, Colo.

Purpose: Mine development and transportation.

Cross-section: Square.

Size: 8 by 8 feet.

Length: 12,000 feet projected; 6,385 feet driven December 1, 1911.

Character of rock penetrated: Hard granite.

Type of power: Purchased electric current.

Ventilator: Pressure blower.

Size of ventilating pipe: 18 and 19 inches.

Drills: Pneumatic hammer, 3 in the heading.

Mounting of drills: Vertical columns.

Number of holes per round: 25.

Average depth of round: 8 to 9 feet.

Number of drillers and helpers per shift: 3 drillers and 2 helpers.

Number of drilling shifts per day: 1.

Explosive: 50 per cent. gelatine dynamite.

Number of muckers per shift: 3.

Number of mucking shifts per day: 1.

Type of haulage: Horses.

Wages: Head driller \$5, drillers \$4, nipper \$3.50, boss mucker \$5, muckers \$4, drivers \$4, power engineers \$4, blacksmith \$5.

Maximum progress in any calendar month: 263 feet, September, 1911.

Average monthly progress: 125 feet per month for the first 4,800 feet, 240 feet per month for the last 1,575 feet.

Average Cost of Driving First 4,800 Feet.

	Cost per foot of tunnel.
Labor	\$ 8.86
Powder	7.86
Fuse and caps	.17
Candles and oil	.21
Horse feed and shoeing	.18
Power	1.64
Repairs	.14
Tunnel equipment	2.75
Surface plant	1.25
	\$23.06

"Tunnel equipment" includes the cost of materials and installation of the pressure air line, the ventilating line, rails, ties and fittings, and the drainage ditch. "Surface plant" includes buildings, compressor, blower, transformers, motors and drill sharpener.

Cost of Driving Next 1,575 Feet.

The contractor received \$21.50 per foot to cover the cost of labor, powder, fuse, caps, candles, oil, horse feed and shoeing, power and repairs, and the installation of the tunnel equipment.

(To be continued.)

REMARKABLE SPEED IN BRIDGE BUILDING.

Since the establishment of the Canadian military camp at Valcartier, Que., there has been much accomplished that reflects credit upon the manner in which the engineering features of the camp have been handled. First, it took but a few days for the Canadian Northern Railway to transform a small flag station into an important terminal point with twenty miles of railway sidings, giving a splendid impetus to the establishment of the camp and expediting the movement of the men and materials which went to make this city of thirty thousand souls.

Now comes news of a bridge-building record made by the men of the Royal Canadian Engineers under the direction of Major W. Bethune Lindsay, of Winnipeg. The Jacques Cartier River separates the main camp from the artillery practice grounds at the base of Mounts Ileene and Irene. Across this 350 feet of waterway, the Royal Canadian Engineers built in four hours, a barrel-pier pontoon bridge, capable of carrying heavy batteries. The major and his three hundred men worked with that well ordered efficiency which characterizes the efforts of the British bred. The race for the record started with the Canadian Northern Railway. The materials—barrels, planking, etc., were freighted on to the ground with remarkable despatch. The casks were made watertight, the timber was made ready, the twenty-foot bank cut down to provide an easy grade for traffic, and the actual test was on.

There is a telephone for every 15.2 persons in Canada, according to official figures.

Promising surface indications of petroleum deposits in Spain have led the government to investigate the discoveries.

Editorial

HAMILTON-TORONTO PERMANENT HIGHWAY.

The plan to proceed without delay on the construction of a $600,000 permanent highway between the cities of Hamilton and Toronto is a very commendable one. Besides providing a thoroughfare for which there has been a distinct need, this work will be a boon to many unemployed in the two terminal cities and in the intervening municipalities.

Various organizations, including city and town councils, boards of trade, automobile, farmers' and fruit-growers' associations, etc., have emphasized for a considerable length of time the necessity for a permanent road which, when constructed, would serve over half a million people. The road will run through fruit and vegetable farming communities for practically its entire length and will be a means of bringing producer and consumer closer together here than it is possible to find them elsewhere in the Dominion. The phrase "deplorable condition" has been associated with the present Lake Shore Road for the greater part of many seasons. This state is very regrettable considering the usefulness of an improved inter-city highway, its picturesqueness and the absence of engineering difficulties along its path.

Last week a program was decided upon by the Provincial Government whereby Toronto and Hamilton will contribute $150,000 and $30,000 respectively, while the counties through which the projected road will pass will assist at the rate of $4,000 per mile. A commission was also appointed to properly manage these funds, to select the route, concerning which, for a small portion of the distance, there has been some controversy, to decide the type of pavement and to take charge of the construction. This commission consists of Geo. H. Gooderham, M.P.P., Toronto; G. Frank Beer, Toronto; T. W. Jutton, Hamilton; M. C. Smith, Burlington; and C. G. Marlatt, Oakville.

The last report of the Public Roads and Highways Commission of Ontario very strongly emphasized the need of this permanent inter-city route. One of its chief recommendations for this season's work constituted a preliminary survey of the line. The government authorized this procedure last winter, and Mr. W. A. McLean, the Provincial Highway Engineer, has had a staff of men engaged upon the work for a greater part of the summer. Hence, little time need be spent upon preliminaries.

What remains of the road-making season has been reduced to a matter of days, but before the interference of severe weather, any necessary re-location may be made, grading may be proceeded with and materials collected. This may mean the employment of from 500 to 700 men.

It is just such undertakings as these, involving the services of large gangs of men, that our cities and towns should hasten to proceed with, in order to reduce as much as possible the distress and want which follows in the wake of unemployment.

ANNOUNCEMENT

In view of the present political conditions in Germany and Austria, which constitute a menace to Canadian interests, *The Canadian Engineer* feels fully justified in excluding from its pages the advertisements of any machinery or materials made in Germany or Austria that can be supplied by Canadian firms, by firms situated anywhere within the British Empire, or by firms in the friendliest of neutral countries, the United States.

ENGINEERS' LIBRARY

Any book reviewed in these columns may be obtained through the Book Department of The Canadian Engineer.

CONTENTS.

BOOK REVIEWS.

Influence Diagrams for the Determination of Maximum Moments in Trusses and Beams. By Malverd A. Howe, C.E., Professor of Civil Engineering, Rose Polytechnic Institute. Published by John Wiley & Sons, New York; Canadian consulting agents, Renouf Publishing Co., Montreal. 65 pp.; 42 illustrations; 6 x 9 in.; cloth. Price, $1.25.

This is the first edition of a very useful work which explains the method of applying influence lines in the analysis of trusses, arches and beams. While their use is not new, the book has for its object the directing of attention to the fact that for loads on all ordinary trusses the influence diagrams for bending moments may be drawn by following a single simple rule and that no computations are required for the direct application of such diagrams when so constructed. In addition, it also brings out the fact that these influence diagrams for loads on continuous trusses, cantilever trusses and arches are based upon the one general diagram for simple trusses. Moreover, the author makes it clear that although the diagrams shown in the book are constructed for moments, yet they can be as easily drawn to indicate stresses or even areas of truss members.

The work is divided into five chapters: Simple trusses, double intersecting trusses, continuous trusses, arches and beams of constant section.

The definition of influence line as given by the author is a very convenient one, viz., "an influence line is one which shows the effect of a unit load moving across a structure upon any function of the structure for any position of the load." As might be expected, the work contains many technical calculations, but they are well illustrated in the diagrams and carefully explained in the text.

The work is well printed and bound, and a structural engineer will find it a valuable addition to his library.

Lackawanna Handbook. Published by the Lackawanna Steel Co., Buffalo, N.Y. 456 pp.; size 4 x 6½ in.; flexible leather binding. Price, $2.00.

This is a 1915 edition of a handbook containing some very useful information for engineers, architects and builders. It comprises diagrams, dimensions and weights of structural steel sections, special shapes merchant bars, sheet steel filing, standard heavy and light rails, track accessories, etc. The usual mathematical tables required in the use of such products are included. Among them might be mentioned the properties of rolled sections; the dimensions, properties and safe loads of steel columns and struts, and the dimensions and safe loads of girders and beams. The handbook also contains mensuration formulæ, notes on roofs and roof trusses, tables of weights, measures, specific gravities and others for arithmetical and logarithmic use.

Waterworks Engineering. By Fred. C. Uren, M. Inst. C.E. Published by Castle Litho, Limited, Bristol, Eng. 270 pp.: 186 illustrations besides numerous plates; size 6 x 9½ in.; cloth.

The author's wide experience in waterworks engineering, comprising company, local authority and parliamentary work is reflected throughout this book, which will be found a practical treatise on the construction of waterworks and therefore of benefit to engineers and engineering students. The work fills a want that has been more or less ignored by many volumes on waterworks engineering that have appeared throughout recent years. The theoretical side of the question has been treated with special brevity in order to devote all possible space to details of actual construction of small and large undertakings from their incipient stages to completed works. The author has recognized the fact that improvements that recent years have brought about in many phases of design and construction, have almost revolutionized former practice; hence, such sections as those on earthen and masonry dams, geology and well boring, distribution and purification, have been given special attention.

The following constitute the chapter headings: Sources—Storage; Impounding Reservoirs, Masonry Dams; Earthwork Dams; Reservoir Accessories; Rivers and Streams; Well Construction and Boring; Geology, Yield of Wells; Service Reservoirs; Raising Water from Wells; Motors for Pumps; Calculating the Dimensions of Pumps and Engines; The Flow of Water in Pipes and Channels; Gauging Water; The Purification and Softening of Water; Distribution and Utilization; Watermains and Accessories; Service Pipes and House Fittings; Metered Supplies, Waste Detection; Administration and Maintenance; and, The Law of Waterworks.

Work, Wages and Profit. By H. L. Gantt. Published by the Engineering Magazine Co., New York. 312 pp.; 27 illustrations; size 5 x 7 in.; cloth. Price, $2.00.

This is the second edition of Mr. Gantt's book. It is considerably revised and enlarged over the first edition which appeared in 1910. The author has taken advantage of the rapid rise that has taken place in public attention to the methods used and the results secured in the application of scientific management to the various industries. In his preface the author is cautionary concerning sudden

changes of management for purposes of inaugurating the principles of modern industrial organization into an industry. He states: "The man who undertakes to introduce scientific management and pins his faith to rules, and the use of forms and blanks, without thoroughly comprehending the principles upon which it is based, will fail. Forms and blanks are simply the means to an end. If the end is not kept clearly in mind, the use of these forms and blanks are apt to be detrimental rather than beneficial."

The work goes a long way towards explaining the principles of modern industrial organization and outlines how to utilize the methods of evolution in the introduction of a system of management based upon these principles. The author's experience in the field of labor management extends over 25 years of close practical application and his own special methods are well known, although perhaps partially or imperfectly understood by many. The book outlines to the full his concept of scientific investigation according to standardization, individual instruction, and interconnected reward to both instructor or supervisor and workman.

The illustrations are for the most part in the form of colored charts, representing conditions associated with scientific management in machine shop, metal working, locomotive building plants, etc.

In its entirety the work offers an interpretation of industrial conditions and a promise for betterment that makes it of extreme value to the managers of industry.

Sub-Aqueous Foundations. By Chas. E. Fowler, M. Am. Soc. C.E., M. Can. Soc. C.E., etc. Published by John Wiley & Sons, New York; Canadian selling agents, Renouf Publishing Co., Montreal. 814 pp.; 477 illustrations; size 6 x 9 in.; cloth.

This extensive treatise on Sub-aqueous Foundations is the third edition of Mr. Fowler's work, considerably revised and enlarged. It includes in revised form the material of several previous publications by the author, the cofferdam process for piers, and dredges and dredging. It is a practical treatment of the whole subject containing numerous examples from actual work. This latter characteristic largely constitutes a new matter incorporated in the third edition. They relate to structures that have had the test of time and use. Many of them were constructed by the author or were under his supervision in a consulting capacity.

The use of compressed air in caisson work has been conspicuously added to, while an entire chapter has been devoted to the use of launches, tugs and scows, as required in foundation work. Characteristic of the publication is the data also on the bearing power of soils, on friction in pile and caisson work and on the quarrying of rock. Entirely new matter has been given on piers and wharves; dams, sea walls and retaining walls; dry docks and locks; cost of construction work, the two chapters on this latter subject covering the subject of foundations so well that the engineer in possession of the volume will find it quite adequate as a source of information to properly execute his work.

The following list of chapter headings is sufficient evidence of the comprehensiveness of the book, and engineers familiar with the author's previous contributions to literature on the subject no doubt find therein sufficient new matter to assure them that the book will fill a very important place:

Historical Development; Construction and Practice—Crib Cofferdams; Construction and Practice—Cribs and Canvas; Pile-Driving and Sheet-Piles; Jetting Piles; Construction with Sheet-Piles; Metal Construction; Cylinders and Caissons; Open Dredged Caissons of Timber; Timber Pneumatic Caissons; Steel Pneumatic Caissons, Forth Bridge; Divers and Diving; Removing Old Piers; Pumping and Dredging; Clam-shell Dredges, Drill Scows and Rock Breakers; Dipper and Ladder Dredges; Suction and Hopper Dredges; Tugboats and Scows; The Foundation; Location and Design of Piers; Rock Fill Foundations and Quarries; Calculation of Piers, Footing and Retaining Walls; Cement and Concrete; Foundations for Piers and Wharves; Timber Piers and Timber Preservation; Foundations for Dams, Sea Walls, and Breakwaters; Foundations for Docks and Locks; Forms for Concrete; Estimating the Cost.

Symmetrical Masonry Arches. By Malverd A. Howe, M. Am. Soc. C.E., professor of Civil Engineering, Rose Polytechnic Institute. Published by John Wiley & Sons, New York; Canadian selling agents, Renouf Publishing Co., Montreal. 245 pp.; 35 illustrations; 6 folding drawings; size 6 x 9 in.; cloth. Price, $2.50.

This is the second edition of Professor Howe's treatise on the design of masonry arches according to the elastic theory. Most of the text has been rewritten and a considerable amount of new matter added, while demonstrations of the formulas presented in the previous edition have been materially simplified. The author has employed the unit load method throughout the work, claiming it to be the only satisfactory method to use if maximum stresses are desired.

In order to facilitate a ready solution of the ordinary problems, such as are encountered by the engineer during his regular practice, a greater portion of the book is taken up with the solution of examples, each step being given in detail so as to be readily followed by the engineer or engineering student who has not specialized particularly along this line.

The general subject is treated under the divisions of: Fundamental Formulas; Symmetrical Arches fixed at the ends (2 chapters); Examples showing the application of the formulas; and Typical Arches.

The work relates generally to masonry arches of natural stone, plain concrete and reinforced concrete. Appendices to the general text are as follows: Physical properties of stone and concrete; Data for about 600 arch bridges.

PUBLICATIONS RECEIVED.

Queen Victoria Niagara Falls Park.—28th annual report of the Commissioners (1913). 42 pages; illustrated; size, 6 x 9 in.

Hydro-Electric Power as Applicable to the Farm.—Evidence given before select standing committee on Agriculture and Colonization, Canada.

Experiments with Furnaces for a Hand-Fired Return Tubular Boiler.—Technical Paper No. 34 of the United States Bureau of Mines. 32 pages; size, 6 x 9 in.

Association of Ontario Land Surveyors.—Proceedings of the 22nd annual meeting, held in Toronto, February, 1914. It contains reports of committees, papers, list of members, etc.

Electric Lights for Use About Oil and Gas Wells.—Technical Paper No. 70 of the United States Bureau of Mines outlining danger from use of ordinary electric lights, suggested specifications, etc.

Ontario Good Roads Association.—Proceedings of the 12th annual meeting, appended to the annual report of the

Commissioner of Highways. It contains the papers, discussions and reports of the February, 1914, meeting.

Proportioning Aggregates for Portland Cement Concrete.—Reprint of paper by Albert Moyer from the proceedings of the American Society for Testing Materials. Issued by the Vulcanite Portland Cement Co., New York.

Accidents from Falls of Rock or Ore.—A circular issued by the United States Bureau of Mines outlining the causes and prevention of accidents from such falls under different conditions of mining, and general hints to miners on the subject.

Forestry.—Report for 1913 of the Director of Forestry, Department of the Interior, Canada, containing the reports also of district inspectors, inspector of fire ranging, and reconnaissance surveys in various Provinces. 136 pages; illustrated.

Trent Watershed Survey.—Map illustrating forest distribution and diagram showing classification of land to accompany previous report of the Commission of Conservation, Ottawa, on the Trent Watershed Survey (already reviewed in these columns).

Tabulation of Water Rates.—Report of Committee on Tabulation of Water Rates and other information of interest to water companies. 337 pages; size, 6 x 9 in.; reprinted from the Journal of the American Waterworks Association, for June, 1914.

Centrifugal Compressors.—By Louis C. Loewenstein, Issued by the Canadian General Electric Co., and reprinted from the General Electric Review. A very comprehensive discussion of the design, construction and operation of centrifugal compressors.

Lands, Forests and Mines.—Report for 1913 of the Minister of Lands, Forests and Mines of the Province of Ontario, including statements and reports of officers, surveyors, superintendents and of Mr. J. F. Whitson on the construction of roads in Northern Ontario.

The Pre-Cambrian Geology of Southeastern Ontario.—By W. G. Miller and C. W. Knight, of the Bureau of Mines of Ontario. The report also contains an appendix on the co-relation of the Pre-Cambrian rocks of Ontario, Western Quebec and Southeastern Manitoba.

Mother Lode and Sunset Mines Boundary District, B.C.—Memoir No. 19, of the Geological Survey, Department of Mines, Canada. Compiled by O. E. LeRoy. It covers the general character of the district, its general and economic geologies and detailed description of the mines.

Clay and Shale Deposits of the Western Provinces.—Part No. 3.—By Heinrich Ries. Memoir No. 47 of the Geological Survey, Department of Mines, Canada. Report of the 1912 investigation of the Survey, including field work and results of tests of samples from a large number of localities in Western Canada.

Factors Governing the Combustion of Coal in Boiler Furnaces.—A 44-page preliminary report issued by the United States Bureau of Mines. It describes the equipment and character of tests constituting an extensive investigation; the coal used; results of the experiments; and discussion of results of tests.

Big Creek Initial Development.—1914 report of the Stone and Webster Construction Co., describing their work in connection with 4 dams, 2 tunnels, 2 power-houses, 2 240-mile transmission lines, sub-station and 56-mile railroad for the Pacific Light and Power Corp. Beautifully illustrated with photographs and colored map.

The Origin of Coal.—Bulletin No. 38, United States Bureau of Mines. 390 pages; illustrated; size, 6 x 9 in. It deals with the geologic relations of coals; analysis of samples; physiographic conditions attending coal formation; rate of deposition; origin and formation of peat; microscopic study of coal, and conclusions.

The Young Man and the Electrical Industry.—A reprint by the Westinghouse Electrical and Manufacturing Co. of an article by Jas. H. Collins dealing with the opportunity afforded a young man in the industry and the different lines in which he may direct his activities as exemplified in the works of that company. Article appeared in "Scientific American," May 16th, 1914.

International Joint Commission.—Opinions, reports of hearings and arguments, and orders of the International Joint Commission in the matter of (1) the application of the Michigan Northern Power Co. for approval of the obstruction, diversion and use of St. Mary's River water on the United States side of the boundary at Sault Ste. Marie, and (2) the application of the Algoma Steel Corp. upon the same problem.

Vitrified Brick, Pavements and Highways.—Specifications for the construction of vitrified brick street pavements and highways, being the 1914 revised edition issued by the National Paving Brick Manufacturers' Association. The specifications cover grading; drainage; stone curbing; concrete foundation; cushion; expansion joints; brick; bricklaying and inspection; rolling; cement grout filler; alternative concrete curbing; with similar specifications concerning cement-filled brick pavement; crushed stone; old gravel or macadam foundation; sand filler; in the case of each, i.e., street pavements and highways.

Poor's Manual of Industrials for 1914 (fifth annual number).—The book contains 2,500 pages, or about 300 pages more than any previous issue. About 750 new companies have been added and many new income accounts and balance sheets. These tables are mostly in comparative form. In addition, the Manual contains an appendix, giving late information on the Railroads and Utilities, supplementing these two Manuals. The publication of this volume completes Poor's Manual for 1914. The three books together contain over 6,500 pages, covering the entire field of corporate investment in America. They give statements of practically every corporation in which there is a public interest, and are noted for their accuracy, completeness and thoroughness.

CATALOGUES RECEIVED.

Morris Overhead Runway.—An illustrated bulletin of the Herbert Morris Crane and Hoist Co., Limited, Toronto, describing the "O. E. F." type of runway as to capacities, construction, accessories, etc.

Storage Battery Locomotives.—A 4-page leaflet issued by the Canadian Westinghouse Co., Limited, Hamilton, Ont., descriptive of the Baldwin-Westinghouse Storage Battery Locomotives, as built in two types for mining and industrial service.

Work Done.—A 48-page illustrated booklet issued by Westinghouse, Church, Kerr and Co., New York, descriptive of some of the work which they have done for industrial plants. The work includes railways, steam and electric, as well as the design and construction of complete plants, etc.

Oil and Gas-Burning Appliances.—An 8-page bulletin issued by the Quigley Furnace and Foundry Co., Springfield, Mass., descriptive of appliances for burning oil and gas fuel, including burners, blowers, strainers, separators, regulating valves, gauges, storage tanks, pumping systems, etc.

Evidence as to Pavements.—A handsomely illustrated booklet published by the Barber Asphalt Paving Company, Philadelphia, describing the work done by them in various cities of the United States, and outlining the durability of such pavements as evidenced by many instances in which they are more than 20 years old.

Rail Bonds and Bonding Tools.—A catalogue issued by the Canadian General Electric Co., Toronto, and containing

information on rail bonds and rail bond tools for various requirements. Recent improvements are described and a considerable quantity of engineering data included. The catalogue is well illustrated and covers 54 pages.

Floor and Ceiling Plates.—A catalogue of special interest to heating and plumbing trades descriptive of various types of plates, automatic wood wheel and key valves, self-cleaning water gauges and various other accessories for steam and hot water systems. Published by the Beaton and Cadwell Manufacturing Co., New Britain, Conn.

Lagonda Multiple Strainers.—It describes a strainer manufactured by the Lagonda Manufacturing Co., Springfield, O., for water intake lines of power plants and pumping stations for the removal of solid matter without any interruption to flow. The catalogue contains much descriptive information; it is well illustrated, and covers 20 pages.

Railway Motor Gears and Pinions.—A 20-page bulletin issued by the Canadian General Electric Co., Toronto, describing their various grades of gears and pinions. The description covers solid cast-steel, split cast-steel and forged gears. It explains their construction and gives some valuable gear formulæ, together with tables of classification and dimensions.

Oil and Gas Engines.—A 50-page catalogue issued by the August Mietz Iron Foundry and Machine Works, New York, descriptive of Mietz and Weiss oil and gas engines, stationary and marine, for operation by kerosene, alcohol, fuel oil, distillate and crude oil; 2 to 400 h.p. Also a catalogue descriptive of Mietz and Weiss marine oil engines, reversing friction clutches, starters, etc.

Chloride and Tutor Accumulators.—A 24-page catalogue issued by the Canadian General Electric Co., Limited, Toronto, descriptive of these types of accumulators for electric railways, central and isolated lighting and power plants, interlocking switch and signal service, telephone, telegraph, fire alarm, laboratory and small motor work. The catalogue describes both types in detail as to sizes, capacities, working conditions, parts, etc.

Measuring Tapes and Rules.—A handsomely illustrated and well-bound 110-page catalogue published by the Lufkin Rule Co. of Canada, Limited, Windsor, Ont., as Catalogue No. 9. A wide assortment of tapes and their accessories, including hooks, tension handles, reels, arrows, as well as a large variety of steel and boxwood rules, yard-sticks, squares, etc., as required by engineers, contractors, surveyors, lumbermen, etc.

Motor-Driven Pumps.—Catalogue No. 3,002-A of the Canadian Westinghouse Co., Hamilton, Ont., describing in 24 pages the motors which that company manufactures for driving all types and sizes of pumps. The catalogue contains quite a supply of information on the requirements of pumps for sewage disposal systems, waterworks, mines, industrial plants, fire departments, irrigation work, dry-docks, contractors' use, etc.

Appliances for burning Fuel Oil.—A large, handsomely illustrated 32-page catalogue issued by the Tate, Jones and Co., Inc., Pittsburgh. It outlines the economy of oil for steam production; the advantages of oil fuel for furnaces; the importance of the burner to success with fuel oil, giving actual results in each case. The remainder of the catalogue describes the company's types of burners, and systems of pumping, heating and regulating oil flow.

BOARD OF HEALTH APPROVALS.

During the week of September 7th the Provincial Board of Health of Ontario approved of the sewer extensions of Arnprior, Kingston and New Liskeard. Water mains for the city of Toronto were also approved of.

Coast to Coast

Moncton, N.B.—The gates of Moncton's new 50-foot reservoir are now closed, according to the recent announcement of City Engineer Edington; and when it has been flushed sufficiently to remove all debris, a water supply will be turned on in the town. It is expected that the supply will be available in about two months' time.

Gagetown, N.B. Finishing touches are being given to the rail-bed of the Valley Railway, which will connect Gagetown and Fredericton, and over which it is fully expected a service will be commenced this winter. Rails have been laid as far as the station, and the station building has been completed. The water tank at the station is not yet in working order. The well in connection with the tank has been dug to a depth of 200 feet; but this depth does not give sufficient depth for the flow of 40,000 gallons per day which is required.

St. John, N.B.—The Dominion Bridge Company has practically reassembled its construction plant at the eastern side of the river at the Falls. The trestle, which starts below the rock cut on the C.P.R. track and crosses over at the corner of Chesley Street to the approach of the bridge, has been finally connected; and the granite work on the skew-back piers on the east side are being finished by Messrs. J. McVey and Son. Within a few days, the Bridge company will be ready to swing out the steel on the eastern part of the arch to complete the bridge.

Saskatoon, Sask.—It is stated that in connection with the work on the large reinforced concrete bridge being erected at Saskatoon, the contractor has installed a pneumatic concrete mixing plant, a patented mixer, in which the mixing is done by compressed air and the concrete is transferred from the mixer to the point of disposal under air pressure. Also the difficulty which was experienced last winter in constructing the river pier third from the east abutment causing this work to be left unfinished, has been overcome; and now but one pier on the whole work remains to be undertaken.

Valcartier, Que.—Since the action of the Dominion Government making Valcartier on the C.N.R. the centre for the Canadian military camp, the railway company has constructed a main line, 8,800 feet long, from mileage 15.05 to a point on the Gosford branch of the system. On this line, 3 sidings have been laid as the main transfer point: one of these is double-ended, the other two entering only from the west. Several additional sidings have also been built, and a 12-degree loop from the west end to the sidings is connected with the Gosford line in the return direction. The engineering work for this new terminal was supervised by Mr. C. H. N. Connell, engineer of maintenance of way on the C.N.R.

Ottawa, Ont.—An announcement made at Ottawa at the beginning of this month stated that Canada has taken over the wireless stations at Port Nelson and The Pas. The stations were erected with government funds by the Marconi company, which had the contract to operate them for a year. The period for their operation by the Marconi company is expiring. It has been decided that the operation hereafter can be best carried on by the wireless branch of the naval service department. The two stations will form part of a wireless chain which the government proposes to provide for Hudson Bay. Both The Pas and Nelson stations are equipped with apparatus of high power. They have a despatching reach of 400 miles overland. Other stations will be erected further north. There will be one on Maunsel Island, at the western

extremity of Hudson Strait, one at Ash Inlet, about the centre of the Strait, and one at Button Islands, at the Atlantic end of the Strait. When these stations are completed it will be possible to speedily convey and receive information over the whole Hudson region.

PERSONAL.

Col. W. P. ANDERSON, C.M.G., chief engineer of the Department of Marine and Fisheries, Ottawa, is in British Columbia on his annual inspection of the works under the control of that department.

D. L. H. FORBES, B.A.Sc., M.E., has been appointed chief construction engineer of the Chile Exploration Company of Chuquicamata, Chile. For some time Mr. Forbes had carried on a consulting mining engineering practice, with offices in Toronto.

Major E. C. NORSWORTHY was last week elected a director of the Canada Cement Company, Montreal. Major Norsworthy, who is at present with the Royal Scots Regiment at Valcartier, is a director of the Dominion Securities Corporation, and its manager for Montreal.

PERCY WILGER, formerly an engineer on the National Transcontinental Railway, has been appointed Professor of Civil Engineering, School of Mining, Queen's University, Kingston. Mr. Wilger is a Queen's graduate of 10 years' standing. He succeeds the late Professor A. K. Kirkpatrick.

E. S. CLEMENTS of the Canada Creosoting Co., Limited, Toronto and Trenton, Ont., has resigned.

OBITUARY.

The death is reported of Mr. Jas. A. Gould, Edmonton superintendent for the Bitulithic Paving Company. Seven years ago Mr. Gould resigned from a position as street superintendent of the City of Toronto to take a position in Edmonton for the above company. In 1910 he resigned to become superintendent of streets for Edmonton, but in 1913 he returned to the employ of the paving firm. Mr. Gould's death was quite sudden and unexpected, heart failure being the cause.

The death occurred last week of Mr. Fred. H. Herbert, a prominent architect of Toronto.

Our readers will no doubt remember the controversy which followed the disastrous storm of November 9th, 1913, and its heavy toll of life and traffic on the Great Lakes. *The Canadian Engineer* of December 11th, 1913, published some valuable suggestions as to the possible prevention of similar disasters to inland freighters from the pen of Mr. Wm. E. Redway, Naval Architect, Toronto. We regret at this time to be called upon to report the death of Mr. Redway, on September 19th, 1914. Since 1884 he had been associated with shipbuilding in Canada, during which period he designed many improvements, and received honored recognition from various naval organizations within and outside the Empire.

CORRECTION IN ADDRESS.

In the advertisement of the De Laval Steam Turbine Co. for several weeks past, the address of the Turbine Equipment Co., Limited, Toronto, who are the Canadian representatives of the De Laval Steam Turbine Co., has been given in error as 204 Peterkin Building. The correct address of the Turbine Equipment Co., Limited, is the Canadian Pacific Building, King and Yonge Streets, Toronto, to which they moved a few weeks ago from the Peterkin Building.

C.G.E. CORPS OF ENGINEERS.

In connection with the mustering of Canadian troops the Canadian General Electric Co. has established a corps of engineers, both electrical and mechanical, and has divided it into three sections to serve at Quebec, Halifax and Esquimalt. The company is maintaining six corps of technical men at its own cost throughout the duration of the war. Prior to taking their departure from Toronto for their respective posts of duty Mr. Frederic Nicholls, President of the General Electric Company, delivered a parting address to the men, exhorting them to be as consistent in the service which they are undertaking as they had been in the service of the company.

The personnel of the three detachments is as follows:—

For Quebec—Messrs. W. J. Swanger, R. W. Nurse, George Monaghan, George Hillier, C. Pink, P. Foster, H. Galvin, of Peterboro, and Colin C. Rous, of Toronto.

For Halifax—Messrs. H. S. McKean, J. C. Munro, Clarence Henry, E. S. Shill, R. Bethune, A. J. Palmer, of Peterboro, and F. G. Jackson, Edward Crockford, of Toronto.

For Esquimalt—Messrs. H. Ritchie, Chas. Stewart, H. E. Elliott, W. S. Johnson, H. Williams, J. S. Dunlop, of Peterboro, and A. T. McLean, Harold Bestard, Alex. Hardie, of Toronto.

COMING MEETINGS.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

MOTOR TRUCK CLUB OF AMERICA.—Annual Convention, Detroit, Mich., October 7th to 9th. President, George H. Duck, New York City.

GULF AND INTEROCEAN NATIONAL HIGHWAY ASSOCIATION.—October 8th, 9th, 10th; conference to be held at New Orleans, La. Secretary, Jno. B. Kent, Lake Charles, La.

INTERNATIONAL ASSOCIATION OF FIRE ENGINEERS.—Annual Convention, Grunewald Hotel, New Orleans, La. October 20th to 23rd. Secretary, Mr. McFall, Roanoke, Va.

ALABAMA GOOD ROADS ASSOCIATION. — Nineteenth Annual Convention will be held from October 21st to 23rd at Montgomery, Ala. Secretary, J. A. Rountree, 1021 Brown Marx Building, Birmingham, Ala.

AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—Charles Carroll Brown, Secretary, Indianapolis, Ind. Meets at Somerset Hotel, Boston, Mass., October 21st, 22nd and 23rd.

NORTHWESTERN ROAD CONGRESS.—Annual Convention, to be held at Milwaukee, Wis., October 28th to 31st. Secretary, J. P. Keenan, Milwaukee.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

WASHINGTON STATE GOOD ROADS ASSOCIATION.—Convention to be held at Spokane, Wash., November 18th, 19th, and 20th. Secretary, M. D. Lechey, Alaska Building, Seattle, Wash.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

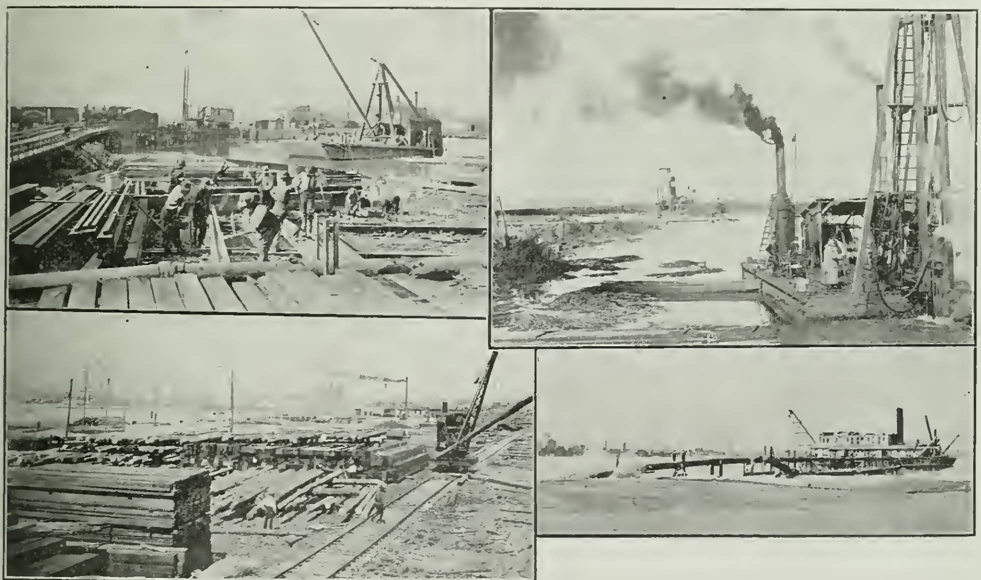
TORONTO HARBOR AND WATERFRONT DEVELOPMENT

ENGINEERING FEATURES OF THE WORK AS OUTLINED IN THE 1913 REPORT OF THE TORONTO HARBOR COMMISSIONERS—SYNOPSIS ALSO OF 1914 ACTIVITIES.

THE report of the Toronto Harbor Commissioners covering the progress made during the year 1913 has just been issued. The general scheme of development was placed before our readers in *The Canadian Engineer* for November 21, 1912. A brief résumé of the project, the estimated cost of which was then stated to be $19,142,088, besides docks to cost five or six millions, is as follows: The construction of a modern harbor with a uniform depth of water capable of accommodating vessels up to 25 ft. draft; modern permanent docks on the central waterfront equipped with up-to-date freight sheds, warehouses and dock apparatus; large docks and industrial district at the foot of Cherry Street, with proper freight shed and warehouse equipment, etc.; a similar dock development at the foot of Bathurst Street, west of the central development; an industrial area of 1,000 acres east of Cherry Street, capable of accommodating factory buildings with a value of $30,000,000 and producing a ground rent revenue of $500,000 per year; a ship channel 6,800 ft. long, 400 ft. wide and 24 ft. deep with a turning basin 1,000 ft. square at its east end, serving the industrial district and the eastern portion of the city generally, and equipped with



Views of 1913 Activities. Preparing Sheet Piling for the North Slip Retaining Wall; Commencing the Construction of the Ship Channel; View of Pile Yard; Harbor Deepening and Reclamation Work.

three miles of dockage; a dock area on the western face of this industrial division to provide an additional three miles of dockage; a new lake-front park, drive and waterway extending from the Eastern Channel to the foot of Woodbine Avenue and containing 352 acres, protected by a breakwater nearly four miles in length; a protected waterway 1 ¼ miles long, averaging 600 ft. in width, from Woodbine Avenue to the city limits on the east; 352 acres of additional park area on Toronto Island and new park areas from Bathurst Street to the Humber River to the extent of 190 acres and fronting on a protected waterway

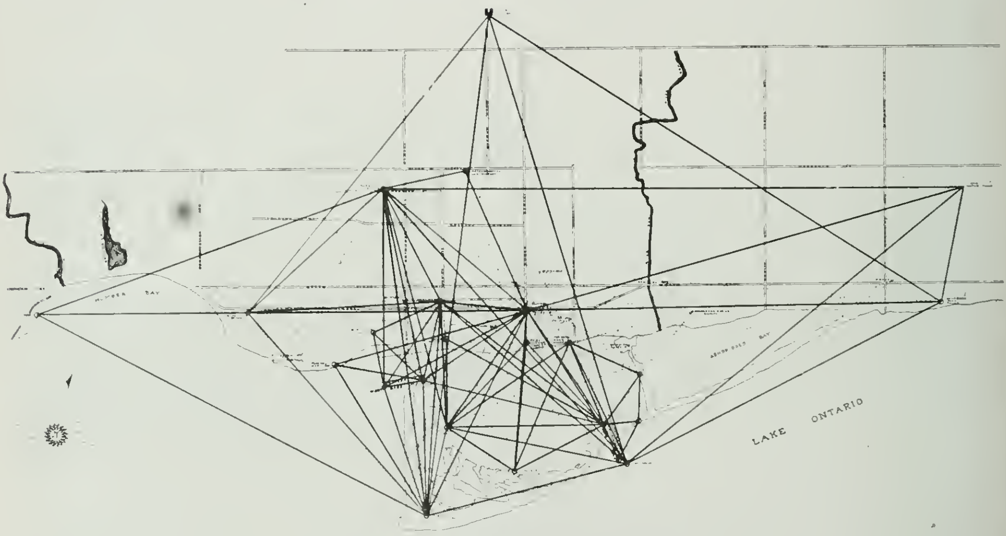
with a minimum width of 300 ft., separated from the lake by a breakwater; a bathing beach 1⅓ miles in length from Sunnyside to the Humber on a similar beach 4¼ miles in length from the Eastern Channel to Victoria Park; a boulevard system of driveways, etc., 11 miles in length across the waterfront; a protected waterway 12 miles in length with provision inside the breakwaters for equatic clubs; promenades, recreation piers, public playgrounds, etc., etc.

Preliminary plans were completed with the close of the year 1912. The general plans, providing for the development of the harbor and of the harbor industrial district, as well as for the general improvement of the outer waterfront and the construction of breakwaters for the purpose of protecting the waterfront east and west of the inner harbor were approved by the Toronto City Council and by the Federal Government in June, 1913. During the year substantial progress was made in the preparation of detailed working plans and a completion of arrangements for letting contracts and starting work. Dredging operations for the filling of the industrial district and the reclaiming of other lands were let by contract to the Canadian Stewart Company, Toronto, the minimum price being $3,950,000, with an option to increase the amount of dredging at the same unit price per cubic yard up to a total of $6,320,000. A contract was also let by the Government to the same company for the construction of a breakwater extending from Woodbine Avenue to the Eastern Channel and another extending from the Western Channel to the Humber River, together with the construction and dredging of the ship channel in the industrial district, the total contract calling for an expenditure of $5,371,372.17. The Government also undertook the construction of lift bridges across the eastern and western entrances to the harbor and across the ship channel in the industrial district, but contracts for this portion of the work have not yet been let.

Another important event of 1913, which is more or less inter-connected with the progress of the harbor work, was the agreement between the city, the Harbor Commissioners and the various railways for the separation of railway and highway grades across the Toronto waterfront by means of a viaduct. On July 29, 1913, an agreement was finally executed and confirmed by the Board of Railway Commissioners for Canada. This agreement affected the Harbor Commission in the matter of property rights along the waterfront.

During 1913 the hydrographic and land surveys commenced in the previous year were completed with the exception of the detailed survey of Toronto Island. This latter work was held over for 1914. A very important undertaking of the Surveys Department consisted of a careful delineation of the amount of land owned by the Commissioners; *i.e.*, property surveys. For the most part, these lands are water lots with their northerly limit an old shore line whose exact position in most cases had never been thoroughly surveyed or tied in. This, combined with the fact that very few lines could be ranged or chained, being mostly over water or marsh, but that all the field work had to be done by offsets or by traverse, engendered a multiplicity of calculation with an attending greatly increased chance of error, made the progress of the work somewhat slow. Permanent monuments were placed to define the ground limits of the Commission. These monuments consist of 3-inch iron pipe filled with concrete, in the top of which is embedded a 5-inch hexagonal plate bearing a serial number and the name "Toronto Harbor Commissioners." The pipes range from 18 feet long in marsh to 3 feet in length where bolted to bare rock. In general, the tops are level with the grade adopted for the waterfront improvements.

During the year, also, a valuable series of water tables and fluctuations of Lake Ontario since 1853 was compiled, as a result of which the elevation of the zero of the Harbor Commissioner's gauge was found to be 245 ft. above mean sea level of New York. The determination of this elevation was followed by the placing of a comprehensive set of levels and bench marks across the



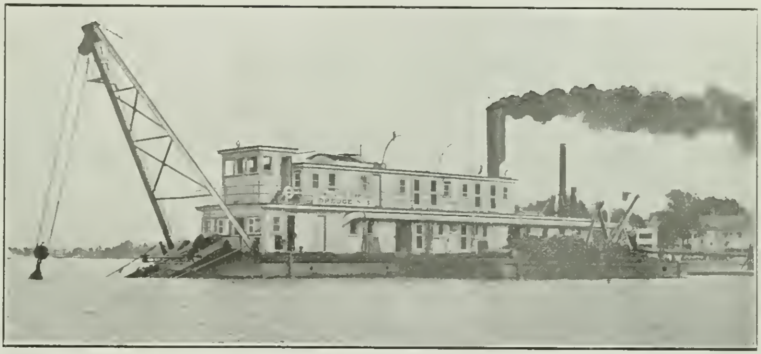
Triangle Net of Main Triangulation.

waterfront. During 1912 the Surveys Department had been seriously handicapped by the extreme lack all along the waterfront of bench marks referred to any single datum. The Department of Works of the city had under way at that time the establishment of bench marks throughout the city, but the number they proposed to establish in the region of the proposed work was insufficient. So, early in 1913, the Surveys Department of the Commission set about to establish bench marks that would be readily available when needed during the development of the waterfront. Sea level at New York Harbor was adopted for the datum, the plane of reference being, as stated, found to be 245.00 feet above such datum.

The method of field work did not involve the methods of precise levelling as used in connection with primary geodetic surveys, but only one of sufficient precision as to render the levels more than adequately accurate for any engineering work which might require them. An engineer's Wye level and a self-reading Chesterman rod were used, great care being taken to equalize the back and foresights. For this purpose, as well as to determine more exactly the rod reading, the reading of all three cross wires were taken. Benches were set about one-quarter of a mile apart and four lines of levels, forward and back and forward and back, run the same day and under the same conditions between consecutive benches, different turning, and set-up points being chosen in every instance. The arithmetic mean of these four differences of elevation was taken as the true instrumental difference in elevation between benches.

At 7 p.m. on Wednesday, July 9th, 1913, an evening of absolute calm, the whole Survey's staff were strung out along the entire waterfront from the Humber to Balmy Beach in thirteen locations and exactly at that hour nails were driven into convenient piles or cribs at the exact level of the water. The water lay dead calm, and there was no hesitation in assuming it a level plane. The elevations of these nails were subsequently tied each by four lines of levels to the nearest benches—in no case more than four hundred feet away—including a connection to the initial bench of the level net. On the assumption that while any two adjacent nails might have a difference of elevation, of such as much as 0.03 of a foot (the maximum sum of the personal errors of the two observers probable), yet this difference in elevation could not be exceeded though the observers were stationed at the extreme limit of the waterfront 10 miles apart. In other words, no adjustment was made to the instrumental elevations on the authority of a single water transfer, but only on the evidence of three or four in series. The level net was closed on the city bench marks. No weight was given to the elevations attached to these bench marks in the adjustment of the net, but on the completion of the adjustment, the elevation found for them by this department differed in no case more than a few hundredths of a foot for the elevation obtained for them by the Department of works.

An extensive precise triangulation was proceeded with and completed in December, affording a means of measurement with the transit or sextant of the angles between any three prominent points on the skyline of the city to determine the absolute position of any point. All angles were read 12 times around the circle, bringing the resultant measured angle within a probable exactitude of at least 2 seconds of arc in the harbor. A comprehensive survey was also made locating all intake pipes, sewer outfalls, drains and conduits along the entire waterfront; and another of the northwestern portion of the industrial district showing all existing structures, power lines, water mains, etc. Survey work was executed to facilitate future construction work, such as for the accurate and speedy laying out of boundary lines and locations of the various works. Extensive hydrographic surveys were also made in connection with the contract dredging and some 8,000 soundings, together with over 200 borings, were taken to obtain the nature of the material and the amount available at various depths. After these were effected detailed plans were prepared and tenders called for. The Canadian Stewart Company was awarded the contract at $19\frac{3}{4}$ cents per cubic yard, which, when the cost of supervision is added, will bring the cost to the Commissioners to practically 22 cents per cubic yard. The preliminary estimate of the engineering department averaged 21.99 cents per cubic yard.

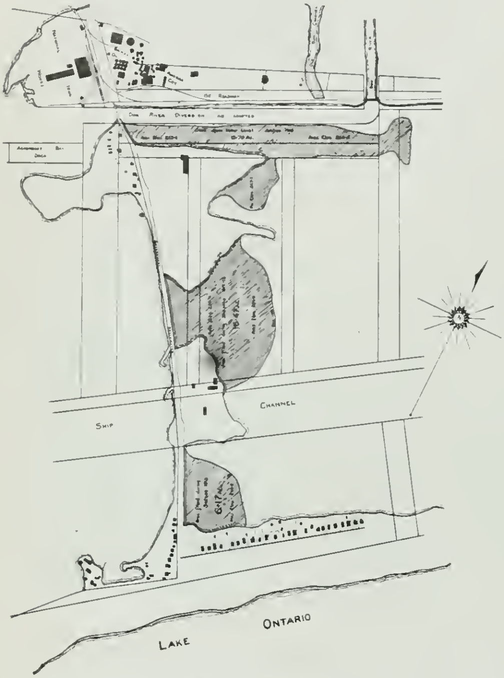


Harbor Commissioners' Hydraulic Dredge No. 3.

The construction department, in addition to general maintenance of all waterfront properties of the Commission, carried out the supervision of the construction of the Ashbridge's Bay docks, the sea wall from Dufferin Street westerly, the trestle across Keating's Channel to carry temporary tracks into the industrial district, the foundations of the Parkdale Canoe Club's new club house, the dredging of Point Anne Quarry slip and the complete supervision of the dredging equipment of the Commissioners. During the year Dredge No. 1 reclaimed for the city some 3.23 acres south of Hanlan's Point. Dredges Nos. 2 and 3 reclaimed to an average elevation of 250, 16.47 acres; to an average elevation of 249.5, 6.1 acres; to an average elevation of 248.5, 15.79 acres, or a total of practically 40 acres, in the industrial district.

The main work of the designing department consisted of details and final studies in connection with the construction of the government portion of the work; *i.e.*, the eastern and western sea walls, the ship channel, the marginal area, and the northern slip. In addition, detailed

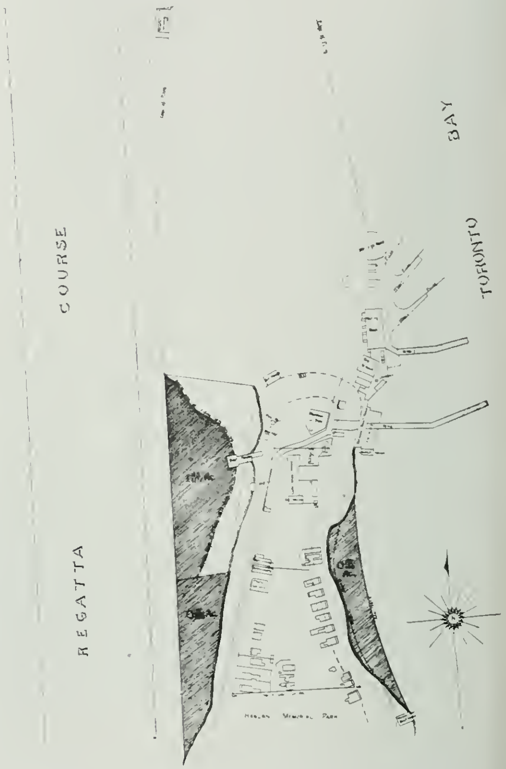
studies were made of the various types of bridges to ascertain those best suited for use over the channels. Over $6,000,000 worth of work was designed by the department for 1913, for which over 5½ million dollars worth of work was let before the end of the year. Detailed plans, specifications and estimates were prepared in connection with the work to be undertaken by the Government, and by the Commissioners, for over $11,000,000 worth of work, of which over $9,000,000 worth was contracted for before the end of the year. The entire scheme is being carried out under the direction of the Toronto Harbor Commission, consisting of L. H. Clarke, Chairman; R. S. Gourlay, T. L. Church, R. Home Smith and F. S. Spence. The Commission holds a Dominion charter with extensive powers in the development and management of the waterfront and harbor. To it the city has deeded its waterfront holdings (85% of the entire frontage) and its right to the marshy sections that are being filled in. Mr. E. L. Cousins is chief engineer to the Commission. His assistant engineers include Mr. J. R. Wainwright, in charge of designing and Mr. N. D. Wilson in charge of surveys. Mr. A. C. Mitchell is superintendent of construction. The consulting engineer of the Commission is Mr. J. G. Sing, Toronto.



Property Reclaimed in Eastern Section by the Harbor Commission During 1913.

While the foregoing notes relate to 1913 operations only, as outlined in the annual report, it will be of interest to observe that during the present year the engineering department of the Commission has been very actively engaged in the furtherance of the work. The foundations for the new building for the Parkdale Canoe Club have been completed. The previous building was burned in February, 1913. Its location was directly in line with the improvements planned by the Commission, and the negotiations between the two organizations included the erection of foundations, by the Commission, on a different site.

The construction of the Don River diversion, a contract amounting to $171,000, and being executed departmentally, will be finished by November 1st of this year. The Commission's dredges have all been actively engaged in reclamation work throughout the harbor during the entire season. The dredge "Shuniah," of the Canadian Stewart Company, has been similarly engaged in reclamation work since July. It is expected that the "Cyclone," one of the new 24-in. dredges being built by the Polson Iron Works for this company, and nearing completion, will commence work late this fall. Its sister dredge, "Tornado," will be completed this winter and ready for operations in the spring.



Reclamation Work During 1913 at Hanlan's Point, by the Commissioner's Hydraulic Dredges.

A length of about 1,600 ft. of the western breakwater extending from the Humber River westward, one of the Government contracts, is already in place. About 8,000 ft. of dock-work is under construction, belonging to a Government contract on the eastern section of the bay. This is in connection with work on the marginal way and ship channel, and on which considerable progress has been made.

ROAD SURFACING COSTS IN NIAGARA FALLS PARK.

SOME interesting cost data was gathered by Mr. John H. Jackson, Superintendent of Queen Victoria Niagara Falls Park, in connection with a five-mile stretch of macadamizing between Chippawa and Bridgeburg, Ont. This work was included in the 1913 parking program of the Commissioners. The following figures are from the 28th annual report, just published.

Part of the mileage under consideration required a light resurfacing, and another portion required the entire reconstruction of the top courses. For these two operations the following figures will show in detail the amounts that were spent per square yard:

The Light Resurfacing Water Bound Macadam Roadway.

Time—August 5th, 1913, to October 21st, 1913.
Location—Boulevard roadway from Slater's Dock, south.
Average length of haul—3.4 miles from M.C.R. siding, Chippawa.
Area treated—Length 14,625 ft. = 2.77 miles; width 18 ft. = 29,250 square yards.

Labor:	Total.	Per sq. yd.
Loading 2-in. stone and screenings	$ 232.56	8 cts.
Hauling	442.95	1.51
Pumping and watering	45.29	.15
Repairing roadway	275.18	.94
Rolling and spiking	97.29	.33
	$1,093.27	3.37 cts.
Material:		
2-in. stone—205.5 tons at $1.25	$ 256.88	.88 cts.
Screenings—150.2 tons at $1.00	150.20	.51
	$ 407.08	1.39 cts.
Summary:		
Labor	$1,093.27	3.73 cts.
Materials	407.08	1.39
	$1,500.35	5.12 cts.

Remarks:

297 cubic yards of stone and screenings were placed on 29,250 square yards.
1 cubic yard of stone and screenings was placed on 98.5 square yards.
Ratio of 2-in. stone to screenings used—1 to .731.
Ton-mile cost of hauling materials—36.2 cts.

Wage Rates:

Teams	55c. per hour
Laborers	22c. "
Foremen	30c. "
Cost per mile	$540.00

The Heavy Resurfacing Water Bound Macadam Roadway.

Time—August 1st, 1913, to December 15th, 1913.
Location—Boulevard roadway, from Black Creek, north.
Average length of haul—1.98 miles from Black Creek siding.
Area treated—Length 14,467 ft. = 2.74 miles; width 18 ft. = 28,934 square yards.

Labor:	Total.	Per sq. yd.
Loading 2 in. stone and screenings	$ 521.00	1.8 cts.
Hauling	1,509.00	5.2
Pumping and watering	215.00	.8
Repairing roadway	547.00	1.9
Rolling and spiking	425.00	1.5
	$3,217.00	11.2 cts.
Material:		
2-in. stone—750 tons at $1.10	$ 825.00	2.9 cts.
Screenings—324½ tons at $1.10	357.00	1.2
	$1,182.00	4.1 cts.
Summary:		
Labor	$3,217.00	11.2 cts.
Materials	1,182.00	4.1
	$4,399.00	15.3 cts.

Remarks:

895.4 cubic yards of stone and screenings were placed on 28,934 square yards.
1 cubic yard of stone and screenings was placed on 32.3 square yards.
Ratio of 2-in. stone to screenings used—1 to .433.
Ton-mile cost of loading and hauling materials—32.3 cts.

Wage Rates:

Teams	45c. per hour
Laborers	20c. "
Foremen	30c. "
Cost per mile	$1,600.00

At Queen Victoria Park rates for teams, .55c., and men .22c., the above ton-mile cost would be 38.4c.

In connection with the scarifying and re-crowning of this section of roadway a bituminous top was laid on a 2¾-mile length, and the following figures show the cost of different operations in connection therewith:

Tarvia "A" and ½-inch Stone Surfacing.

Time—September 2nd to October 16th, 1913.
Location—Boulevard roadway, vicinity of Usher's Creek.
Length of haul—3.4 miles.
Area treated—Length 14,625 ft. = 2.77 miles; width 18 ft. — 0 in. = 263,250 square feet = 29,250 square yards.
Depth—½ inch.

Labor Cost:	Total.	Per sq. yd.
Loading, hauling and placing stone	$ 861.05	2.90 cts.
Loading, hauling and placing tarvia	353.71	1.19
Placing and removing plant	56.50	.19
	$1,271.24	4.28 cts.
Material Cost:		
½-in. stone—487.5 tons at $1.30	$ 633.75	2.14 cts.
Tarvia "A"—14,307 gallons at 10c.	1,430.70	5.58
Freight, $188.35; demurrage, $32	220.35	
Soft coal for heating and operating roller	88.90	.30
	$2,373.70	8.02 cts.
Summary:		
Labor	$1,271.24	4.28 cts.
Materials	2,373.70	8.02
	$3,644.94	12.30 cts.

2.77 miles cost	$3,644.94
1 mile cost	1,300.00
1 square yard cost	12.30

This was a carpet treatment undertaken with refined tar, known as Tarvia "A." The material was shipped in tank cars to the nearest railway siding, and heated by means of a steam boiler to a temperature of 100° F. when it was forced by steam pressure into the distributing apparatus, and then hauled to the site of the work where it was attached to the steam roller. Connection was here

made with the boiler and the material further heated to a temperature of between 175° and 200° F. Steam pressure at thirty-five pounds was then applied to spray it on to the road surface. The apparatus used is supplied at the rear with nozzles so constructed that upon the application of pressure the hot material is forced to the surface of the road in a fine spray. The heated tar penetrates the top surface, and the remainder is then absorbed by means of one-half inch stone chips in the proportion of one cubic yard over about sixty-five square yards of surface giving a depth of stone and tar equal to a little over one-half inch. The quantity of bituminous material for this treatment was one-half gallon to the square yard, and as indicated the total cost including labor was 12.3c. per square yard, or about $1,300 per mile for an eighteen-foot roadway. It is estimated that the only cost of upkeep to this surface will be an annual tar spraying of about one-eighth of a gallon per square yard at a cost of between three and four cents per square yard, or about $320 per mile for an eighteen-foot roadway.

In comparison with the heavy water bound macadam resurfacing it is interesting to note the details of figures for extra heavy resurfacing with a chemical binder. The following figures show the details of cost for a Rocmac resurfacing upon the main driveway of the park where the road metal was four inches:

Rocmac Resurfacing at Rambler's Rest.

Time—May, 1913.
Location—Main driveway, opposite Rambler's Rest loop.
Length of haul—3,400 ft. = .644 mile, (from Victoria Park siding).
Area treated—Length 370 ft.; width 21 ft. = 7,760 square feet = 863 square yards.
Depth removed—4 inches.
Material removed—370 ft. x 21 ft. x 4 in. = 2,590 cubic feet = 96 cubic yards (in place).

Labor Cost:	Total.	Per sq. yd.
Removing old surface (96 cu. yds.)	$ 97.20	11.26 cts.
Hauling 144 cu. yds. of stone and screenings from Victoria Park Station	119.08	13.80
Rolling	28.00	3.25
Resurfacing	63.16	7.31
Foreman	60.20	6.97
	$367.64	42.59 cts.

Material Cost:	Total.	Per sq. yd.
2-in. stone, 114 cubic yards—136.8 tons at $1.25	$171.00	19.82 cts.
Screenings, 30 cubic yards—36 tons at $1.00	36.00	4.17
Rocmac solution, 374 gallons at 45c.	168.30	19.50
	$375.30	43.49 cts.

Summary:	Total.	Per sq. yd.
Labor	$367.64	42.59 cts.
Material	375.30	43.49
	$742.94	86.08 cts.

The American Society for Testing Materials has added to its specifications for reinforcing steel rolled from billets, an intermediate grade between the structural and hard grades. This new grade is to have a yield point of 40,000 lbs., and an ultimate tensile strength of from 70,000 to 85,000 lbs.

INSTALLATION OF TRANSFORMERS FOR TORONTO POWER COMPANY.

An installation of considerable inportance has been made recently by the Toronto Power Company in the way of six kv.a, single-phase transformers at the Niagara Falls step-up station, and six 5,500 kv.a. similar single-phase units at the Toronto terminal station of the company. This installation is of special interest in view of the fact that the new transformers were especially designed and constructed to fit the existing transformer pockets which were laid out originally for lower voltage units of less than half the present capacity. The original transformers were single-phase, water-cooled units designed for 2,670 kv.a., 60,000 volts, at the generating station and for 2,400 kv.a., 55,000 volts at the terminal station. These transformers were of the familiar oval type. The new transformers are single-phase, water-cooled units of 6,000 kv.a. unit capacity at the Niagara station, designed for 86,500 volts, and similar units of 5,500 kv.a. each at the Toronto terminal station, designed for 76,100 volts.

They were built by the Canadian General Electric Company at its Peterborough factory and are assembled in square or slightly rectangular boiler plate tanks, having all seams oxy-acetylene welded. The flat sides of the tanks are braced by "T" iron straps for mechanical stability. The transformer tanks were required to stand a 26-inch vacuum test at the factory before acceptance. The usual heavy castings have been replaced in this design by channel core plates riveted together in pairs. A space is left between the channels which is arranged to come directly over a vertical duct in the iron, allowing a free circulation of oil up through the centre of the iron. These features and others which it is understood have been adopted as standard by the manufacturers of these transformers account for the remarkable increase in capacity per unit space over the original transformers in the same stations. The same factors are reflected in the gradual tendency toward smaller dimensions and lighter weights in power transformers making use of rolled steel instead of heavy castings.

STEEL RAILROAD TIES.

Steel railroad ties are being extensively used in Switzerland. At present 65 per cent. of the Federal Railways employ them. They have the form or profile of a trough into which shape they are rolled at the mills. The ends are bent down, the profile of the trough being thus closed. Holes are provided for the attachment of the rails by means of clamp plates and no tieplates are used under the rails. The weight of the trough profile is 55.47 lbs. per meter and the ties complete, with holes bored, weigh 159.84 lbs. each. According to the requirements of the Federal Railways the steel in these ties must have a tensile strength of about 59,000 to 64,000 lbs. per square inch and an entire trough piece shall admit of being bent together on its back without showing any breaking fissures.

The Gun-crete Company, of Chicago, informs us that, taking effect September 1st, 1914, they have purchased all the rights, titles, contracts and interests of the Cement-Gun Construction Company, and have also taken over the construction department of the General Cement-Gun Company. In future, the combined business will be conducted under the firm name of Cement-Gun Construction Company, with offices at 914 So. Michigan Avenue. The officers of the company are Carl Webber, C.E., president; John V. Schaefer, M.E., secretary and treasurer; C. L. Dewey, construction manager.

LOCK GATE LIFTER FOR TRENT CANAL.

THE accompanying illustrations show the steel pontoon dock that was recently built for the Department of Railways and Canals for service on the Trent Canal, by M. Beatty and Sons, Limited, of Welland. It was designed and built to lift and place into position the lock gates, and its capacity of 50 tons and clearance of 37 feet above the dock will enable it to step

Fig. 1.—The Gate Lifter Just After Completion, Showing the Top of Derrick Raised.

any of the mitred gates throughout the entire length of the Trent Canal. The general design comprises a structural steel collapsible derrick mounted on a steel pontoon, with separate steam engines for each operation.

The pontoon supporting the derrick is made of steel plating with extra strong steel frame work, there being two longitudinal and three transverse trusses, so as to provide for the severe loads it will have to bear. The hull is constructed with rounded bilges and each end has a rake of 45 degrees. The length is 55 feet, beam 27½ feet, depth 9 feet.

The derrick is built of structural steel in two units. When in working position, the derrick is erect, as shown

Fig. 2.—Gate Lifter with Top of Derrick Lowered for Passing Under Overhead Bridges.

in Fig. 1. In transporting the lifter from one lock to another, the upper part of derrick is lowered where necessary, as per Fig. 2, which allows of its passage under overhead bridges along the canal. The operation of raising and lowering the derrick is performed by a 6 x 6-in. double cylinder engine mounted on one of the back legs. Two swivel hook padlocks are suspended, one from each overhanging top of front legs of derrick, each carrying 8 parts of ⅞-in. steel cable. The main engine has 9 x 9-in. double cylinders, double drums and is link reverse. The operating levers are brought to one position for the convenience of the engineer.

The pontoon is kept on an even keel by two movable ballast cars under deck. Each car is moved by a steel screw operated by independent 6 x 6-in. reversing engine. These engines are controlled by pendulum governors, automatically shifting the ballast to the proper position to put the pontoon on an even keel, whether it is under load or light, with the derrick upright or folded. In addition to the automatic control, the ballast car engines can be operated from the engine room above deck. Dial indicators are provided to show the position of the ballast cars at all times.

The machine has stepped to date the gates for Locks No. 1, 2, 3, 4, 5 and 6 of the Ontario-Rice Lake division of the Trent Canal and in operation has met all expectations. The total time for stepping each leaf from picking up in water to releasing in gate recess varied from twenty to forty minutes, according as an upper or lower gate

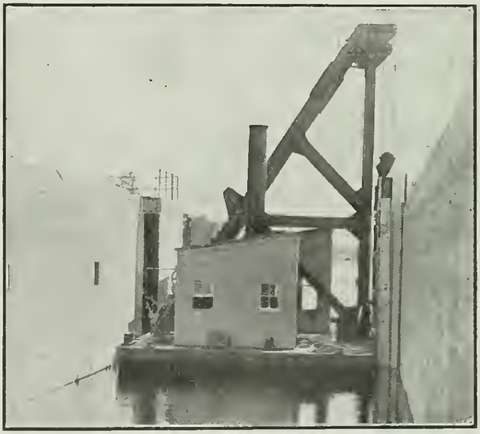


Fig. 3.—Gate Lifter Placing a Leaf in the Gate Recess of Lock No. 4, Rice Lake Division, Trent Canal.

leaf was handled respectively. At Lock No. 3 the lower gates are 37 feet high over timbers and these represent the heaviest gates the lifter is designed to handle. A view is shown in Fig. 3 of the gate lifter in the operation of stepping a gate.

SLAG IN RAILWAY BALLAST.

Slag is very largely used as railway ballast in the district of Lorraine, Germany. About 250 miles, or two-thirds of the total mileage, are ballasted more or less completely with that material. It is used chiefly on roads that have been constructed or reballasted in recent years and especially on the roads over which traffic is heavy. On smaller, less used lines where the traffic is light, gravel or whatever suitable material is at hand, is used. Slag costs about 14½ cents per cu. yd. at the furnace. It is regarded as economical ballast within a radius of 15 to 30 miles, but cannot compete with rock at a greater distance than that on account of the cost of transportation, except, of course, in places where no suitable rock ballast is to be found. It is said that the slag is far superior to gravel as ballast and that it is equal to the best variety of rock.

REINFORCED CONCRETE DOCKS IN NORTH AMERICA.

In *The Canadian Engineer* for August 27th, 1914, an article appears dealing with the application in England of reinforced concrete to dock construction. The following article supplements the former by outlining the extent of similar construction in North America, with special reference to such works in the United States. We are indebted to the same source for this information, viz., a paper by Harrison S. Taft, read before the American Society of Civil Engineers on May 20, 1914, which paper reviews the reinforced concrete dock construction of the world.

In recording what has been accomplished in the construction of reinforced concrete docks in North America, including Porto Rico, Cuba, the Canal Zone, and Canada, such undertakings are so few and of such recent date, compared with those in European countries, that the art of building reinforced concrete docks there may be said to be hardly beyond its infancy, especially as regards out-and-out docks or piers, as the American usually understands the word, viz., long structures running out from the shore in such a way that vessels can lie on each side. Unfortunately, it will be necessary to make note of some failures among North American concrete docks.

Atlantic Coast.

Boston.—The first concrete dock built in Boston Harbor has perhaps caused more discussion as to the feasibility of using concrete in sea water than any other American structure of this type, and, therefore, is far-famed in itself. This dock, or pier, was built at the Charleston Navy Yard about 14 years ago. The first section, consisting of a long, straight wall, was built in 1899-1900, without any resort to a cofferdam. The other two sections, consisting of plain reinforced arches, 20 ft. wide, with spandrel walls, were constructed in 1901, the space between the two walls being filled with earth and stone. The first section was built of 1:2:3 concrete throughout, and it was all placed in the wet, with an open-top bucket. The second and third sections were of different mixtures, the main body being of 1:3:6 concrete, the outer 2 ft. consisting of a 1:2:4 mixture, and the whole exposed surface was faced with 3 in. of 1:1 mortar. In these two sections the concrete was placed very dry, as was the practise at that time.

During 1913 one of the Boston public docks, Pier No. 5, was partly rebuilt in concrete. This dock consisted of a timber platform deck, 50 ft. wide and 1,150 ft. long, on each side of a solid earth fill. The new wooden piles needed were driven, and all the piles, new and old, were cut off at mean high water and capped with a deep reinforced concrete beam running athwart the piles, in the way of curtain-walls. These curtain-walls support two longitudinal reinforced concrete beams, the third or inner beam resting on the earth retaining wall. There are also two additional concrete beams under the track along the outer face of the dock, with special supporting piles. On top of the curtain-wall and longitudinal girders is laid a reinforced concrete floor-slab with a 2-in. bitulithic top. Wooden longitudinal tie members are run from top of pile to top of pile under the concrete curtain-walls, the whole timber structure being well braced with piles and wooden ties. To provide against accident from disintegration of the lower part of the curtain-walls, due to frost action or other cause, cast-iron columns, 30 in. long, are attached to the top of the piles and made integral with the curtain-walls, thus guarding against weakness in the concrete, rather than in the piles, as done in other harbors.

New York Harbor and New Jersey Coast.—A reinforced concrete dock of an experimental nature was constructed at Ellis Island, New York Harbor, in 1911. It is a rather small structure, 30 ft. wide and 50 ft. long, resting on thirty-six driven concrete piles 18 in. square. The piles were made of different mixtures, for experiment purposes, and various kinds of waterproofing were used in order to determine their efficiency under the same conditions. This was the first complete concrete pile and deck dock built in New York Harbor.

During the past seven years a semi-concrete type of dock has been under development in New York Harbor, viz., wooden piling, wooden caps, and concrete decking. In one dock, on the New Jersey side of the Hudson, the caps on top of the piles are also of concrete. In the final type, as worked out by the Department of Docks and Ferries,* the concrete slab rests directly on wooden caps secured to the tops of the wooden piles, a genuine flat slab between bents, the entire timber floor system being wholly eliminated. At present some 25 or 30 semi-concrete docks have been built on this system in New York Harbor. It has been stated authoritatively that they have proved a great success.

In building two semi-concrete docks at the Brooklyn Navy Yard a few years ago, the objectionable features of docks of the foregoing type—viz., part of the wooden pilings and bracing exposed to wet and dry conditions between low water and the decking, and the wooden cap as an additional temporary item helping to support a permanent structure—were eliminated. In the two Navy Yard docks the wooden piles were cut off a little above low water and capped with a wooden grillage. Pre-moulded concrete columns, mixed with waterproofing compounds, were set on and dovetailed into the caps, and a concrete girder-beam and deck-slab system was worked over the tops of the columns. The wearing surface consists of a creosoted wooden block pavement. Down each side of the dock there is a standard-gauge railroad.

A small concrete dock was constructed at Glen Cove as a yacht-landing, in the winter of 1909-10. It consists of eight reinforced concrete rock-filled caissons, supporting an overhead footbridge, the total length of the pier being about 330 ft.

Long Branch.—At Long Branch a Hennebique type of concrete pile dock was constructed in 1911, running some 848 ft. out into the Atlantic Ocean, as a boat landing and recreation pier. At present the pier is only 75 ft. wide, except for an 80-ft. length at its outer end, where its width is 150 ft., the intention being to make the whole pier of that width at some future time. The deck is 22 ft. above low water. The piles are 16 ft. from centre to centre longitudinally, but 20 ft. from centre to centre across the pier, except the outer two rows, which are 15 ft. from centre to centre. Most of the piles are of hollow cross-section, 22 in. external diameter, 13 in. internal diameter; the penetration was about 22 ft. To provide sufficient impermeability, the shells of the piles were made of $1:1\frac{1}{2}:3$ concrete, the fill being of a weaker mixture. Apparently, no cross-bracing system was used, the outer end of the pier being stiffened laterally by inclined bracing piles at regular intervals.

Atlantic City.—At Atlantic City the famous steel pier was widened and protected in 1906 by the use of concrete. The original pier was founded on steel-pipe piles resting

*Transactions, Am. Soc. C.E., Vol. LXXVII., p. 503

on cast-iron disks, a type of construction quite common during the last part of the 19th century. The pier extends out into the Atlantic Ocean a total length of 1,600 ft. In rebuilding the pier all the original metal work was encased in concrete and the pier was widened on both sides, 12-in. and 25-in. reinforced concrete piles, with enlarged footings, being used. The smaller piles were pre-moulded vertically, on a small platform, each pile at its final location. After hardening sufficiently they were lifted off their platform and jetted into place through from 8 to 14 ft. of sand. The larger piles were given a penetration of 16 ft. The lower 12 ft. of these piles were pre-moulded on a platform, a water-tight iron casing was secured to the upper end, and the whole was jetted into place. The dry caisson was then filled with concrete up to the proper level, the maximum total length of the 25-in. piles being 52 ft. In protecting the original piles, concrete shells were cast around them, with sufficient interior clearance, and the space was afterward filled with grout.

After the concrete work of this structure had been in the sea water for 6 months, the piles became coated with a sort of gelatinous matter which seemed to act as a most excellent protective coating against any deterioration. The same peculiar action has also been noticed in California.

Although not exactly a dock, it is of interest to note the concrete pile Boardwalk at Atlantic City. Not only is it necessary to guard against dry and wet conditions at such resorts, but the fine sands act like a sand-blast when driven like snow before the wind. In 1908 part of the old wooden structure was rebuilt with 16-in. concrete piles, supporting a concrete cap, and that in turn carried the wooden decking.

Baltimore.—It is perhaps at Baltimore that the most extensive reinforced concrete docks on the Atlantic seaboard have been built. Although the water in Baltimore Harbor may not have the same density of salt as in ports nearer the sea, these docks, thus far, have shown no sign of deterioration, though at times subject to frost action. Three of these piers are of a back-filled concrete bulkhead type, and are not docks resting on piles. Pier No. 4 is 978 ft. long and 220 ft. wide; Pier No. 5 is 1,245 ft. long and 200 ft. wide at the shore end, but 243 ft. wide at the water end; Pier No. 6 is 1,456 ft. long and 93 ft. wide at the shore end, but 212 ft. wide at the water end; all were built in 1908.

In general, these three docks consist of a series of oval-shaped concrete cylinders 25 ft. apart along the face of the docks, and sunk to about 25 ft. below low water. Along the face of the cylinders, and just above high water, there is a concrete-encased iron girder, tied back to a deadman some 28 ft. in the rear of each cylinder. A row of concrete sheet-piling was driven back of the girders to form a vertical retaining wall, the upper ends of the sheet-piling bearing against the girder, and the lower ends being driven into the muddy bottom. A horizontal box-girder encased in concrete runs along the upper face of the dock, supporting the outer edge of the concrete curb slab, on which are laid the paving blocks. The cylinders are tied together in certain cases by ties extending entirely across the docks. The face of each dock is protected by wooden fender-piles, 8 ft. apart. Another concrete dock has been completed recently in Baltimore by the Harbor Commission, the details of which are lacking. In the same harbor is found a concrete bulkhead dock, built for a private corporation—a reinforced concrete sheet-piling structure capped with a concrete girder tied back to deadmen by reinforced concrete ties.

At Sparrows Point, near Baltimore, a reinforced concrete ore dock, 600 ft. long, was built in 1911. It consists of two parallel concrete walls, about 46 ft. apart, viz., (1) a sheet-pile bulkhead on the water-front capped by heavy concrete girders with a cantilevered shelf, as it were, on the outer face, running the full length of the bulkhead; (2) a heavy retaining wall in the rear, the two walls being tied together by reinforced concrete ties about 30 ft. apart. The back wall, resting on wooden piles, not only acts as a deadman for the outer wall, but affords a means for carrying one track of the large, heavy, ore unloading crane that straddles the filled-in space between the two walls, the front track of the crane running along the outer wall. The dock face is protected by a substantial system of fender-piles and wales with heavy helical car-springs at each buttress of the face wall.

Norfolk.—In constructing the Virginian Railway Coaling Terminal, at Sewells Point, in 1907, it was not practical to carry the massive steel superstructure on creosoted piles. In place thereof groups of wooden piles were driven and cut off 1 ft. below the mud line. On top of these piles were built monolithic concrete piers, of pyramidal shape, to 4 ft. above high water. All the concrete work was done in the dry, inside a cofferdam. These piers are reported to be in as good condition as when first built.

Brunswick and Charleston.—Perhaps the most extensive development of concrete dock construction, combining concrete piles with wooden decking, is found at Brunswick, Ga., and at the U.S. Navy Yard, Charleston, S.C., built in 1906.

The Brunswick terminal consists of two piers, 500 and 900 ft. in length, respectively, and each is 140 ft. wide; there is also a coaling pier about 300 ft. long. The 16-in. bearing piles, of pre-moulded concrete, are 12 ft. from centre to centre each way. They are from 30 to 51 ft. in length, with the lower 10 ft. tapering to 8 in. The piles have a penetration of 40 ft. Their upper ends are corbeled out to support the double 8 by 16-in. wooden caps. The decking consists of 6 by 14-in. stringers and a 3-in. flooring. Each bent is well braced with creosoted wooden cross-bracing.

The Charleston Navy Yard dock is 60 ft. wide and 250 ft. long, and of the same type of construction as the Brunswick structures. The piles, 10 ft. from centre to centre each way, are 18 in. square, instead of 16 in. square, and have an 8-ft. taper to 12 in. square at their lower ends, thus giving a heavier structure than those at Brunswick. The test load on the Charleston dock was 30 tons per pile for 48 hours, though the specification required only 20 tons, or 400 lb. per sq. ft.

The outer row of piles in these docks consisted of three creosoted yellow pine sticks, two of which were driven on a batter; all were bolted together to afford sufficient protection to the dock in the form of a fender-pile system.

During the building of the Brunswick dock it was rammed by a large steamer. Although a number of the pine piles were broken, it has been stated that the concrete piles withstood the shock successfully.

Savannah.—A rather unique type of concrete dock was built at Savannah, 17 miles from the sea, in 1913. The design seems to contain many of the excellent features of the Ambursen dam. This dock consists of a series of pile bents athwart the dock supporting reinforced concrete brackets of triangular shape, the brackets in turn supporting a concrete deck-slab sloping down and toward the rear of the structure. This deck was afterward back-

filled and finished off with a suitable working face. The dock forms a water-front structure, and is protected by wooden fender-piles.

Jacksonville.—In the construction of a semi-concrete dock at Jacksonville, the Braxten concrete pile was used, with very satisfactory results. In another case the Ripley concrete-encased wooden pile was adopted.

Key West.—A reinforced concrete quay wall dock, 1,589 ft. long, was completed at the U.S. Navy Yard at Key West in 1912. The main wall consists of a series of pre-moulded concrete pile bents capped by a concrete girder and a deck-slab 40 ft. wide on top. From the inner edge of the deck-slab a sloping concrete apron runs down to the top of a row of sheet-piles which forms a retaining wall for the reclaimed land. The piles are from 16½ to 20 in. square, and vary from 25 to 60 ft. in length. The bents are 10 ft. apart, with the same spacing for the piles, each bent having six piles. The face of the dock is protected by a system of creosoted fender-piles placed midway between each bent.

Port Arthur.—A reinforced concrete pile-bent dock, 1,050 ft. long and 25 ft. wide, was constructed at Port Arthur, Tex., in 1911-12. In general, the piles are 16 in. square, 44 ft. long, and 5½ ft. from centre to centre. The pile bents, of five piles each, are about 23 ft. apart, and are capped with a reinforced concrete girder. Five concrete beams, running from bent to bent, and a 4½-in. concrete slab, form the deck structure. The dock is tied back to the concrete trestle built for carrying the railroad tracks in the rear of the dock. No provision is made for any spring or other device to take up the impact forces on the fender system, as it is believed that the wooden fender-piles will afford sufficient elasticity to prevent any injury to the dock from this source.

Cuba.—Two reinforced concrete docks, 620 and 670 ft. in length, respectively, and 160 ft. wide, were built in 1911-12 at Havana, the depth of the water varying from 12 to 40 ft. Each consists of a concrete floor-slab resting directly on concrete caps placed on top of clusters of from four to eighteen reinforced concrete piles, the clusters being about 23 ft. from centre to centre in each direction. The concrete piles, 18 and 20 in. square, were designed for a load of 32 tons each. The design of the floor slab would indicate a cantilever effect longitudinally between each row of longitudinal piling.

One of the railroad companies of Cuba, also, has built a reinforced concrete dock at Havana, for coaling purposes. The structure, which is subjected to very heavy loading, rests on Chenoweth concrete piling, and was but recently finished.

Haiti.—In constructing a reinforced concrete dock at Port au Prince, during 1913, the Ripley type of concrete wrapped wooden pile was adopted. This dock has a total length of 2,326 ft., varying in width from 24 to 60 ft. The piles are 10 ft. from centre to centre, longitudinally and transversely, and are capped by heavy concrete girders of rectangular section for the inshore end of the dock, otherwise by arched girders. The deck system consists of a series of reinforced concrete beams supporting the concrete deck-slab, built with a crown, in order to shed water. The dock is protected by a creosoted fender-pile system.

Panama and Canal Zone.—The United Fruit Company in 1909 built a combined reinforced concrete and wooden pile dock at Bocas del Toro, for the docking of fairly large steamers. The wooden piling is surrounded by a 4-in. concrete shell up to about 1 ft. above the high-water line. The piles are extended up to the deck as reinforced columns, with a concrete beam and deck-slab system. Up to the present time the dock is said to have given good results.

In the Canal Zone the U.S. Army Engineers have constructed a reinforced concrete dock, 706 ft. long and 55 ft. wide, for unloading timber. There are fifty-five concrete piers or columns, 8 ft. in diameter and about 80 ft. long arranged in two rows, 35 ft. from centre to centre across the dock, and 30 ft. from centre to centre longitudinally, and built in the form of hollow reinforced concrete sectional cylinders. After these cylinders had been sunk to bed-rock, they were filled with concrete, being reinforced vertically with eight rails. On top of the columns there is a concrete girder, deck-beam, slab system. The girders are about 5½ ft. deep, the beams about 4½ ft. deep, and the slab 6 in. thick. The railroad track runs over one row of columns. The floor system is designed for a load of 400 lb. per sq. ft., with a concentrated load of 105 tons over the track beams. The depth of water for a mean sea-level tide is 40 ft., the total fluctuation in the tide being 20 ft.

Two other concrete docks of extensive size are now in course of construction in the Canal Zone, with still more to follow.

Pacific Coast.

On the long stretch of our Pacific Coast, perhaps is found the greatest development of reinforced concrete dock construction in the United States. This section is making vast harbor improvements in anticipation of the opening of the Panama Canal.

San Diego.—At this most southern port on the California Coast an extensive reinforced concrete dock is now under construction. It consists of two parts, viz., the dock itself, 800 ft. long and 130 ft. wide, and a quay wall or bulkhead, 2,675 ft. long and 25 ft. wide. Wooden piles are driven into the soil and cut off "at any point between mean and low water and 18 ft. below city datum." Each of the 42-in. concrete columns encases one wooden pile and supports a system of structural deck-beams, a concrete slab covering the whole. The columns are 15 and 13 ft. 4 in. from centre to centre. The entire structure is protected by a wooden fender-pile system having the so-called San Francisco type of steel spring shock-absorbers.

San Pedro.—In connection with extensive port developments at San Pedro, a semi-reinforced concrete dock was recently completed in the outer harbor. It consists of pre-moulded concrete piles, 10 ft. from centre to centre in each bent, the bents being 16 ft. apart. The tops of these piles are corbeled out to support two 10 by 16-in. wooden caps, which in turn support the wooden floor joist and wooden decking. The piles are tied together with a wooden cross-bracing system above mean high tide. The structure is also stiffened against lateral blows on its face by inclined bracing piles. The wooden pile fender system has a car-spring to assist in taking up lateral forces. The dock is of the quay type, 48 ft. 6 in. in width, the total pier head frontage being 12,000 lin. ft. A railroad runs parallel to the inner edge on the inshore fill.

Redondo.—It is of interest to take note of the ocean pier at Redondo, Cal., though it is not a dock. It extends some 637 ft. out into the Pacific Ocean, and supports the intake pipe (for cooling purposes) of a power station. The pier consists of concrete pile bents, 20 ft. apart, each bent having four piles. As considerable surf runs at times under this pier, the outer bents have an extra outside pile driven with a batter of 2 in. per ft. The piles consist of a thin steel shell, 18 in. in diameter, closed at the lower end. After the steel cylinder had been driven to the

proper depth of penetration, the reinforcement was inserted and the cylinder was filled with concrete. The piles of each bent have a structural steel cap encased in concrete, with a system of diagonal bracing in a horizontal plane connecting the tops; there is also a longitudinal system of ties at the tops of the piles, above the reach of the water. This structure, as a whole, is said to possess considerable elasticity.

Long Beach, Cal.—In 1907 a concrete pile pier was built at Long Beach, extending some 1,300 ft. out into the ocean. The head of the pier is 100 ft. long and 300 ft. wide, the approach being 1,299 ft. long and 32 ft. wide. The deck is 30 ft. above mean low water, so as to be kept clear of the 24-ft. waves which at times roll in from the ocean. The piles and columns are 4½ ft. in diameter, and are arranged in bents. Under the head of the pier the bents and piles are 16 ft. from centre to centre. The approach bents are 20 ft. apart, with two columns each. The columns are sunk from 10 to 18 ft. into the sand, in order to be absolutely safe, as it is said that at times the undertow digs out the sand to a depth of 13 ft. The pile caps consist of steel I-beams, on top of which rest wooden stringers carrying a wooden decking.

Santa Monica.—At Santa Monica, an ocean pier, built in 1908-09, extends 1,600 ft. out into the ocean. It was built on driven concrete piling, ranging from 14 to 22 in. in diameter, in lengths up to 75 ft., with from 16 to 20 ft. penetration. Although the pier was built primarily to support the outfall sewer carrying the sewage effluent to a point far seaward, it is also used for recreation purposes. The pier is about 35 ft. wide at the deck line, with three platform spaces of 43 by 89 ft. at intermediate points and at the end. The bents are 20 ft. from centre to centre and consist of three piles, the piles being 13 ft. 6 in. from centre to centre. Each bent has a concrete cap on which rest the wooden joists covered with 2-in. planking, and the latter is covered with a 3-in. wire-mesh concrete slab, having the proper pitch to carry off the water. The bents are tied together by three longitudinal reinforced concrete tie-beams running from top of pile to top of pile. The piles are bulb-pointed.

San Francisco Bay.—Although the dock engineers of New York City have developed a type of semi-reinforced concrete dock, viz., a wooden pile structure supporting a concrete slab, especially adaptable to local conditions, the dock engineers of San Francisco have developed a type of full reinforced concrete dock based on wooden sub-piling, concrete column piers, steel or concrete deck-beams, and concrete floor slab, the concrete encasing the steel beams and the floor being made monolithic, with details varying to suit special conditions. Although the type as worked out presents no difficulty in the way of construction, outside of building the main columns, that part of the work has been done successfully, but with considerable difficulty. The mud line at the bottom of the bay is said to be approximately level, yet, at the outer ends of some of the piers there is a depth of only about 18 in. of mud over the rock; at the shore end, however, there is a depth of 35 ft. of mud. Piles can be driven to a rock bearing in some places, but it is impossible to use wooden piles throughout. Along a portion of the waterfront, where it is not possible to reach the rock, there is a hard soil capable of bearing from 4 to 6 tons per sq. ft., thus doing away with the necessity of any sub-piling.

The method used in building the column piers is to sink a hollow steel caisson, of such length that it will not be overtopped by the water, dredge out the interior to the desired depth, and build the reinforced column in the dry. In some cases the columns rest on solid rock, in others, wooden piles have to be driven inside the cylinders to obtain the necessary bearing support. The size of the columns varies according to conditions. In two docks built in 1910, 140 ft. wide and 780 ft. long, where the mud covering the rock was less than 50 ft., the columns were seated directly on the rock. Where the mud is more than 50 ft. deep the columns rest on five 15-in. wooden piles driven to refusal, the piles being cut off 35 ft. below the water line and encased by the concrete columns to that height. The columns are 6 ft. in diameter to a height of 7 ft., and then 3½ ft. to the top.

In laying out a vast dock improvement proposition at Fort Mason, San Francisco, the government has planned for the immediate construction of three docks of the usual San Francisco type, each to be 500 ft. long, two 81 ft. wide, the third 118 ft. wide. The concrete columns are to be supported by groups of seven wooden piles driven in a circle 6½ ft. in diameter, and 18½ ft. from centre to centre each way. The piers are to be 8 ft. in diameter up to 12 ft. above the dredge line, and are then to be reduced to a diameter of 4 ft. for the remainder of their length. The wooden piles will extend some 11 ft. up into the concrete columns, the bottom of the concrete being well below the mud line. In building the first of these docks, an attempt was made to construct the column forms of 4-in. staves, sufficiently reinforced with bands, and sink them into position by driving. The method did not prove a success, and resort was made to the steel cylinder caisson method, as described previously.

Up to 1911 there were only four modern reinforced concrete column docks under the control of the San Francisco port authorities. Since that time they have added largely to the number by replacing some of the older wooden pile docks with reinforced concrete structures. The first addition was Pier No. 17, 800 ft. long and 126 ft. wide, with suitable railroad track accommodations. It consists of wooden piles protected by concrete shells, the deck-beams being of structural steel encased in concrete, and the stringers and decking are of timber—a sort of semi-concrete pile semi-concrete dock.

The next docks reconstructed were Piers Nos. 26, 28, 30, and 32, all of the same type, having reinforced concrete columns resting on the hard bottom, without any piling, with a complete system of reinforced concrete deck-beams, girders, and slabs. These docks are equipped with up-to-date cargo-handling machinery.

The net addition was Pier No. 39, 150 ft. wide, this being in process of construction at the present time. The concrete columns rest on groups of from 4 to 10 wooden piles, the entire deck system being of reinforced concrete.

In another type of construction at San Francisco the wooden piles are wrapped with wire fabric, or otherwise, and a concrete shell is placed around them after the piles have been driven to place. This method, apparently, has proved successful, though it must be carried on in such a way that the concrete can be poured, set, and hardened in the dry, and not in sea water, if permanent results are to be obtained.

Recently, the City of Oakland, Cal., built a genuine reinforced concrete pile dock, 295 ft. long and 124 ft. wide, standing in 30 ft. of water. The piles are of premoulded concrete, 16 in. in diameter, octagonal, and of a 1 : 1½ : 3 mixture for a distance of 5 ft. from the top, the remainder of the pile being of a 1 : 2 : 4 mixture. The bents and piles are approximately 10 ft. apart. Each row of piles has a concrete cap or girder running athwart the dock, the deck-beams and deck-slab being also of con-

crete. For lateral stiffness, 12-in. concrete curtain-walls were built at three points in the dock, for about one-third of its width, between the piles in three bents.

Portland.—Being 112 miles from the ocean, on a fresh-water river, it is possible to use wooden piling at Portland, in the construction of docks. A massive concrete dock terminal, now being built by the city, consists of four concrete warehouses along the water-front. The dock part of this project as designed consists of a reinforced concrete platform, 1,030 ft. long and 100 ft. wide, 32 ft. above low water, resting on wooden piles driven in groups and cut off at about mean low water. Resting on each group of wooden piles, 20 ft. from centre to centre, are the reinforced columns supporting the upper platform, composed of steel I-beams encased in concrete, and a concrete floor-slab. For a length of 300 ft., a low-level deck, 14 ft. below the main deck, is provided. As the Columbia River is subjected to high- and low-water stages, due to floods, it was necessary to provide this lower platform for use by river steamers during low-water periods. The rise and fall of the Columbia River attains a maximum of about 28 ft., though 18 ft. is about the average, all based on mean low-water level. Thus the lower platform will seldom be under water.

Puget Sound.—Though there are several large shipping ports on Puget Sound, up to the present time, no reinforced concrete dock construction of a commercial nature has been undertaken in these waters. As lumber is so plentiful in that part of the country, it is only natural that such a section should be one of the last shipping centres to take up the building of reinforced concrete docks; but as the destructive teredo is very active there, the engineers of the Northwest are beginning to seek a more stable type of construction than creosoted wooden pile docks, especially the United States and Canadian governments, and some of the railroads, because "in government (and publicly owned) docks, a small saving in first cost is of minor importance, but weakness and frequent need of repairs are well nigh intolerable. On the other hand, in private ownership of docks a saving in first cost is usually of serious importance, while the cost of maintenance, repairs, etc., is met by earnings of the dock and is less felt," unless they become so excessive as to make a concrete proposition more economical in the long run.

At the U.S. Navy Yard in Bremerton, Wash., a reinforced concrete dock, consisting of concrete columns, steel and concrete beams, and a concrete slab, was completed in 1912. It is 402 ft. long and 60 ft. wide. The columns are 3 ft. in diameter, with a flared-out footing to a diameter of 6 ft., 16 ft. from centre to centre, each way, there being four columns to each bent. The caps and girders over the tops of the columns are of I-beams encased in concrete. A concrete beam is run midway longitudinally between each of the four steel beams. The I-beam caps are cantilevered out 6 ft. on each side of the dock. The columns were built as hollow concrete cylinders with a 3-in. shell of 1 : 2 mortar, and filled with a 1 : 2 : 4 concrete after being sunk to place. As hollow cylinders, they avoided any coffer-dam work. The dock has a standard railroad track down each side over the outside columns, also an ordinary wooden fender system.

A still heavier concrete dock is now in course of construction at the same Navy Yard. It is 490 ft. long, 80 ft. wide, and is designed for a load of 600 lb. per sq. ft. The approach of the dock consists of a wooden pile structure, 210 ft. long, of triangular shape. As designed, the structure is supported by sixty-eight concrete columns, 4 ft. in diameter, with an 11-ft. base (of the same type as in the dock just mentioned), 20 ft. from centre to centre athwart the dock, and 30 ft. longitudinally. The columns are capped by extremely heavy reinforced concrete beams which support a series of built-up structural beams, about 36 in. deep, carrying a thick concrete floor-slab. The side of the dock is cantilevered out 8 ft. beyond the columns. A standard railroad track runs over the centre line of the outside rows of columns on each side of the dock. On account of the nature of the soil, some of the piers rest on sub-piling, others, nearer the shore, on hardpan.*

Vancouver.—The Great Northern Railroad has very recently completed an extensive reinforced concrete dock of the quay type, in connection with a new terminal it is building at Vancouver. The total width of the terminal dock is 302 ft., the concrete dock proper being 456 ft. long, and 50 ft. wide on each side of the terminal, the space between being a rock and earth fill, with a proper rip-rapped slope at its faces. Each concrete dock structure consists of nineteen reinforced concrete columns, 4½ ft. in diameter, 25 ft. from centre to centre, parallel to the face of the dock, resting on the rock stratum that underlies the location of the terminal. These columns support a heavy longitudinal concrete girder into which are tied heavy cross-girders, 12½ ft. apart. The cross-girders are cantilevered out beyond the longitudinal girder about 16½ ft., and their inboard ends rest on two driven concrete piles 34 ft. back from the centre of the columns. Four concrete beams of suitable size are run longitudinally with the dock. The entire girder and beam structure supports a concrete slab. The railroad track is over the longitudinal girder running from column to column. The two parts of the dock are tied together by suitable concrete beams running across the interior fill. The terminal is considered to be one of the most substantial and up-to-date structures on the Pacific Coast. The dock is well protected by a wooden fender-pile steel-spring system.

Great Lakes.

Although extensive use of concrete has been made in some of the ports of Lakes Superior, Michigan, Huron, Erie, and Ontario, in the construction of massive ore-docks, it is not proposed to discuss that particular phase of the subject in this paper. These docks are of excellent design, some built on concrete piling, others on wooden piling or cribs. Concrete piles in fresh water are not subject to the same deterioration as those in salt water. On the other hand, they have to withstand extremes of temperature, frost and ice, in addition to severe treatment, due to the heavy traveling machinery above them.

Some of these docks will be discussed, in order to bring out the important features of their special design.

Chicago.—One of the first attempts at using concrete for dock work on the Great Lakes was made at South Chicago, in the winter of 1898-99, in the rebuilding of an old wooden quay dock wall. The concrete structure is 1,680 ft. long, and consists of a heavy mass concrete stepped-back wall, 10½ ft. high, 8 ft. wide on top, and 18 ft. on the bottom, supported by a timber structure consisting of three rows of piling cut off 3½ ft. below mean water level, with longitudinal caps crossed by a heavy wooden grillage. A timber sheet-piling bulkhead under the face of the wall acts as a retainer for the slag fill. On one occasion the wall was rammed by a large steamer, but suffered absolutely no damage. The damage to the steamer, however, was rather extensive. A year or so later, a similar quay dock wall, 2,300 ft. long, was constructed at the same steel plant.

*In the actual construction the built-up structural beams were replaced by reinforced concrete.

Due to the decay of a long wooden water-front bulkhead on the Chicago River, it became necessary to replace it. This was done by constructing a reinforced sheet-pile bulkhead almost ½ mile in length, capped by an I-shaped concrete beam, some 3 ft. wide and 5 ft. high. This beam rests on pre-moulded piles, which are 20 ft. apart and are secured to buttresses, also 20 ft. apart, which run back about 12 ft. from the sheet-piling, the land ends of the buttresses being supported by other piles. The buttresses are also tied back to deadmen some 35 ft. back from the wall. As the bulkhead has about 18 ft. of water along its front, vessels can dock alongside.

Marquette.—The most extensive reinforced concrete ore-loading docks on the Great Lakes are without doubt at Marquette, Mich., and were built in 1912. The substructure consists of a heavy concrete slab and facing-walls, similar to a channel beam placed on its back, 1,500 ft. long and 60 ft. wide, resting on wooden piling. Under the face of the walls there is a wooden sheet-piling bulkhead which retains the sand fill around the piles under the dock structure. The depth of the concrete web is 3 ft., the walls that correspond to the flanges being 9 ft. high. The substructure supports a very massive reinforced concrete superstructure for loading ore into vessels, the whole dock being a very substantial and shock-resisting structure. A steel plate is worked along the face of the two concrete walls from 6 in. below the water level to 3 ft. above it, to prevent disintegration of the concrete due to frost and ice action at the water level.

Two Harbors.—At Two Harbors there is an ore-loading dock consisting of a steel superstructure supported by a mass concrete wall running along each face of the dock, and tied together with concrete beams at regular intervals. The concrete walls rest on wooden piles with a wooden sheet-piling bulkhead to retain the interior fill. The substructure is 1,400 ft. long and 52 ft. wide.

Detroit.—The concrete ore-loading dock at Detroit is 200 ft. long. It consists of three bearing walls of a T-rail shape, 9 ft. deep, running parallel to each other, the two outer walls being 28 ft. apart, the third or back wall being 173 ft. from the middle wall. The three walls rest on a double row of oak piling cut off 3 in. above the water level. Being capped by the concrete walls, no part of the wooden piling is exposed to the air. The outer wall stands in about 10 ft. of water, the middle wall in 3 ft., and the rear wall is far back on the dry land. The two outer walls are tied together by reinforced concrete beams, 5 ft. deep, at intervals of 10 ft., with cantilevered brackets on the water face of the outer wall opposite the tie-beams. The concrete deck-slab on top of the brackets is 12 in. thick, but only 6 in. thick between the two outer walls. The dock has a suitable wooden fender-pile system.

Between the middle and back walls there is a 12-in. reinforced concrete floor-slab, supported on a series of piles, 5 ft. from centre to centre each way, stated to have been designed for a load of 6,800 lb. per sq. ft., or 85 tons per pile. The ore floor is tied into the middle and back bearing walls opposite each cross-beam in the dock proper. The three walls support an ore bridge tower, used for unloading ore from vessels to cars on the track just behind the middle wall, or into the ore bin between the middle and back walls.

Toledo.—At Toledo, Ohio, there is an ore-unloading dock, consisting of a plain concrete wall running along the water-front, resting on wooden piles, and tied back to deadmen some 100 ft. in the rear. The land is reclaimed back to the middle wall, a row of sheet-piling under the river wall retaining the earth in place. Parallel to the river there are three other walls to support the legs of the ore-unloading bridges which run on tracks placed on all four walls, spanning the four car tracks and the ore piles. The distance from the front wall to the inmost land wall is 419 ft.

Cleveland.—There is a full reinforced concrete ore-unloading dock at Cleveland, Ohio, completed in 1912 by the Pennsylvania Railroad. It consists of a reinforced concrete water-front wall, 985 ft. long, supported by a double row of pre-moulded concrete piles. The face wall is tied back by reinforced concrete tie-beams to another reinforced concrete wall supported by three rows of concrete piles about 81½ ft. in the rear. The tie-beams are 30 ft. apart, and rest on concrete piles 6 ft. apart. The space between the two walls, that is, under the concrete tie-beams, is back-filled with rip-rap, the whole mass being pumped full of sand. A concrete sheet-piling bulkhead under the front wall retains the fill in place. The dock has the usual wooden fender-pile protection. The tracks for four 17-ton Hewitt unloading machines run along the inner and outer walls. So far as the writer has been able to discover, this was the first concrete pile dock built on the Great Lakes.

Another ore-unloading dock at Cleveland consists of a reinforced wall of the same type as that at Detroit, the two structures having been designed by the same engineers. The cantilevered face of this wall is supported by brackets at intervals of 15 ft., with rear buttresses opposite them. The buttresses rest on a concrete base slab, the rear edge of which rests on a row of wooden sheet-piling, the base-slab evidently being monolithic with the rest of the wall. The space between the sheet-piling and the wooden piles that support the concrete wall (11 ft.) is filled with slag. In general, the cross-section of the wall is dumb-bell shaped.

General.—In discussing the ore docks of the Great Lakes, it is necessary to consider the special and peculiar conditions under which they are operated, as they are designed to meet these conditions, and not vice versâ. The larger portion of the freight carried on the Great Lakes is of heavy bulk form, viz., ore and grain on the downward trip, coal on the upward trip. Thus ore and coal cargoes form the two heaviest items handled in bulk masses at the terminals. Nowhere in the world is found such massive and modern machinery for the economical and expeditious handling of bulk freight as at the upper and lower ports of the Great Lakes. Consequently, such docks, wooden or otherwise, must not be judged by the type used along the seaboard of the Atlantic, the Gulf, or the Pacific.

It appears that the various types of reinforced concrete docks as worked out by the American engineers are far more numerous than in foreign practice, as is evident from the foregoing descriptions. Although the Atlantic Coast engineers seem to favor pre-moulded concrete piles, the Pacific Coast engineers apparently favor large concrete columns. Perhaps in time a typical American concrete dock will be designed or devised, as in the case of the long-standing type of wooden pile dock structures.

In the foregoing review of American reinforced concrete docks, an effort has been made to include each and every port wherein such types of docks exist, as well as to mention each and every dock already built, so far as the writer has been able to acquire sufficient information concerning them, in order that the exact situation as regards the development of reinforced concrete dock construction in America up to the present time may be known to all.

ROGER'S PASS TUNNEL CONSTRUCTION.

NOTABLE progress has been made by the Canadian Pacific Railway Company on the construction of its double-track tunnel, 26,400 feet in length, through Mt. Macdonald of the Selkirk Range. The following information, together with the illustrations, show that there has been great activity since the establishment of plant and actual commencement of operations.

The elimination of the loops referred to means a reduction of the summit of the line from 4,330 ft. to 3,791 ft., and a reduction of the distance between certain points on the line of from 23 miles to 18 miles. Further, the length of maximum grades upon the present line is 22.15 miles, whereas the length of maximum grade on the proposed line will be only 6.61 miles.

The preliminary work included a large amount of excavation and fill in order to obtain grade for entering the

Enormity of Roger's Pass Tunnel Scheme as Viewed from One of the Portals.

Readers of *The Canadian Engineer* are referred to our issue of April 23, 1914, for a general description of the undertaking and also for a detailed outline of the plan adopted by the contractors for its successful carrying out. The tunnel, it will be remembered, is to enable the Canadian Pacific Railway to dispense with its "loops," together with many miles of snow sheds, to reduce the distance from valley to valley, to effect an enormous grade reduction, to obviate the use of "pusher" engines over the long section of main line, and, in short, to eliminate the use of one of the most costly sections, from a railway operating point of view, to be found on the continent.

tunnel at the western portal. At the present time this work, with the exception of a small portion, has been completed. Another preliminary undertaking, and one that had some very novel features connected with it, was the deviation of the Illecillewait River so as to utilize its old bed for an approach. A trench nearly a mile in length was excavated and the river now takes a new course in front of the spot chosen for the entrance of the tunnel, while lower down the valley a culvert was constructed to return it to its original course. A similar task was necessary in the Beaver Valley on the eastern slope.

As stated in the article previously referred to, the method of tunneling includes the driving of a "pioneer" shaft. This is a heading 7 x 9 ft. in cross-section, which is being driven 45 ft. from the centre line of the main tunnel, but with 10 ft. greater elevation. The main line of the tunnel will then be worked from cross-cuts. This is a new method of tunnel projection which is being tried out by the contractors to expedite operations. The pioneer bore, when completed, will be an entirely separate tunnel paralleling the course of the main passage through the mountains. The activities of drillers can thereby be concentrated at many different points simultaneously.

handfuls between the stoping and its use has been pronounced exceedingly satisfactory. The excavation is being effected by steam shovel, which will be used until rock has been encountered. The 600 men at present at work on the tunnel are accommodated in two camps, one at each portal.

The work commenced in June and is to be completed by December, 1916. It is under the direction of Mr. J. G. Sullivan, Chief Engineer for Western Canada of the Canadian Pacific Railway. The contractors are Messrs. Foley, Welch and Stewart, of Seattle, Wash. The estimated cost of the scheme, with related improvements in

Roger's Pass Tunnel, Selkirk Mountains, B.C., Present Terminal Stations and Constructional Views.

The course of the pioneer bore on the west side of Mt. Macdonald is in a downward direction, beginning several hundred feet above the cutting. It descends on a 50% grade for the first 300 ft., after which it proceeds horizontally. Since last April, when it was stated in these columns that over 1,100 ft. of the pioneer tunnel had been driven from the eastern portal, over 2,000 ft. more has been projected, while practically 1,000 ft. of the main tunnel has also been driven from the eastern portal. On the west side the bores for the main tunnel are not advanced to such a stage, but are well under way, and three cross-cuts have been driven.

An interesting feature of the boring operations in the soft material at the western entrance of the main tunnel is the use of hay to arrest the flow of loose earth and water as the excavation proceeds. The hay is placed in the way of electrification of the tunnel portion of it and double tracking, exceeds $10,000,000.

At the Foundry and Machine Exhibit held in Chicago, September 5 to 11, the Wernicke Hatcher Pump Co., Grand Rapids, Mich., displayed in operation a new compact type of air compressor. It has a balanced rotary movement giving positive displacement, and works up to 100 lbs. or more in a single stage. This is obtained with unusually efficient cooling and low-power consumption; while the rotary principle means a steady flow of air uniform running and low-starting torque. It also permits direct connection to a high-speed electric motor, with ready control at all speeds up to maximum. The machine is portable and requires neither a heavy foundation nor piping.

HARRISBURG FILTER CASE.

In *The Canadian Engineer* for September 18, 1913, a review was given of a decision handed down by the United States Circuit Court of the Middle District of Pennsylvania in connection with the "negative-head" patent case between the New York Continental Jewell Filtration Company and the City of Harrisburg, Pa.

The case, which has been on trial since 1908, has just been the recipient of another decision, this one from the United States Circuit Court of Appeals of the Third Circuit. It was handed down on September 15th, 1914, and reverses the decision of the Lower Court.

In view of the attention which the long trial has occasioned, the following notes respecting the new decision may be of further interest.

The opinion starts with a brief statement of the claims of the patents in suit and follows with a general discussion of the principles of filtration and the state of the art. A very extended review of the language of the various patents referred to in the suit is then given, followed by a discussion of the principles of suction as applied to this case.

The court points out various patents which were cited by the city as anticipations of the patents in suit and reviews in this connection several instances of prior use claimed by the city, and proceeds then to a discussion of the scientific principles involved in the patents in suit and the theories of the patents as disclosed by the evidence. The judge writing the opinion gives the impression that the plaintiff company has not proved its case in this regard, and cites the testimony of several witnesses on both sides which apparently created in the court's mind a doubt about the matter, but the judge expressly refrains from making any decision on these matters. This is clearly indicated in the summing up of all this discussion in the following words:

"However, it is probably enough to say that (at the best) the evidence in behalf of the company leaves us in much uncertainty whether the theories of the patents are sound. We do not feel bound to go the length of declaring the patents invalid—the re-issue patent, indeed, has already expired, leaving the patentee only a claim for royalties—but we are prepared to say that while the subject is so surrounded by uncertainty the company cannot reasonably object to the application of a test that tries the Harrisburg filters by the theories of the patents."

The court specifically declines to state that the patents in suit are not valid, or that the scientific principles and theories upon which the plaintiff company based its claims are incorrect.

But in reviewing the testimony of what actually happened at Harrisburg, the court decides that that was not sufficient to create an infringement, concluding with the following words:

"In our opinion, therefore, the case may safely be decided by finding upon the evidence that the city has not infringed either patent."

In brief, it appears that this decision, while reversing the decision of the Lower Court as to Harrisburg, does not decide that the theories of the court below were wrong with respect to the basic principles upon which that court decided the case, and leaves open the entire question as to validity of the patents.

It is reported that probably one of the largest contracts ever secured by Chilean manufacturers was recorded on July 6, when the Government placed a home order for railway equipment to the value of $8,240,000.

SOME TUNNELING COSTS.

(Continued from last week's issue.)

Marshall-Russell Tunnel.

Location: Empire, Colo.

Purpose: Mine drainage, development and transportation.

Cross-section: Rectangular.

Size: 8 feet wide by 9 feet high.

Length: 11,000 feet projected; 6,700 feet driven January 1, 1913.

Character of rock penetrated: Granite and gneiss.

Type of power: Purchased electric current; also a small auxiliary hydraulic plant.

Ventilator: Fan.

Size of ventilating pipe: 12 and 13 inches.

Drills: 2, pneumatic hammer.

Mounting of drills: Vertical columns.

Number of holes per round: 18 to 20.

Average depth of round: 9 to 10 feet.

Number of drillers and helpers per shift: 2 drillers and 2 helpers.

Number of drill shifts per day: 1.

Explosive: 40 per cent. gelatine dynamite; with some, 80 per cent.

Number of muckers per shift: 4.

Number of mucking shifts per day: 1.

Type of haulage: Horses.

Wages: Drillers $4, helpers $3, blacksmiths $4, helpers $3, muckers $3.25, trammers $3.75, dumpmen $3.25, power engineer $3.50, shooters $3.25.

Maximum progress for any calendar month: 187 feet, June, 1909.

Average monthly progress: 125.

Cost of Driving Tunnel 6,700 Feet.

	Cost per foot of tunnel.
Labor	$ 9.37
Powder, fuse, caps and blacksmith coal	3.35
Drills, steel and repairs (less 30 per cent. salvage)	1.34
Power	1.41
Permanent equipment and general expense (less 30 per cent. salvage on permanent equipment)	3.41
	$18.88

Mission Tunnel.

Location: Santa Barbara, Cal.

Purpose: Water supply.

Cross-section: Trapezoid.

Size: 6 feet wide at the base, 4½ feet wide at the top, 7 feet high.

Length: 19,560 feet.

Character of rock penetrated: Shale, slate and hard sandstone.

Ventilator: Pressure blower.

Size of ventilating pipe: 10 inches.

Drills: 1 pneumatic hammer.

Mounting of drills: Horizontal bar.

Number of holes per round: 12 to 14.

Average depth of round: 7 to 8 feet.

Number of drillers and helpers per shift: 1.

Number of drilling shifts per day: 3.

Explosive: 40 per cent. and 60 per cent. gelatine dynamite.

Number of muckers per shift: 4.

Number of mucking shifts per day: 3.

Type of haulage: Electric.

Wages: Drillers $3.50, helpers $3, muckers $2.75, blacksmiths $4, helper $3, motormen $2.75, dumpmen $2.50, power engineers $2.75.

Maximum progress in any calendar month: 414 feet, February, 1911.

Average monthly progress: 210 feet.

Cost of Driving the South Portal, Mission Tunnel, 5,515 Feet.

	Cost per foot of tunnel.
Administration	$ 1.14
Labor	9.20
Power	2.12
Explosives	1.97
Timbering (563 feet)	.30
Track and pipe	1.22
Miscellaneous supplies	2.46
Drill parts (including steel)	1.02
Bonus	.48
	$19.91

"Administration" includes superintendence, office supplies and general charges. "Miscellaneous supplies" includes candles, light globes, shovels, picks, blacksmiths' supplies and fuel and machinists' supplies.

NEWHOUSE TUNNEL.

Location: Idaho Springs, Colo.

Purpose: Drainage and transportation.

Location: Idaho Springs, Colo.

Purpose: Drainage and transportation.

Cross-section: Square.

Size: 8 by 8 feet.

Length: 22,000 feet.

Character of rock penetrated: Idaho Springs gneiss.

Type of power: Purchased electric current.

Ventilator: Pressure blower.

Size of ventilating pipe: 18 inches.

Drills: Pneumatic hammer.

Mounting of drills: Vertical column.

Number of holes per round: 14 to 22.

Number of drill shifts per day: 1 and 2.

Explosive: 40 per cent. gelatine dynamite, with some 100 per cent. in the cut holes.

Number of muckers per shift: 3.

Number of mucking shifts per day: 1 to 2.

Type of haulage: Electric.

Wages: Drillers $4 to $4.50, helpers $3.25 to $4, muckers $3.50, motormen $3.50, dumpmen $3, blacksmiths $3.50 to $4.50, helpers $3.

Cost of Driving the Newhouse Tunnel.

	Jan. to Aug. 1909, 2,233 feet.	Sept. to Dec. 1909, 1,098 feet.	April to Aug. 1910, 693 feet.
Labor	$ 6.72	$ 6.98	$11.73
Explosives	4.15	3.52	4.57
Fuse and caps	.39	.36	.44
Transport'n of materials broken	1.49	1.47	2.22
Power	1.99	2.16	2.82
Blacksmithing	1.57	2.61	2.00
Use of drills, repairs and steel..	1.50	2.74	2.86
Equipment, ties, rails, pipe, etc.	1.74	1.78	2.19
Sundries	.79	.80	1.85
	$20.34	$22.42	$30.68

RAWLEY TUNNEL.

Location: Bonanza, Colo.

Purpose: Mine drainage and development.

Cross-section: Trapezoidal.

Size: 8 feet wide at the base, 7 feet wide at the top, 7 feet high.

Length: 6,235 feet.

Character of rock penetrated: Tough, hard andesite.

Type of power: Steam with wood for fuel.

Ventilator: Pressure blower.

Size of ventilating pipe: 12 and 13 inches.

Drills: 2 pneumatic hammer.

Mounting of drills: Horizontal bar.

Number of holes per round: 23 to 25.

Average depth of round: 8 to 9 feet at first, 5 to 6 feet later.

Number of drillers and helpers per shift: 2 drillers and 2 helpers.

Number of drill shifts per day: 2 at first, 3 later.

Explosive: 40 per cent. and 60 per cent. gelatine dynamite (in the proportion of about 2 to 1).

Number of muckers per shift: 4.

Number of mucking shifts per day: 2 and 3.

Type of haulage: Horses and mules.

Wages: Drillers $4.50, helpers $3.75, muckers $3.50, blacksmiths $4.50, drivers $3.50, power engineers $4.

Maximum progress in any calendar month: 585 feet, July, 1912.

Average monthly progress: Approximately 350 feet.

Cost of Driving the Tunnel 6,235 Feet.

	Cost per foot of tunnel.
Drilling and firing	$ 5.25
Mucking	2.16
Tramming	1.13
Track and pipe	.44
Miscellaneous underground expenses	1.44
Power plant	2.50
Blacksmithing	.73
Miscellaneous surface work	.83
General expenses	1.98
Permanent plant	3.24
Timbering (1,618 feet)	1.18
Boarding house, debit balance	.04
	$20.98
Credit by salvage on permanent plant	1.11
	$19.87

ROOSEVELT TUNNEL.

Location: Cripple Creek, Colo.

Purpose: Mine drainage.

Cross-section: Rectangular, with large ditch at the side.

Size: 10 feet wide by 6 feet high.

Length: 15,700 feet.

Character of rock penetrated: Pikes Peak granite, chiefly.

Type of power: Purchased electric current.

Ventilator: Pressure blower.

Size of ventilating pipe: 16 and 17 inches.

Drills: 3 pneumatic hammer.

Mounting of drills: Horizontal bar.

Number of holes per round: 24, usually.

Average depth of round: 6 to 7 feet.

Number of drillers and helpers per shift: 3 drillers, 2 helpers.

Number of drill shifts per day: 3.

Explosive: 40 per cent., 60 per cent., and some 100 per cent. gelatine dynamite.

Number of muckers per shift: 4, usually.

Number of mucking shifts per day: 3.

Type of haulage: Horses and mules.

Wages: Drillers $5, helpers $4, muckers $3.50, power engineer $4, blacksmith $5, helper $3.50, dumpman $3.50, drivers, inside, $5, outside, $4.

Maximum progress in any calendar month: 435 feet, portal heading, January, 1909.

Average monthly progress: Portal heading, 300 feet; shaft headings, 270 feet; all headings, 285 feet.

Cost of Driving Tunnel.

Total cost of portal work	$111,980.06
Contractor's percentage	11,404.88
Cost of shaft headings	262,126.55
Total cost of tunnel	$386,421.49
Number of feet driven	14,167
Average cost per foot	$27.27

Cost of Driving the Portal Heading.

	Feet.	Cost per foot.
1908—February and March	514	$22.690
April	262	30.970

	$30.636

(To be continued.)

Preparations have been completed by the Quebec Government to open new districts to the lumber and pulp industries. During August and September, limits in the Abitibi and Lake St. John districts were auctioned off. In the Lake St. John region, the territory to be opened is north of the lake and in the basin of the Mistassini and Rat Rivers. In the Abitibi district, it is situated south of the Transcontinental, but on the north slope in the basin which empties into James' Bay. This tract is traversed by the Poisson Blanc, Harricana and Bella Rivers. Both limits have been carefully surveyed by the forestry service.

Editorial

AVOIDING THE MUNICIPAL BREAD-LINE.

Directly in line with what we have been endeavoring to impress upon public bodies throughout the Dominion in the matter of undertaking works such that will provide employment to those whose need of it is to be anticipated, it is worthy of note that the Toronto Hydro-Electric Commission has sought special permission to borrow $2,000,000 for extension work to be carried out this fall and winter. It is reported also that the town of Orillia has made arrangements with the Ontario Government for the clearing of a large tract of bush land during the winter by the unemployed, it being anticipated that the work will be sufficient to provide all the employment required in that town. It is also notable that the Toronto City Council has agreed to the Hamilton-Toronto highway proposal, commented upon in our issue of September 24th, thereby authorizing the expenditure of Toronto's share, $150,000, toward the enterprise.

Such undertakings as these are admirable at this period when so much depends upon the projection of work that will reduce as low as possible the numbers of unemployed that will accumulate in our towns and cities as winter sets in. The Lord Mayor of London recently expressed a feeling that is prevalent at this time not only in England but throughout the Empire's Dominions: "If we can go forward as far as possible," he said, "with our building, manufacturing and other enterprises, limiting unemployment and preserving wages, we shall be doing a very patriotic work." Even in England, whose connection with the European combat is incomparably closer than our own, the enlargement of enterprises of local authorities and other public bodies is going on apace. On the suggestion of the Local Government Board of England, most of the corporations and district councils in the country have already begun to prepare and carry out important schemes of engineering in order that during the coming winter full employment may be found for every workman, and any men thrown out of work from other industries may be kept fully employed. Special facilities for the immediate execution of such schemes are being afforded by loans and by grants from the Local Government and Road boards. Manufacturers of plant and materials for municipalities are acting upon the wise counsel to prepare well in advance for the demands which the above activities will make upon them. It is also to be remembered that the British Parliament has passed the Housing Act providing £4,000,000 for the erection of laborers' cottages. Moreover, H.M. Office of Works has decided to proceed with all services in its charge, to employ as many men as possible in the carrying out of such services, and to develop and expedite its building program in every practicable way. Optimism prevails throughout Great Britain that private individuals, companies, firms and contractors will spare no effort to follow the policy of the government in this matter.

The provision of employment is a subject which should be more seriously considered by our municipal councils. Every town or city has works of some light and unimportant nature that have been persistently overlooked and sidetracked for the sake of more important undertakings. There may be small matters of grading or diversion within the corporation, cleaning of water mains and sewerage systems, or any one of a number of odd jobs which have long awaited attention and which may well be taken up at this time. There is, for instance, always a greater or less need for more activity in the matter of street and property cleaning. Clean-up weeks have produced very beneficial results in a few cities at home and many abroad. A widespread activity throughout the Dominion would mean much toward the health and picturesqueness of communities. Besides, the cleaning up of our streets and alleys and the straightening up of our parks and playgrounds, if completed this fall, will have a decided effect upon the health and appearance of our cities when the snow takes its departure in the spring. There is always the possibility of work going ahead with such a rush at the opening of the season as to necessitate the shelving, once again, of such jobs as these, with undesirable result. Every small amount of work of this nature afforded by our municipalities is going to make better citizens, prevent long bread-lines, and display a true spirit of patriotism.

LIEUT.-COL. HON. JOHN STRATHEARN HENDRIE.

The appointment of Lieut.-Col. Hon. J. S. Hendrie, M.P.P., C.V.O., to succeed Sir John Gibson as Lieutenant-Governor of Ontario, is one that has come to pass during the past few days. Those who are familiar with Col. Hendrie's devoted service as a member of the Hydro-Electric Power Commission of Ontario, and with his connection with the Hamilton Bridge Works Company, now as president, and for many years as general manager, know him to be an engineer with high technical attainments and business qualifications. It is conceded that it will be difficult to fill his place so adequately upon the Commission, but undoubtedly the service which he will render to the province in his new office will be most creditable, both to himself and to the choice of man for the high position he has undertaken to fill.

RUBBER-PAVED ROADS.

It is not yet practicable to construct roads with surfaces of rubber except at a cost of $25 per super yard. But there is little doubt that they will ultimately be adopted. At the International Rubber Exhibition held in London last July, rubber paving was shown both for use on footways and on carriageways which attracted a considerable amount of attention. In each case the rubber constituted a surface cushion on blocks of jarrah wood, the material being held tightly in position by dovetailing, while a special joint locked the paving, preventing, when laid, the access of water to the concrete foundations. It is contended that thinner foundations are necessary owing to the reduced amount of vibration which occurs by heavy and fast-moving traffic, and further, that it never becomes slippery and that motor vehicles do not "skid" upon it under unfavorable conditions of weather. A section of rubber paving has been laid in the Old Kent Road, Lon-

don, for nearly 12 months where the traffic is heavy, amounting to 90 tons per square foot per hour for 24 hours, and is not perceptibly worn.

Another section of road is about to be laid in Cannon Street in the heart of the City of London, the corporation having granted the necessary permission to the acting agent of the Federated Malay States Government in order that its advantages can be better observed by all interested in the new development.

ROAD OIL SPECIFICATIONS AND TESTS.

IN the California Highway Bulletin for July, 1914, Mr. Clarence B. Osborne, Geologist to the California Highway Commission, presents the following specifications for and results of tests of asphaltic oil for road building. He states that in the preparation of such specifications the engineer has three problems presented: (1) He must have requirements controlling the chemical purity of the oil, i.e., he desires an oil that is free from foreign material and products of decomposition produced during refining. (2) He must control the chemical composition of the oil. (3) He must control the physical properties of an oil so that it will actually perform its proper function in the road construction.

Specifications for chemical purity of road oil are as follows:

(1) It shall not contain more than one-half of one per cent. of sediment by volume.

The presence of even ten times this amount of sediment is not detrimental, as the oil in use on the road eventually carries as high as 90% of mineral aggregate. This specification is used to prevent the buying of sediment at the price of road oil.

(2) It shall not contain more than one per cent. of water by volume.

The presence of water in a road oil makes the oil difficult to handle when heated above 212° F., because the steam formed makes the oil boil or froth. Also, as in the case of sediment, unless the proper deduction is made water will be paid for at the price of road oil.

(3) It must, when freed from water, be soluble to at least ninety-nine and five-tenths per cent. (99.5%) in pure carbon disulphide.

This will give the per cent. of bitumen in the road oil.

(4) The bitumen soluble in carbon disulphide must be soluble in carbon tetrachloride to the extent of at least ninety-nine per cent. (99.0%).

The failure to pass this specification is supposed to be an indication of an overheated or "cracked" oil. Carbon tetrachloride is not a stable solvent in bright light and the solubility test is influenced if the test is performed in bright light.

Another specification sometimes used to determine a "cracked" oil is as follows:

(5) In CS_2 bromide solution. The bitumen soluble in carbon disulphide must be soluble to the extent of at least ninety-nine and eighty-five one hundredths per cent. (99.85%) in a solution of one hundred and thirty-five (135.0) milligrams of bromine to one hundred (100.0) cubic centimeters of the carbon disulphide, when twenty-five (25.0) cubic centimeters of the solution are poured on two (2.0) grams of the oil in an Erlenmeyer flask, which is then shaken in the dark for three (3.0) minutes, the solution being immediately filtered through a Gooch crucible using a suction equal to a column of mercury more than eight (8.0) inches high.

When the solution has all passed through the crucible, the crucible is washed with pure carbon disulphide, dried at from two hundred and twelve (212.0) to two hundred and twenty degrees Fahrenheit and weighed.

This test had its origin in the examination of vegetable and animal fats. The unsaturated fatty acids form insoluble bromides. This bromide carbon disulphide solvent is not stable, however. An oil having an excess of 0.15% of insoluble material would fail to pass this specification, and yet this failure might be due entirely to the unstable solvent.

The specifications to govern the different constituents that make up the bitumen of the road oil are partly included in the specifications numbered (3), (4) and (5).

The road oils are generally classified as to their asphalt content. This asphalt is not a definite chemical compound determined by chemical analysis. To determine the asphaltic content, the road oil is hardened by heating it in an asphalt oven at a high temperature. Part of the light or volatile oils, is driven off in this heating and the residue is hardened. The degree of hardness is measured by the depth of penetration of a No. 2 needle when acting under a load of 100 grams for five seconds, the residue being maintained at 77° F. If the needle penetrates 8 mm. in this test the residue, called asphalt, is said to be asphalt of 80 penetration. As can readily be seen, this residue may contain many different bitumens. The test is not a measure of a definite chemical compound.

If the assayer for copper should call all the metal extracted "copper" when the metal was of a certain hardness, then it can readily be seen that any alloy of soft and hard metals that made this certain hardness would be classified as copper. This is the practical result of the specification for a road oil when it is required to contain a certain percentage of asphaltum.

The early oil-bound macadam roads built with asphaltic oils usually required an oil containing 70 to 75% of asphalt of 80 penetration. This oil was not heavy, that is, it lacked body (*i.e.*, low viscosity), and it was a weak binder but it was easily applied to the road surface.

The use of pressure tank wagons with sprayers for applying heated road oil has made it possible to use an oil of much higher asphalt content and of higher viscosity. The road oil that is now commonly demanded for oil-bound macadam, or for bituminous-covered concrete highways, is one that contains 90% of 80 penetration asphalt. The following specifications are suggested for such an oil:

(6) It shall contain 90 per cent. of 80 penetration asphalt.

This per cent. of asphalt is determined by heating 20 grams of the road oil in a 2-oz. salve tin in a standard asphalt oven, the temperature of the oven being maintained at 400° F. When the asphaltic residue has a penetration of 80, the oil shall not have lost in excess of 10% by weight.

The asphaltic content is the classification of the oil refineries of their different grades of road oil. The specification is of value more on this account than for any information of practical value furnished to the road builder.

(7) It shall show an open flash point not less than 350 degrees Fahrenheit.

This requirement prevents the use of an oil carrying very volatile constituents that would readily evaporate and might also be dangerously combustible at the time

the oil was being sprayed on the road at the high temperature necessary for spraying.

The physical properties of a road oil are of the greatest importance to the road builder. The following specifications deal directly with the measurement of the important physical properties:

(8) It shall show a float test of not over 1,000 seconds when tested at 90 degrees Fahrenheit. This test is described in Bulletin No. 38 issued by the Office of Public Roads, United States Department of Agriculture.

This float test is the measurement of the viscosity of a road oil. The requirement will prevent the use of excessively viscous road oil, one that is difficult to apply and is slow to absorb the mineral aggregate necessary to the building up of the proper wearing surface.

(9) The oil shall show a specific viscosity of not more than one hundred (100) when tested with the Engler viscosimeter at a temperature of two hundred and twelve (212) degrees Fahrenheit.

This test will prevent the use of an oil that is too viscous to be readily applied to the road surface from the oil-spraying wagon.

(10) It shall show an adhesive test of not less than 300 seconds for three revolutions with the Osborne adhesive machines, when the oil is tested at a temperature of 77 degrees Fahrenheit, the load being 3 kilograms.

This test is the measure of the oil's power to prevent relative motion of two concentric cylinders which the oil acts as a binder between the surfaces of the two cylinders. The inner cylinder is 1.995 in. in diameter, the outer cylinder is 2 in. in diameter, the outer cylinder being in the form of a loose collar 2 in. wide. Its inner surface is coated with the oil to be tested. The outer surface of the inner cylinder is coated with oil and the collar then forced on the inner cylinder, which is maintained in a stationary position.

The outer collar is wound with cord to which a three-kilogram weight is attached; the pull of this weight causes the collar to revolve; the thin film of road oil between the two cylinder surfaces offers a resistance to this turning. The temperature of the oil being tested is maintained at 77° F. by means of water circulating in the inner cylinder. The measurement of the adhesive value of the oil is the length of time required for three complete revolutions of the collar.

Oils containing the same percentage of asphaltum will often show the greatest difference in their binding properties. Oils possessing the same viscosity will likewise often show a wide difference in adhesiveness.

As an example, one oil may be largely made up of heavy lubricating grease, another may be very free from lubricating material but they may both flow through a given-sized orifice at the same rate, when heated to the same temperature, that is, they have the same viscosity. The lubricating oil would lack binding power and be unsatisfactory for road construction; the other would be desirable. The adhesive specification would prevent the use of the unsatisfactory lubricating oil.

The asphalt contained in a road oil is required by some road builders to possess a certain ductility.

(11) The ductility of the asphalt which has been reduced to a penetration between 75 and 85 shall not be less than 110 centimeters.

This test is made with asphalt maintained at 77° F. and the pulling shall be at the rate of 5 cm. per minute, using the Dow ductility machine.

There is a woeful lack of uniform specifications for road oil and uniform methods of performing the tests. In the determination of the asphaltic content of an oil, the temperature for the asphalt oven is specified sometimes at 325° F., and from that to as high as 500° F.

The dish containing the road oil during the reduction is in some laboratories as small as a thimble, and in others, large enough to hold 500 grams; sometimes cylindrical, and others times semispherical in shape. Some tests require the use of an oven, others require heating in the open air. As has been shown, the "asphaltic content of an oil" is, at best, a rather indefinite term, and when we have added to this the different methods used and the wide range of equipment used, the "asphaltic content" becomes even more of a vague description.

The asphaltic road oils are, for the most part, a by-product of the oil refineries. They are a relatively cheap material. This cheapness saves the road oils from being adulterated with other material. It is expensive to add anything to the oil. The natural oil itself rarely carries undesirable material. The tests for water and sediment will take care of foreign materials brought in by the crude oil.

Some road engineers have regarded oil containing sulphur as dangerous to use because the sulphur is supposed to make the product unstable. Many oils and asphalts carrying sulphur have given good service for long periods of time and if sulphur does tend to make the oil unstable, this action is too slow to be of importance in the life of the oil used in the road construction.

MANY EUROPEAN NATIONS TO BE REPRESENTED AT PANAMA EXPOSITION.

In answer to numerous inquiries, President Charles C. Moore of the Panama-Pacific International Exposition, to open in San Francisco on February 20, 1915, has issued the following statement:

"One month ago, the decision of the Panama-Pacific International Exposition management not to postpone was first published. At the time the decision was made no word had been received from any foreign nation as to the effect on its plans caused by the European war, but it was hoped that at least those nations not fighting would go on with their plans. Later developments have proven that hope well founded; in addition, we have definite assurances from France, from Italy, from Turkey and from Japan that their intentions are unchanged. Holland has added $300,000 to her original appropriation. Italy has ordered work on her building and exhibits rushed. Japan has asked for and received an increase of space. The Argentine Republic has increased its appropriation from $1,250,000 to $1,750,000.

"We shall undoubtedly lose some of the promised exhibits from Europe, but not by any means all of them and not by any means the most important of them. Both Germany and Great Britain will be represented by individual exhibitors or by associations thereof.

Another evidence of the growing demand for American steel for South America was shown when orders were received at Pittsburg, Pa., for 100 miles of 80-pound steel rails. The order is the largest that has reached Pittsburg rail mills since the trend of the business to this country from South America began. The contract was placed with the United States Steel Products Company, the export department of the United States Steel Corporation.

Coast to Coast

Edmonton, Alta.—The 3-story structure being erected by the Bank of British North America has been completed at a cost in all of approximately $160,000.

Collingwood, Ont.—The corner-stone of the new Federal building, which is being erected at Collingwood by the Dominion Department of Public Works, was laid on September 10th.

Hamilton, Ont.—Much satisfaction is being expressed by citizens of Hamilton with the work being done on new civic roadways this year under the supervision of Mr. Eugene Whitley, assistant city engineer.

Regina, Sask.—The operation returns of the Regina Street Railway Department for the week ending September 5th showed a revenue of $3,322.60; while for the week ending August 29th, the revenue shown was $3,378.05.

Oakville, Ont.—Repairs to the piers at Oakville harbor are in progress. The wall has been raised at the east side, the floor has been levelled, and new sleepers have been installed. When the east pier has been fully repaired, the west pier will also receive attention.

Saskatoon, Sask.—The Dominion Interior Elevator at Saskatoon was to be ready for operations about 15th September. The structure is considered to be one of the finest pieces of construction of the kind on the American continent. The capacity of the present initial unit is 5,000,000 bushels, and its cost is about two million dollars.

Windsor, Ont.—On September 12th, Sir Adam Beck, chairman of the Ontario Hydro-Electric Commission, performed the inauguratory function of releasing to public service in the entire business section and many of the principal residential districts of Windsor electric light and power generated at Niagara Falls, 250 miles from the former city.

Winnipeg, Man.—During August the steam and electric pumps at Winnipeg handled 328,697,210 gallons of water as compared with 342,426,000 gallons in the corresponding month of 1913, a decrease of 13,545,390 gallons. The rate per 24 hours for August this year was 10,603,135 gallons, as compared with 11,040,083 gallons in 1913, a daily decrease for August this year of 436,948 gallons.

Fort William, Ont.—The financial report of the utilities of Fort William for the first six months of 1914 shows a total profit on the operation of all utilities of $20,954.34. Water shows a surplus of $5,463.97 above maintenance and fixed charges, the revenue being $47,653.44; light, a surplus of $14,245.55, and revenue of $59,912.80; and telephone, surplus, $1,244.82, revenue $31,565.16.

Regina, Sask.—A recent report made by the superintendent of the Regina street railway department to the utilities committee of the city council showed that expenses on that department are being steadily curtailed. Receipts for this year compared favorably with corresponding periods of 1913; and the operating expenses showed a decrease over last year, current figures being 92.9 per cent. as against 115.7 per cent. in 1913.

Regina, Sask.—A report upon the work being done by the provincial public works department on a large reinforced concrete culvert near Clark's Crossing, announces that this work is well under way and will be completed within a few days. Announcement is also made that the concrete bridge and dam being undertaken by the department near McTaggart E. 3-10-15 w. 2 are now under way and will be carried to completion.

Peterborough, Ont.—Work to proceed and be completed at Peterborough this autumn includes street paving and sewer construction, and the reconstruction by the G.T.R. of 50 miles of roadbed between Lindsay and Hastings. Moreover, it is understood that the Utilities Commission has under contemplation the extension of its mains, and that the Peterborough Radial Railway Company is prepared to rebuild immediately a portion of its Charlotte street line if the city will decide to pave the same section at the same time.

Fort William, Ont.—The depression caused by the outbreak of the war at Fort William was of short duration. About two weeks ago work was recommenced with a rush by the three transcontinental roads which make that city their lake terminus. The C.P.R., C.N.R., and G.T.P. doubled their rolling stock and equipment to provide for the shipping of grain into the city; and it is expected that this state of affairs will last well on into the winter, since rail shipments to west St. John this year will doubtless be the heaviest in history.

Victoria, B.C.—The tunnel at Macaulay point for the Northwest sewer at Victoria has been pierced after over 5 months' work, and is the first of 4 to be completed on this project. A second, that at Gore street, will be finished in about six or seven weeks, as there is only another 180 feet to complete. The other tunnels will not be finished this year. About 450 feet of the 1,800 feet in the Sunnyside tunnel has been pierced; while the other long tunnel of 2,700 feet will not be finished till the new year. The tunnel between Thomas and Robert streets, which is now opened, will be cleaned up and finished shortly, and the sewer pipe will be laid.

Regina, Sask.—Considerable work has been undertaken by the board of highway commissioners in Saskatchewan, arrangements having been made for an expenditure of $500,000 in road and bridge work. At the beginning of the current month, 150 road gangs, with crews of from 15 to 20 men each, and using 10 to 12 teams, commenced work. According to the recent statement of F. J. Robinson, chairman of the commission, these numbers will be considerably increased, since the commission is operating with the municipalities, using municipal equipment, and in general is seeking to turn municipal organization everywhere to the very best advantage.

Dunnville, Ont.—Satisfactory progress is reported at Dunnville on the Erie and Ontario Railway. The right-of-way for this road is 75 feet wide, and the grading now being done is 31 feet from one side, so that if later on the road is double-tracked the two tracks will be in the centre of the right-of-way. The grading is for single track, and the work is being advanced from 3 points,—Smithville, Attercliffe, and Dunnville. The switch from the Michigan Central to the Erie and Ontario has been graded; and the rails are laid on it for the greater part of the distance. Revised tenders for the stations and freight sheds were received recently, and it is expected that the contracts for these will soon be let.

London, Ont.—The major portion of the work on the London breakwater provides for a 3-foot by 2-foot concrete base toe line and a 26-foot natural slope front of embankment faced with reinforced concrete 11 inches thick at the base and 7 inches thick on the top of the slope, where provision is made for a substantial concrete cap and a 5-foot sidewalk with guard tubular iron railing. Short lengths of vertical retaining walls will be necessary at the Oxford and Blackfriars bridge ends of the breakwater. The proposition is to provide for a top area of embankment, giving provision for a driveway, and utilizing existing conditions without disturbing trees or making excessive filling necessary in fixing face line of embankment. The estimated expenditure, as authorized, is $25,000.

Empress, Alta.—The construction of the large bridge which the C.P.R. company is erecting across the Saskatchewan river 6 miles east of Empress is nearing completion. All of the 36 massive piers have been completed. The contract for the steel work on the structure is held by the Canada Bridge Company, and the steel material is arriving at the site. The company commenced work however, on August 31st; and it is expected that the bridge will be entirely complete by October 15th, and that the new C.P.R. line will be connected from Swift Current to Bassano. The ballasting of the line is nearly completed to the bridge, both from the east and west, and it is expected that a train service will be established at an early date the full length of the new line.

Montreal, Que.—A recent important announcement from the headquarters of the G.T.P. system is to the effect that a through passenger and freight service would be put in operation the third week of September between Fort William, Ont., and Price Rupert, the Pacific terminus of the line. The line from the head of the Great Lakes at Fort William to Winnipeg and Edmonton has been in operation for some time. Trains have also been operated westward from Edmonton to Prince George, a distance of 486 miles, and from Prince Rupert eastward to Priestly, a distance of 335 miles. A gap of 131 miles between Priestly and St. George remained unfinished. The laying of the steel was actually completed in April last; but aiming at absolute safety and efficiency, the opening of the system was delayed until the present time.

Fenelon Falls, Ont.—The new dam which has been under construction by the Dominion Government just below Fenelon Falls, and has been supervised by Mr. Alex. Spence and erected by Messrs. McPhee and Kehoe, of Brechin, is now almost complete, and will soon take the place of the old wooden structure which has served at that point for many years. The length of the new dam is 325 feet between the abutments; and consists of 12 large piers, with grooves in either side, for holding the stop-logs. A platform runs from end to end above the sluices connecting the piers; and both platform and piers are built entirely of reinforced concrete. On the platform a track is laid for the purpose of conveying the machinery necessary for adjusting the stop-logs. In the construction of the dam about 2,000 barrels of cement and 2,500 cubic yards of gravel were used. Altogether $47,000 has been granted for the work by the Government; but with the improvements on the original plans and other necessary expenditures above the estimates the total cost will doubtless be $55,000.

PERSONAL.

Lieut.-Col. Hon. J. S. HENDRIE, of Hamilton, has been appointed Lieutenant-Governor of the Province of Ontario, succeeding Sir John Gibson.

R. M. MILAN, of Saskatoon, has been appointed electrical superintendent of the Dominion Government interior storage elevator at Moose Jaw. He will have charge of both installation and operation.

DR. G. G. NASMITH, director of the civic laboratories at Toronto, Ont., has been appointed advisory officer on sanitation to the Canadian expeditionary force, and is leaving Valcartier this week with the first contingent.

BOARD OF HEALTH APPROVES.

During the week ending Sept. 19th the Provincial Board of Health of Ontario approved of the waterworks extensions for the town of Smith's Falls, and of the construction of sewers in Smith's Falls and York Township.

W. H. ELLIS, M.A., M.B., ACTING DEAN OF ENGINEERING, UNIVERSITY OF TORONTO.

The Faculty of Applied Science and Engineering of the University of Toronto resumes activities this week under the direction of William Hodgson Ellis, M.A., M.B., as acting Dean, thereby temporarily filling the vacancy occasioned by the death of Dr. John Galbraith on July 22nd.. Dr. Ellis' appointment to the head of the faculty council comes after a maximum period of connection with the institution, which, until 1906, had been known, since its organization in 1878, as the School of Practical Science. In fact, in the earlier seventies he was a member of the staff of the College of

W. Hodgson Ellis, M.A., M.B.

Technology, the prototype of the institution. In 1878 he became assistant to the Professor of Chemistry, Dr. H. H. Croft. Later, he assumed the professorship in Applied Chemistry.

VICTORIA BRANCH, CANADIAN SOCIETY CIVIL ENGINEERS.

The Victoria branch of the Canadian Society of Civil Engineers recommenced its activities by a meeting on Sept. 17th. Committees were appointed and a program for the season's work discussed. On Sept. 19th the members of the Branch paid a visit to the works of the Pacific Lock Joint Pipe Company at Cooper's Cove, where pipe is being manufactured for the Sooke Lake water supply system.

BURRARD TUNNEL AND BRIDGE COMPANY.

At the annual meeting of the Burrard Tunnel and Bridge Company, of Vancouver, held early last month, officers of the previous year were re-elected. The standing committees are also the same as last year. The company was formed to undertake the construction of the Second Narrows Bridge across Burrard Inlet for details respecting this work the reader is referred to *The Canadian Engineer*, August 27th, 1914, issue. The board of directors of the company is as follows: President, Mr. F. Carter Cotton; vice-president, Reeve May, North Vancouver, and Messrs. Woodside, Loutet, Bridgeman and Vance, with the mayors of Vancouver city and North Vancouver, and the reeves of North Vancouver municipality and West Vancouver, members ex-officio.

CANADIAN GAS ASSOCIATION.

Last week the 7th annual convention of the Canadian Gas Association was held in Ottawa, about 150 representatives of gas plants throughout the Dominion being present. The following officers were elected for the ensuing year: President, H. E. Mann, Chief Engineer, Montreal Light, Heat and Power Company; first vice-president, R. A. Wallace, Manager Quebec Railway, Light, Heat and Power Company; second vice-president, J. M. H. Young, Manager London Gas Company. Executive Committee— A. A. Dion, General Superintendent Ottawa Gas Company; Arthur Hewitt, General manager Consumers' Gas Company, Toronto; Mayor Samuel Carter, Guelph; J. P. King, Manager Stratford Gas Company.

The next convention will be held in Montreal.

C.G.E. CORPS OF ENGINEERS.

In our issue of last week mention was made of the corps of engineers established by the Canadian General Electric Company for service at Quebec, Halifax and Esquimalt. We are able in this issue to reproduce from a photograph taken prior to their departure. Reading from the left, they are:—

Back Row, Standing—H. S. Elliott, Charles Stewart, C. Pink, W. J. Swanger, F. G. Jackson, H. Williams, E. S. Shill.

Front Row, Standing—Capt. Ritchie, A. T. McLean, W. S. Johnson, J. S. Dunlop, G. Hillier, C. Henry, George Monaghan, A. Hardie, J. C. Munro, C. C. Rous.

Front Row, Seated—P. Foster, E. Crockford, H. S. McKean, A. J. Palmer, R. W. Nurse, H. Calvin, R. Lethune, H. Bestard.

COMING MEETINGS.

MOTOR TRUCK CLUB OF AMERICA.—Annual Convention, Detroit, Mich., October 7th to 9th. President, George H. Duck, New York City.

GULF AND INTEROCEAN NATIONAL HIGHWAY ASSOCIATION.—October 8th, 9th, 10th; conference to be held at New Orleans, La. Secretary, Jno. B. Kent, Lake Charles, La.

INTERNATIONAL ASSOCIATION OF FIRE ENGINEERS.—Annual Convention, Grunewald Hotel, New Orleans, La. October 20th to 23rd. Secretary, Mr. McFall, Roanoke, Va.

ALABAMA GOOD ROADS ASSOCIATION.—Nineteenth Annual Convention will be held from October 21st to 23rd at Montgomery, Ala. Secretary, J. A. Rountree, 1021 Brown Marx Building, Birmingham, Ala.

NORTHWESTERN ROAD CONGRESS.—Annual Convention, to be held at Milwaukee, Wis., October 28th to 31st. Secretary, J. P. Keenan, Milwaukee.

AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—Charles Carroll Brown, Secretary, Indianapolis, Ind. Meets at Somerset Hotel, Boston, Mass., October 21st, 22nd and 23rd.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

WASHINGTON STATE GOOD ROADS ASSOCIATION.—Convention to be held at Spokane, Wash., November 18th, 19th, and 20th. Secretary, M. D. Lechey, Alaska Building, Seattle, Wash.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

The Robert W. Hunt and Company, Limited, has removed its Vancouver, B.C., office and cement and physical testing laboratories from the Bank of Ottawa Building to the Standard Bank Building, 508 Hastings Street West.

Volume 27. Toronto, October 8, 1914 Contents of this issue on page 3

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

POWER DEVELOPMENT AT WASDELL'S FALLS, ONT.

A LOW-HEAD PLANT OF EXTREMELY INTERESTING DESIGN—INITIAL UNDERTAKING OF THE HYDRO-ELECTRIC POWER COMMISSION OF ONTARIO IN THE FIELD OF POWER PRODUCTION.

THE approaching completion of the plant at Wasdell's Falls will mark the beginning of a new epoch in the history of the Ontario Hydro-Electric Commission, meaning as it does the entry of the Commission into the field of actual power production at cost as an adjunct to the policy of cost price transmission and distribution heretofore pursued.

The result of this expansion of policy in the present instance will be that connected consumers will derive the utmost economic benefit which can result from the development of a water-power.

The development project arose out of the necessity of meeting requests from a number of municipalities on the east shore of Lake Simcoe to be supplied with power through the Commission, investigation having indicated conclusively that the Wasdell's Falls site was the only source of power from which the present and immediate future needs of this district could be adequately supplied. Following the receipt of signed contracts from five of the municipalities involved, covering the supply of about 625 h.p., plans and specifications were prepared and authority to proceed with the work was obtained from the Provincial Government.

Natural Conditions.—Wasdell's Falls is located on the Severn River, about three miles below the outlet of Lake Couchiching. Owing to backwater effects the natural head was subject to considerable variation throughout the year, ranging from about six feet at extreme high water to ten feet at low water. It was determined, however, that with the forebay levels which would result from development, the head under the worst anticipated backwater conditions would never be less than 9 feet. Similarly the maximum head was determined to be 15 feet. Apart from the low head, the topographical conditions at Wasdell's Falls are most favorable for development, and the solid granite formation on which the works are founded has nowhere developed serious faults or fissures.

The drainage area of the Severn River above Wasdell's Falls is about 2,075 square miles. About 700 square miles of this area is included in the basin of the Black River, which joins the Severn about midway between Wasdell's Falls and Lake Couchiching, while the remaining 1,375 square miles of watershed is practically all tributary to the immense storage basin of Lake Simcoe, 297 square miles in extent.

Fig. 1 (left) View of Wasdell's Falls Power House, Showing High-tension Line Outlets. Fig. 2 (right) View Showing Dam.

The maximum discharge of the Severn River at Wasdell's Falls, as so far determined by gauge records and discharge measurements, is 9,050 sec.-ft., which is equivalent to a run-off of 4.36 sec.-ft. per square mile of watershed. The minimum flow, 260 sec.-ft., is equivalent to a run-off of .13 sec.-ft. per square mile, and the average flow for 1913, 2,489 sec.-ft., corresponds to a mean annual run-off of 1.2 sec.-ft. per square mile.

Other figures relative to the flow characteristics of the river are shown in the following table:

Table I.—Monthly Discharge of Severn River at Wasdell's Falls for 1913.

Month	Discharge in second-feet Maximum	Discharge in second-feet Minimum	Discharge in second-feet Mean	Discharge in second-feet Per square mile Maximum	Per square mile Minimum	Per square mile Mean	Run-off Depth in inches on drainage area
Jan. ..	4,840	1,840	2,419	2.33	.89	1.17	1.30
Feb. ..	3,120	2,050	2,432	1.51	.99	1.17	1.26
Mar. .	8,785	1,640	4,231	4.24	.79	2.04	2.42
Apr. ..	9,050	5,600	7,790	4.36	2.70	3.76	4.20
May ..	5,525	3,375	4,175	2.66	1.63	2.01	2.32
June ..	3,375	2,225	2,680	1.63	1.07	1.29	1.44
July ..	2,200	1,175	1,644	1.06	.57	.79	.91
Aug. ..	1,075	800	937	.52	.39	.45	.52
Sept.. .	1,025	700	815	.49	.34	.39	.43
Oct. ..	875	260	570	.42	.13	.27	.31
Nov. ..	1,475	450	897	.71	.21	.43	.50
Dec. ..	1,505	905	1,276	.73	.44	.62	.73
Total..	9,050	260	2,489	4.36	.13	1.19	16.43

It may be mentioned that some doubt attaches to the figures for minimum flow as shown in Table 1. owing to the extremely low velocities which obtained at the metering station during periods of very low water. The actual minimum discharge is doubtless somewhat greater than indicated above, but in the interests of safety the figures relative to minimum flow have been left exactly as recorded.

The dams now being constructed at the outlet of Lake Couchiching in connection with the Trent Canal project will make available at least 12 inches depth of storage on Lake Simcoe. Properly regulated flow from this storage alone would meet the maximum requirements of the Wasdell's Falls plant for a period of six months in any ordinary dry year, while the records to date show that the period of deficient flow in an abnormally dry year is not of more than three months duration.

Permanent Works.—The dam is of the pier and stop-log type with six 14-foot sluices and a central overflow section 25 feet long which can be used during the high-water periods for driving logs. This section of the dam is closed by vertical needles, which will sustain a head of about 4 feet at maximum headwater level. When wide open, the dam can safely pass a discharge of 15,000 second-feet.

The power-house foundations, including inlets, wheel-chambers and draft tubes, are of mass concrete, only the wheel-chamber and generator arches and a portion of the draft-tube arches being reinforced. The whole of the superstructure, including the roof and crane-girders, is of reinforced concrete. The panel sections between the main columns consist of two layers of hy-rib reinforcement so placed as to provide a 4-inch air-space. The outer layer is plastered with a 2-inch coat of 1 : 2½ cement mortar and the inner layer with a coat 1¼ inches thick. The forebay walls, and the partition wall between the generator room and the forebay, consist of a single coat of plaster 2½ inches thick laid on hy-rib. The hy-rib was set in 2-inch checks left in the columns and girders and was further supported by light 4-inch channels set vertically in the air-space on 5-foot centres.

The wheel-chamber inlets are divided by a centre pier and in each of the four openings is placed a wooden head-gate spanning a clear waterway of 12 feet 1½ inches. These gates are built of 8-in. x 8-in. and 8-in. x 10-in. yellow pine, and in one gate of each pair is placed a 16-in. x 16-in. wicket gate for filling the wheel-chambers. The head-gates are not intended to be opened under full static pressure under normal conditions, although the operating mechanism is sufficiently powerful to admit of such operation if necessary.

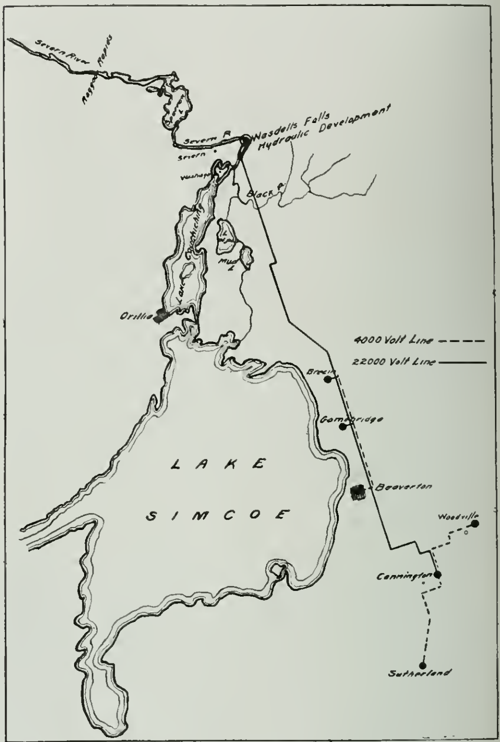

Fig. 3.—Location of Development on Severn River and Main Transmission Lines.

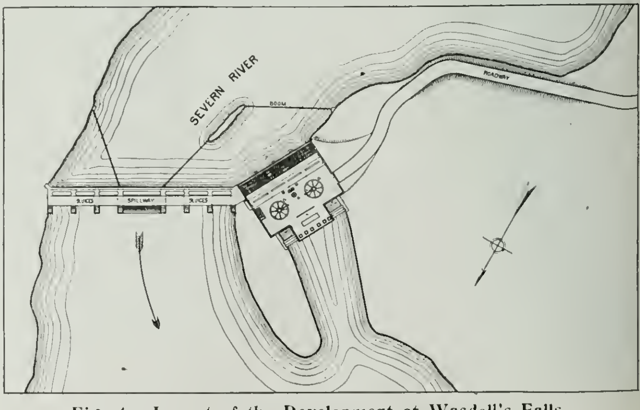

Fig. 4.—Layout of the Development at Wasdell's Falls.

As will be seen in the accompanying illustrations, the racks are entirely enclosed, making it possible to exercise a certain amount of control over rack temperature as a means of coping with frazil trouble.

It will also be noticed that the forebay curtain wall is located approximately parallel to the natural stream lines, so that by opening the sluices next the power-house,

Fig. 5.—Racks and Head Gate Mechanism.

a deflecting current can be utilized to clear the outer forebay of debris, floating ice and frazil.

Hydraulic Equipment.—The hydraulic equipment was manufactured and installed by the Boving Company of Canada, Limited, having comprised the first order filled from the company's new plant at Lindsay, Ontario. The two main units are of the vertical, double-runner, mixed

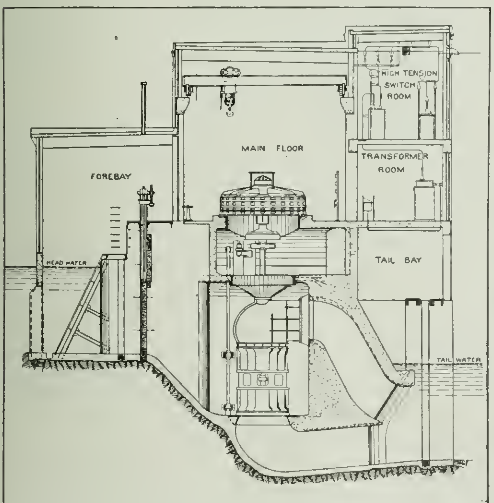

Fig. 6.—Cross-Section Through Power House.

flow, open flume type with separate draft-tubes, and are designed to operate at best efficiency under a 12-foot normal head, at 90 r.p.m. Under normal head, each unit has a guaranteed three-quarter gate capacity of 600 b.h.p. and a full gate capacity of 500 b.h.p. under a 9-foot head. The guaranteed efficiencies for ½, ⅔, ¾, ⅞ and full gate are 75, 80, 83, 85 and 80 per cent. respectively, at 12-foot head. Maximum output, and not efficiency, is the governing factor under low-head conditions, owing to the abundant supply of water then available.

The exciter turbine is of the same general type as the main units, but has a single runner only. It is designed

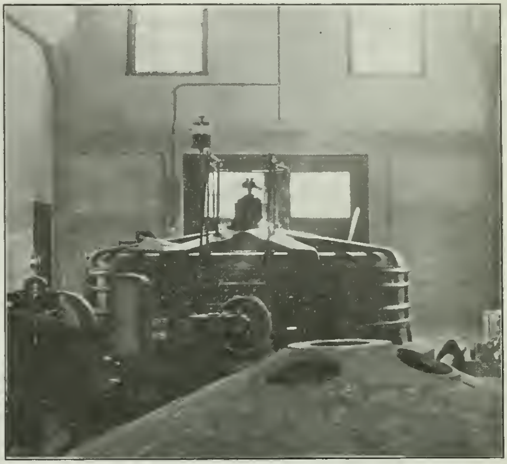

Fig. 7.—Main Generator.

primarily to produce sufficient power for full plant excitation under an 8-foot head. The operating speed is 190 r.p.m. and the ¾ and ⅞ gate efficiencies under normal head are 81 and 83 per cent. respectively.

The governors of the main units are of the self-contained oil pressure type, with a hand regulating attachment. Each governor is provided also with an electric servo-motor which enables the operator to make speed adjustments from the switchboard.

Fig. 8.—Erection of No. 1 Generator. The View Also Shows the Shaft and Lower Runner of No. 2 Turbine.

The governors are adjusted for 1½ seconds closing time and will handle a momentary fluctuation of 25% of full load with a speed variation not exceeding 6½ per cent.

Electrical Equipment.—The main generators and exciting equipment were manufactured and installed by the

Swedish General Electric Company. The equipment supplied under this contract comprised two main generators each of 400 k.v.a. capacity, vertical water-wheel type, 3-phase, 60-cycle, 2,300-volt, 90 r.p.m.; one 20-kw., 125-volt, 190 r.p.m. direct current water-wheel type exciter generator; and one 30-kw. motor generator set.

The total revolving weight of the main generators and exciter is carried on specially designed ball thrust bearings mounted on the top of the generator frame, and connection is made to the turbine shaft by means of flexible couplings.

The transformer and switching equipment was supplied by the Canadian Westinghouse Company. The present transformer installation consists of three single-phase, 60-cycle, 150-k.v.a., oil-insulated, self-cooling transformers wound for 1,900 to 2,500 volts on the low-tension and for 22,000 to 25,006 volts on the high-tension side, both sides being connected in delta. One spare transformer is also supplied.

In the high-tension switching gallery are located two 25,000-volt, 3-pole, remote control oil switches, the high-tension busses, two 25,000-volt electrolytic lightning arresters, and a choke coil on each outgoing line.

Auxiliary Equipment.—The stop-log winch was installed by the Wm. Kennedy Company, of Owen Sound, being their No. 1 type of 17 tons capacity. This winch is at present arranged for hand operation, but is so designed that a motor drive can be added at any time. The head-gate operating mechanisms were also supplied by the Kennedy Company.

Fig. 9.—Crane Girders and Hy-rib Reinforcement Previous to Plastering.

A 10-ton hand-operated travelling crane has been installed. This was supplied by the W. D. Beath Company, of Toronto, as was also a 1-ton trolley block which travels on an I-beam hung from the forebay roof girders, and is used for handling the racks.

Personnel.—The development was officially opened on Tuesday, October 6th, by Sir Adam Beck, chairman of the Hydro-Electric Power Commission of Ontario. Mr. F. A. Gaby is chief engineer to the Commission; Mr. H. G. Acres, hydraulic engineer; and Mr. E. T. Brandon, electrical engineer.

At the present time there are in India 2,331 miles of railway in course of construction or planned for construction during the year 1914-15. Of this total 1,575 miles are already under way and 856 miles are merely proposed. Of the former 220 miles are being constructed by the state and 1,355 miles by private companies. Of the latter, 173 miles will be constructed by the state and 583 miles by private companies. The total cost of the 2,331 miles of line is estimated at $80,000,000.

Steel railroad ties are being extensively used in Switzerland. At present 65 per cent. of the Federal railways employ them. They have the form or profile of a trough into which shape they are rolled at the mills. The ends are bent down, the profile of the trough being thus closed. Holes are provided for the attachment of the rails by means of clamp plates, and no tie-plates are used under the rails. The weight of the trough profile is 55.47 lbs. per metre; and the ties complete, with holes bored, weigh 159.84 lbs. each. According to the requirements of the Federal railways the steel in these ties must have a tensile strength of about 59,000 to 64,000 lbs. per sq. in., and an entire trough piece shall admit of being bent together on its back without showing any breaking fissures.

Pittsburgh manufacturers have received numerous inquiries for prices on all kinds of steel. The inquiries have come for the most part from England, Japan and South America. The announcement made recently that manganese would be manufactured in the United States to offset the closing of European ports was a welcome one to manufacturers generally. Pittsburgh firms now say that their production of steel will not be hampered by the war.

R. D. Featherstonhaugh, mining engineer, reports that he has filed for the Omenica Exploration Syndicate of the Tegler Building, Edmonton, silver claims that will produce 600 ounces of metal to every ton of ore. Mr. Fetherstonhaugh has staked 5 dredging leases for the concern, these being 15 miles on the Omenica River, 5 miles on the Findlay River, and 3 miles on the Ospica River. Three copper and silver claims were also filed at Lake Tacla; 10 mineral claims on Mount Selwyn, located off the banks of the Peace River. According to the engineer, the latter promises to develop into an important and extensive proposition. Anthracite coal claims were also filed upon by Mr. Featherstonhaugh for the Edmonton syndicate, which are so rich that samples have proved to contain 90 per cent. carbon, the richest of the reported anthracite coal claims in the west.

INFORMATION RESPECTING PATENTS OF INVENTION.

A FEW weeks ago a reader of this journal favored us with some useful information as to the position of an applicant for the patent, or a patentee, who has volunteered for active service and is thus unable to attend to the prosecution of his case.

It is generally known that in all patent offices certain rules are laid down restricting the length of time in which certain documents may be filed, renewal fees paid, and so on.

In Great Britain, he stated, an act has now been passed under which the comptroller of patents has the authority to grant extensions of time for the filing of such documents, the duration of such extensions being governed by the particular conditions of the case. This provision is made for the benefit of applicants or patentees who are absent from their country on active service or for any other justifiable reason are prevented from attending to their cases by circumstances arising from the present state of war.

The extension may be also granted when it is shown that the documents could have been filed, but under the circumstances arising from the state of war this would be prejudicial to the rights or interests of the applicant or patentee.

"The provisions apply only to patents in Great Britain and it remains yet to be seen whether a similar act will be passed in Canada and other British possessions.

"The British Patent Office has also made arrangements regarding documents intended for countries at war, in which the lodging of documents may be difficult. These documents should be filed through the British Patent Office, when the comptroller will date-stamp them and retain until such time as conditions would make it safe to forward to their destination. By this means, official evidence will be shown that the papers were duly executed and forwarded for filing on specified dates. Foreign renewal fees, etc., may also be paid in a like manner."

A copy of a special Act which has been passed to govern conditions due to the present trouble in Europe, and applying to patents in Canada, has since been received. Its principal clauses are as follows:

Orders and Regulations respecting patents of invention, made under the "The War Measures Act, 1914."

1. "Commissioner" means Commissioner of Patents and includes the Deputy Commissioner of Patents.

2. The Commissioner may, on the application of any person, and subject to such terms and conditions, if any, as he may think fit, order the avoidance or suspension, in whole or in part, of any patent or license, the person entitled to the benefit of which is the subject of any State at war with His Majesty, and the Commissioner, before granting any such application, may require to be satisfied on the following heads:—

(*a*) That the person entitled to the benefit of such patent or license is the subject of a State of war with His Majesty;

(*b*) That the person applying intends to manufacture or cause to be manufactured, the patented article, or to carry on, or cause to be carried on, the patented process within the Dominion of Canada;

(*c*) That it is in the general interests of the country or of a section of the community, or of a trade, that such article should be manufactured or such process carried on as aforesaid.

The fee payable on such application shall be ten dollars.

The Commissioner may at any time, in his absolute discretion, revoke any avoidance or suspension of any patent or license ordered by him, but if any person during the period of such avoidance or suspension begins to manufacture, use or sell in Canada the invention covered by said patent, such person may continue to manufacture, use or sell such invention in as full and ample a manner as if such revocation had not been made.

Provided always that the Commissioner may at any time, if in his absolute discretion he deem it expedient in the public interest, order the avoidance or suspension in whole or in part of any such patent or license upon such terms and conditions, if any, as he may think fit.

3. The Commissioner may, at any time during the continuance of these Orders and Regulations, avoid or suspend any proceedings on any application made under the Patent Act by a subject of any State at war with His Majesty.

4. The Commissioner may also, at any time, during the continuance of these Orders and Regulations, extend the time prescribed by the Patent Act or any rules made thereunder, for doing any act or filing any document, upon such terms and subject to such conditions as he may think fit in the following cases, namely:—

(*a*) Where it is shown to his satisfaction that the applicant, patentee, or proprietor, as the case may be, was prevented from doing the said act, or filing the said document, by reason of active service or enforced absence from this country, or any other circumstances arising from the present state of war, which, in the opinion of the Commissioner, would justify such extension.

(*b*) Where the doing of any act would, by reason of the circumstances arising from the present state of war, be prejudical or injurious to the rights or interests of any applicant, patentee or proprietor as aforesaid.

Such extension of any prescribed time, if granted after its expiration, shall have the same effect as if granted prior thereto, provided such expiration occurred on or after the fourth day of August, 1914.

5. The Commissioner may refuse to register the assignment of any patent made by a subject of any State at war with His Majesty, and filed in the Patent Office on or after the fourth day of August, 1914, unless satisfied that such assignment was made in good faith and not for the purpose of evading any of the provisions of the foregoing Orders and Regulations.

CEMENT USED IN TURKEY.

Cement is scarcely known in Turkey, but very good results are said to be given by a substitute consisting of slaked lime, linseed oil, and cotton fiber. The oil being poured on a small quantity of cotton and the lime dusted in, the mixture is kneeded thoroughly. The dough-like mass is used for filling crevices in water-pipes, covering cracks in stone floors, and for various other purposes. The material resists water, though it must be thoroughly dry before submerging.

The Taghum bridge, an ordinary type steel highway bridge over the Kootenay River, about five miles from Nelson, B.C., has recently been completed. The structure consists of three steel truss spans and two girder spans, supported on concrete piers and abutments. The bridge was designed by the Public Works Department of the Province of British Columbia and was erected for the Government by Hodgson, King and McPhalen Brothers, of Vancouver, at a cost of approximately $100,000. On account of difficulties in erecting the falsework, occasioned by the swift current of the river, so much time was lost in the early stages of the work that the contractors were obliged to employ three shifts of eight hours each in order to complete the structure before the coming of the spring freshets.

WIRELESS STATION AT NEWCASTLE, N.B.

THE most powerful wireless station in the world is just being completed at Newcastle, N.B. Its main tower is 500 ft. in height and is surrounded by six 300-ft. auxiliaries. The antenna forming the network around these towers comprise 120,000 ft. of silicon bronze wire, while over 140,000 ft. of wire have been laid in trenches around the station to secure proper ground connections. The operating house is at the base of the main steel tower, while the power house is situated outside of the line of towers. The latter is equipped with two 225 h.p. motors direct connected to two 1,000-volt d.c. generators. The total cost of the station is about $175,000. The sending and receiving instruments which are of the type known as the Poulsen System, were manufactured in Copenhagen, Denmark. The distance across the Atlantic to the corresponding station at Ballybunion, Ireland, is about 2,700 miles.

It may be stated that among wireless systems now in use are the Marconi, Poulsen, Goldschmidt, Lodge-Muirhead, Slabyarco, Braun-Sienens-Halske, Braney-Popp, Rochefort, Dueretet Popoff and the Guarini.

The system used in Newcastle was invented in 1905 by Dr. Poulsen, a Danish scientist, and while fundamentally like the other systems, differs materially in many essential features. The Marconi system makes signals by closing and breaking on electric circuit. Every dot and dash signal represents an independent electric current impulse transmitted through the air. The Poulsen system makes signals by varying—at the will of the sending operator—the electric wave length in a continuous current. The Marconi system opens the line of transmission for each separate signal. The Poulsen system opens the line once and keeps it open by continuous electric impulses, while the signals are being transmitted.

In the Marconi system, the question whether these intermittent waves sent out reach a certain point depends upon the energy of each initial impulse. In the Poulsen system the waves not all preserve their original form, but as the energy is being sent out constantly, one wave reinforces the other. This system operates night and day with the same efficiency, sunlight having very slight effect on transmission. A drawback to which other systems are subject is their efficiency—as far as distance is concerned—is three or four times greater at night than in the day time. Stations that can reach a ship 1,000 or 2,000 miles at night cannot reach over 200 or 300 in the day time. This is caused by the electrification of the ether by the sun's rays, which presumably makes it more difficult for the artificially created waves to travel through the ether, and also causes a greater absorption of energv by the earth.

Duplex sending and receiving have been accomplished by this system, which means that two messages can be sent or received by the same antenna simultaneously.

The commercial speed expected from the wireless station at Newcastle is 150 words a minute, while the greatest speed worked by cables across the Atlantic is 50 words a minute.

The Washington bureau of statistics of the American Iron and Steel Institute gives the production of all classes of ingots and castings in Canada in 1913 as 1,042,503 tons, an increase of 189,472 tons over the previous year. All kinds of finished rolled iron and steel produced are placed at 867,097 tons against 861,224 tons the year before. Pig iron production in Canada for the first six months of 1914 is placed at 442,430 tons against 469,137 tons for the last half of 1913.

PAVEMENT ECONOMY.*

THE economical pavement is a subject of much discussion, but like the proverbial fountain of youth it still remains undiscovered. Many claims have been made for the different types of pavements on the market and almost any promoter, material man or contractor, believes that he can, if given the proper amount of time, convince you that his is the only economical pavement. The truly economical pavement is the one best suited to meet the local conditions which will withstand the ravages of time and traffic with the least possible maintenance, first cost considered.

The old Roman roads with their foundations two or three feet, and in some cases as much as six feet in thickness, were economical roads and pavements for their time, for they not only met the conditions of their time, but have stood the traffic of centuries. To build a Roman road in modern times, however, would not be economical or wise. An administration attempting to lay a Roman road would probably not only start a vigorous protest of abutting property owners but would find a quick demand for a change in administration. While the history of the old roads of the Roman Empire, France and England, is interesting and they have been of great service in the development of modern type of pavements, they can no longer be used as models.

Americans, with their nervous, progressive and energetic spirit, must solve their own paving and road problems to meet their own particular conditions.

The principal considerations in determining the economical pavement are the traffic and climatic conditions to which the pavement must be subjected, available materials and their cost, assessed valuation of abutting property, and the probable result of the improvement.

Before a pavement is laid the climatic and traffic conditions should be given most serious consideration and should be a big factor in making the final determination. In the large cities where traffic is heavy, granite or wood block are very largely used. This is because these two types of pavement have been found to withstand heavy traffic more satisfactorily. Where the question of excessive noise is not material, the long life and small difference in cost, and the ease of repairs and low cost of maintenance, make granite block the favorite; while on a heavy traffic street lined with office buildings or stores, where the question of noise must be taken into consideration, wood block is constantly increasing in favor. It would be folly indeed to lay a concrete pavement, bituminous or water bound macadam, or any other cheaper type of construction under such conditions. In considering the traffic conditions to which a pavement must be subjected, it is always necessary to take into consideration the probable increase in traffic after the pavement has been laid, and in many instances it is advisable to take traffic census for the proposed improvement. It is not uncommon for the traffic of a road or pavement to double in volume after the improvements are made.

Another very important matter in considering the traffic conditions, is the kind of traffic. Where horse-drawn traffic prevails, a pavement should be made to aid this class of traffic; and where motor traffic prevails, a different type of pavement entirely may prove to be the most economical. Probably one of the best examples of

* Notes from a paper read by H. B. Pullar, Engineering Chemist, Detroit, before a recent meeting of the League of Michigan Municipalities.

this kind can be cited in Wayne County, Michigan. Almost everybody interested in paving has heard more or less favorable comments as to this large mileage of concrete roads. The traffic on the Wayne County roads has been reported as being over 80 per cent. motor traffic, and a large per cent. of this motor traffic is pleasure vehicles. The roads are and have been constructed by the most up-to-date methods and repairs are made immediately any defects appear. Were these conditions reversed, and the concrete roads in Wayne County compelled to withstand over 80 per cent. of horse-drawn traffic or even a much higher per cent. of heavy commercial car traffic, they would probably not prove to be the most economical, and the reported low cost for repairs and maintenance would be considerably increased.

Climatic conditions should be given consideration when determining upon the most suitable type of pavement. In England it was found that asphalt pavements laid similar to those in America deteriorated rapidly, and the cause was found to be the heavy fogs. A higher percentage of asphalt was used to overcome this trouble and more successful results were obtained. The southern part of this country requires a bituminous material of different consistency than that used in the northern section.

Bituminous pavements to give most successful results must have suitable drainage, and while this is true of other pavements it is specially true of all bituminous work. The climatic conditions of Michigan permit the use of many and various types of pavements, and they are not as important a matter as in other parts of the country.

The availability of materials is often given but slight consideration in determining the type of pavement to be constructed, and yet it is of the utmost importance in some localities. Where good sand is available at a low cost and where other conditions are equal, how foolish it is to import brick from another state in preference to laying sheet asphalt pavement, which is composed of about 80 per cent. of sand, whereas the reverse would be true if it were necessary to import sand into a town in which there is a brick plant turning out high quality brick. There are conditions in different cities which make it advisable, even at a much higher cost, to favor one type of pavement over another, but where the truly economical pavement is desired and other conditions are equal, the availability of materials should be given careful consideration.

In determining the most economical pavement the assessed valuation of the property is too often considered to be of minor importance, and politics and real estate promoters are frequently the cause of sheet asphalt pavements being laid out in the country, while the old unreliable water-bound macadam pavement remains in the heart of the city. We find many instances where wooden block pavements are laid on light traffic residence streets with heavy assessments made against the abutting property owners, who can ill afford them, while in the main business strees a cheaper type of construction is used with a heavy maintenance coming out of the general taxation fund. This practice is certainly contrary to all ideas of economy, and there has been much waste of public funds in cities where such conditions exist. A careful consideration of the needs of a street and the assessed valuation of the abutting property will not only result in better streets, but will cause a much lower general maintenance charge on all paving in the city and a more equal and just distribution of the paving fund.

The medical profession, with its great scientists and students, is continually finding new cures for what have been previously considered incurable diseases. Likewise the engineering profession, by its scientific studies and research work, will continue to overcome the numerous and difficult problems of paving construction. The economical type of pavement is distinctly an engineering problem and its solution for any particular street or locality will depend upon the efficiency of your engineer. The time is coming when the city engineer will be given more authority to direct and more opportunity to study and work out to advantage his paving problems. A successful manufacturer would soon lose his business and turn his dividends into losses were he to employ a new superintendent each year; as he would, also, if he should employ a capable superintendent to look after his business and then only spasmodically assist him in his work, or fail to give him authority to go ahead. So the choice of the economical pavement must be left with a capable engineer, receiving a big compensation and with full authority to direct his work, and in this he should receive the co-operation and help of all officials and citizens.

While I have endeavored to give you a general idea as to some of the important features to be taken into consideration when deciding upon the economical pavement for your city or town, I will endeavor to give you a short description and history of what we believe to be one of the coming types of economical bituminous construction. This is known as the open type of asphalt or bituminous concrete.

With the advent of the automobile and the demand for a more permanent type of construction than the water-bound macadam, the bituminous macadam laid by the penetration method was one of the first to be considered and has been most extensively used. For a time it seemed to have solved the problem, but failures have been too frequent and costly. While there are many good bituminous macadam roads which were constructed by the penetration method, the many small details which must be carefully looked after in order to get successful results have made the proportionate chances of failure so numerous that it is always with more or less uncertainty of results that a penetration job is constructed. The principal causes of the failure of bituminous pavements laid by the penetration method are the impossibility of thoroughly coating each particle of stone and the segregation of the stone, making it impossible to obtain an even distribution of the bituminous material. The result of this is that there are numerous spaces in the road which allow water to penetrate, causing the pavement to disintegrate rapidly.

Another type of bituminous pavement which has found great favor, is the bituminous concrete, which is a mixture of asphalt, sand and stone. This type of pavement would find greater favor were it not for the fact that certain patents to cover practically all mixtures of stone and sand have been held valid in some of the courts; and on account of the undesirability of getting into any patent litigation cities have hesitated in adopting this type of construction.

Because of the uncertainty as to the results obtained from the penetration work and because of the desirability of getting a cheaper type of bituminous pavement than the asphaltic concrete or sheet asphalt, the open type of asphaltic or bituminous concrete has been developed and has met with much favor in different sections of the country. This type of pavement, however, is not a new one, having been used many years ago with a tar binder. The pavement consists of a mixture of stone and bituminous cement acting as a binding medium.

The stone is heated to a suitable degree of temperature, depending upon the bituminous material used, and then mixed with bituminous binder in suitable proportions. It is laid similar to sheet asphalt or asphaltic concrete. The mixture is laid from 2 to 3 inches in thickness and properly rolled. After rolling there is applied a squeegee coat of pure asphalt cement and while the coating is still hot stone chips are thrown over the surface. The whole pavement is then re-rolled so the squeegee coat is forced into the voids, making a tight, uniform, waterproof and durable surface. Heating the stone and then mixing in asphalt so that each particle is thoroughly coated, prevents the trouble which causes so many failures in the penetration method and prevents any segregation of stone.

The city of Lansing last year tried out this type of pavement on some of the principal streets with excellent results at a very low cost. On account of the results obtained the State Highway Department of Michigan will put in a strip of this same type of pavement in Oakland County, which is an extension of the Woodward Avenue pavement of Detroit. This section of pavement will join the concrete road of Wayne County and will afford an excellent opportunity for a comparison of the two different types for the same traffic. There are a number of other cities in the state which have already laid considerable yardage of this open type, and which contemplate laying in the future a large amount of this work.

The open type of asphaltic concrete pavement is free from infringing on any patents, thus removing any cause for litigation. Although there are about 35 per cent. of voids in the mix as it comes from the mixer the stones key in together giving the wearing surface stability, thus preventing shoving and rutting. In fact, the finished pavement is similar to water-bound macadam with the exception that each stone is bound together with asphalt cement. The asphalt cement prevents any dislodgement of the stone from either horse-drawn or motor traffic.

The first cost of this pavement is very nominal compared with other types, being slightly higher than that of the penetration and considerably less than the closed type of bituminous concrete or sheet asphalt. With average conditions these pavements can be laid by contractors for from $1.10 to $1.40 per square yard, including 6-inch concrete foundation, but if the pavement is put in by the day labor plan, under the supervision of the city engineer, the cost should be considerably lower. In fact, I believe the total cost of the paving at Lansing did not exceed $1.10 per square yard, and the city used crushed cobble stone instead of limestone, which added considerably to the expense.

The open type asphaltic concrete pavement after traffic has been on it for some time looks almost the same as the closed type, or like bitulithic. It is easy to repair, pleasing in appearance and makes a sanitary and noiseless pavement. There are many cities and towns throughout Michigan, especially in the residential sections, where this type of construction would be advisable. I think it would prove to be the economical pavement and I believe that it will constantly grow in favor with engineers and officials in charge of paving work.

There is another item to be taken into consideration in discussing the economical pavement. No type of construction and no materials, no matter how high the quality or how successful they have been in other places, will be satisfactory in any locality unless they are properly constructed. Just because a pavement or a particular type of construction has given successful results in one town or one locality is no indication that it will be equally successful in your city or town unless every precaution is taken to see that the numerous small but important details are carefully looked after. The best of materials cannot give good results unless properly handled, while better results can be obtained with poor materials properly applied.

It is not, by any means, always economical to award contract to the lowest bidder and a difference of 5, 10, or even 25 or 50 cents per square yard in the original cost may in the end prove most economical.

In conclusion, I would state that the economical pavement of to-day is not any particular type or any particular material, nor is it a pavement put in at any particular cost. It is a pavement carefully selected after an exhaustive preliminary examination by an efficient engineer to best meet the demands of the particular locality in which it is to be constructed. It is a pavement laid in direct accordance with the requirements of carefully prepared specifications, which should be reasonable and just to both the city and contractor. It is a pavement in which only the most suitable available materials for its particular type of construction are used; a pavement laid under the direction of an efficient and capable engineer, with authority to direct and supervise the many details of construction and to appoint inspectors for their efficiency and ability to carry out his orders, rather than for their ability to obtain votes at the next election. The city or town in which this condition exists, while it may continue to have a failure now and then, and while it may not find the one economical pavement, will come nearer to solving the problem and satisfying the taxpayers, to whom all public officials in the end must look for commendation.

WATER RIGHTS LAW PROBLEM.

The American Society of Civil Engineers has recently appointed a special committee, composed of eminent engineers, to ascertain the need for a national water law in the United States to protect existing rights and future engineering developments from interstate difficulties.

The enumeration of possible difficulties, as prepared by this committee, is of interest in Canada, where some of them may exist as interprovincial difficulties. Some of the interstate difficulties may be caused as follows:

1. From taking water across state lines;

2. From the use of water in an upper state which may jeopardize the quantity and quality for use in a lower state;

3. From approximations on border streams where the controlling works are in two states;

4. From the storage of water in an upper state for transit in stream channels through several states and use for navigation, power, etc., at the lower end of the stream;

5. Because of judicial decisions in one state prohibiting the diversion of water from one drainage basin into another, or across state lines;

6. From the construction of unsafe works in one state which menace lives and property in adjoining states;

7. From the drainage of swamps or lakes in one state which removes the natural regulation of flow and which may cause destructive floods in adjoining states;

8. From the pollution of water in one state to the detriment of lower states;

9. Because of international treaties and controversies where state or federal jurisdiction is questionable.

THE MECHANICS OF REINFORCED CONCRETE UNDER FLEXURE IN BEAM AND SLAB TYPES.*

By C. A. P. Turner, M.Am.Soc.C.E.

THE co-operation or combined action of the two materials, concrete and steel, to resist bending, depends solely on the bond between the two. In the case of plain rods this bond is in reality a shrinkage grip which prevents the steel from sliding through the hardened matrix in which it is embedded and the resistance afforded is subject to well-defined laws which may be stated as follows:

The bond shear is zero wherever the tension in the steel is constant. It passes through zero where the increment of the moment passes through a maximum or minimum. It must be depended upon whether the reinforcement is in one direction only as in a beam, or in multiple directions in the slab.

Bond shear generates stresses emanating from the surface of the bars which may be treated as lines of force. These lines of force follow the general laws of distribution of force through any medium; that is, their intensity is inversely as the square of the distance from the surface of the steel on which they are generated.

These general laws enable us to investigate or follow out the part played by bond shear in the mechanics of a slab or beam. In the case of a simple beam, in accordance with the law stated, the intensity of the bond shear is zero at the centre for uniform load and a maximum toward the end of the beam, and it is the bond shear or the lines of force generated thereby to which we may attribute the difference in the failures of an over- and an under-reinforced beam. In the case of the beam with light reinforcement, failure takes place at the centre by the yielding of the steel. With heavier reinforcement, however, failure is more liable to occur toward the end by diagonal tension induced by web stresses, which are greater toward the ends of the beam and which may rupture the concrete across the lines of tension in it. Perhaps the largest part of these web stresses originate in the bond shear at the surface of the reinforcement.

The deportment of the simple beam as affected by the stresses set up by the bond shear is of interest. In a newly cast beam, in the preliminary stages of the loading, the stress in the steel, as determined by the extensometer, is much less than that figured on the assumption that the steel only resists tension. In fact, it is only about one-half as great as we should compute the stress to be on that basis, until the steel is stressed up to four or five thousand pounds per square inch. When this point has been reached there is a rapid increase in the stress in the steel, with no corresponding increase in the load until, when the steel is stressed up to twelve or fifteen thousand pounds per square inch, the concrete has relieved itself of a large portion of its tensile resistance and the measured stress in the steel corresponds closely to the computed stress in the steel, assuming that the steel is not assisted by the concrete in tension.

With the slab reinforced in two directions, however, the phenomenon differs from that observed in the beam. Take for example the case of such a slab, bent in such manner that the rods in both directions are brought into tension at the same time. The indirect stresses generated by the two sets of rods will, under this condition, react upon each other, since the lines of force diverge from each rod they may meet, and coact through the concrete as a medium of transmission of the stress, which is not possible in the beam with one-way reinforcement, since in the beam these stresses cannot coact with each other, there being one kind only, and not two kinds acting in different directions. This fundamental difference in the induced stress generated by the bond shear in the case of a beam and slab render the two types of structure mechanically different, and necessitates their treatment in a manner which takes into consideration the difference in the mechanical operation of the indirect stresses referred to.

A crack in the slab would not materially interfere with the operation of these indirect stresses in each segment of the multiple-way reinforced slab, while a crack in a beam normal to the direction of the steel would intercept any indirect tensions induced by the bond shear at the section checked, and prevent the accumulated resistance afforded by these indirect stresses from being effective in direct resistance to moment.

In treating the combination of the two materials, it has been customary to consider their combined action as determined by the elastic properties of each taken separately, that is, by considering the ratio of the modulus of elasticity of the concrete in compression and tension to the modulus of elasticity of the steel in tension and compression. In a homogeneous elastic slab, such as steel in the form of a plate, there would be taken into consideration in addition to the modulus of elasticity of the metal in tension and compression in one direction, the additional coefficient of modulus of lateral deformation known as Poisson's ratio. This ratio, or lateral effect, in a combination of steel and concrete which is sufficiently fine-grained to be regarded as acting like a homogeneous material, as is the case with reinforced concrete slabs, cannot be correctly considered as an elastic property of either the concrete or the metal, but on the contrary must be treated as a coefficient expressing the efficiency of the lateral action of the indirect stresses induced by the bond shear in the case of multiple way-reinforcement in the slab, which coefficient, for the reasons above explained, must be zero in the case of the beam type, with reinforcement in but one direction, or the case of the slab in which the reinforcement under strain runs in but one direction only. Although transverse reinforcement may be introduced in a beam, it can perform no useful function in reducing the stress on the carrying-rods, since the indirect stress induced by one series of rods under strain cannot converge to react upon another set of rods not under stress, but can react with that set of rods only when both are generating indirect lines of force arising from bond shear.

The indirect stress from bond shear to be depended upon must react upon other indirect stress and be held in equilibrium by these stresses generated by the steel. Otherwise, we are depending upon the direct tensile resistance of the concrete for bending, which is not considered permissible by those experienced in reinforced concrete design.

In the case of the beam with one-way reinforcement, there is no way for these stresses to react upon each other and be held in equilibrium by each other. The slab, however, furnishes a condition by which this desirable end is obtained.

The law governing the generation of bond shear indicates clearly that if this element of strength is to be

*Read before the Boston Society of Civil Engineers, on September 16, 1914.

utilized, wide-spreading reinforcement must be used. Otherwise, its efficiency is negligible. This law eliminates from consideration as an economic and successful flat slab, any arrangement of narrow belts or strips of reinforcement in a flat slab of uniform thickness which does not permit, by virtue of the arrangement, efficient operation of the forces outlined.

That the performance of a flat slab with multiple-way reinforcement is essentially different from the mechanical operation of one-way reinforcement in a beam is apparent if we consider that as a mechanism its operation is governed by the fundamental law known as the law of conservation of energy and its various corollaries. As a substantially elastic structure—and we are dealing with an elastic theory—the external work of the load must equal the internal work of deformation. It is true, of course, that the slab is not perfectly elastic because of shrinkage stresses, and because the concrete does not completely fulfil the conditions of a perfectly homogeneous elastic solid, but when the slab is thoroughly cured and of good concrete, its deportment for practical purposes may be treated on this basis.

The utility of the flat slab, as compared with beam construction, depends on lateral resistence, enabling the same resistance to be secured with a smaller thickness.

"The external work of the load equals the internal work of deformation, or the product of the force multiplied by the distance through which it moves is a measure of the internal work of resistance of the structure withstanding this force."

This statement (Clapeyron's Theorem, 1866) gives a basis for ascertaining the manner of the storage of potential energy in a reinforced concrete structure by which can be demonstrated the difference between the circumferential cantilever action, as in a Turner slab, and the lineal cantilever action, such as that of Hennebique, of the beam type. In considering this matter we will assume a Hennebique structure with the slab of the same thickness as the Turner floor-slab, and assume the same amount of cross-section of steel in the two cases.

Since the steel runs in multiple directions in the belts of Turner, having substantially uniform spacing, and since the material is strained circumferentially as well as radially, and in such a way that the circumferential and radial deformation must, from the geometry of the slab, be equal, it can be shown that the energy stored circumferentially about the cantilever head in the belts of rods is equal to that which is stored radially. Now if half our energy is stored circumferentially and half radially, it is evident that while the circumferential deformations are coincident with, and their magnitude dependent on, the radial deformations, it is the radial deformations or extensions along a meridian line which determines the vertical geometry of the slab. In other words, as half our energy is stored circumferentially, we have established a different method of storage of energy in the circumferential cantilever of Turner from the lineal cantilever of Hennebique. In the lineal cantilever no energy can be stored circumferentially, because the steel does not run in that direction; there is no reservoir, so to speak, in which to store it.

Suppose we assume that the same quantity of energy (symbolizing it by Q) is stored in each respective structure. Then, if the load be applied gradually, and we use W_1 to represent the load and H_1 the mean deflection of the lineal cantilever, we have

$$Q = \tfrac{1}{2} W_1 H_1 = \tfrac{1}{2} W_2 H_2,$$

W_2 and H_2 referring to the load and the deflection, respectively, of the circumferential cantilever. Now, if half the energy in the circumferential cantilever is stored circumferentially, and half radially, and that stored circumferentially produces no deflection, then $H_2 = \tfrac{1}{2} H_1$. That is, the mean deflection of the circumferential cantilever, represented by H_2, is only one-half the mean deflection of the lineal cantilever, represented by H_1. Likewise, Q being the same for each, $W_2 = 2 W_1$. But if we assume for purposes of closer comparison that the deflection be the same with each, instead of the quantity of energy stored being the same in each, then W_2 (the load of the circumferential cantilever) must equal $4 W_1$ or it will require *four* times the load to produce the same deflection with a circumferential cantilever, it being assumed, of course, that the same amount of steel is used that it will require with a linear cantilever in each, and that the same depth of slab is employed.

From this relation of the storage of energy, it is evident that a circumferential cantilever and suspended span slab of half the thickness will present the same rigidity as a continuous beam construction of double the depth, being a measure of the difference in deportment of beam action and slab action.

Bending Moments.—Regardless of the manner in which the load is carried to the support, it is an invariable or fundamental law for uniform loading that half the sum of the bending moments over the support, plus that at mid-span, equals a constant, equals $\frac{1}{8} WL$. This is true for a continuous beam, simple beam, a continuous slab, or a simple slab, or one fixed at one end and free at the other. From this relation we would have for a slab of indefinite extent, supported at points, as the magnitude of the moment at the support, $WL/12$, and the moment to be resisted at the centre, $WL/24$, and we are now in position to consider the modification due to the size of the capital. For the usual proportions this would reduce the moments just given to $WL/15$ and $WL/30$, respectively, for a single panel, but in the cantilever portion about the column these external moments or apparent moments, as Dr. Eddy treats them, are resisted in two ways—by true moments, in the steel radially, assisted by the bond shears coacting with each other and by true moments in the steel circumferentially, also assisted by the bond shear. Thus the radial moment in a line at the critical section about the cap to be resisted would be $WL/30$, which in the mushroom type is provided for by the combined radial rods and slab rods.

In the discussion thus far I have dealt generally with slabs of uniform thickness, and it is in order now to make a few remarks applicable to slabs not presenting this characteristic—that is, with a thickening up of the concrete at the column.

The general principle of rigidities must apply to this case. This principle may be stated as follows:

Where there are two or more paths by which the load may travel to the support, the load divides itself between the paths in proportion to their rigidities.

Increase of the rigidity of the cantilever portion throws the line of inflection outward, increasing the moment at the support and decreasing the moment at mid-span to the extent that the load is a balanced load and the column rigidity permits its action in this manner. As the writer views this modification of the slab, it is not an altogether desirable modification, for the reason that it involves increased bending at the column, a large increase in the apparent moment to be resisted over the support, decreased toughness and ability to resist unbalanced load.

I have pointed out the comparative stiffness and strength of a linear cantilever and a circumferential cantilever. It is next in order to show that in the suspended span-portion covered by crossed belts in a diagonal direction, the same relation holds true because of coaction between the two belts. In the direct belt there is no such action at the centre. The moment there, however, is reduced by the stress in the diagonal belt crossing and assisting it where there are four belts used. This assistance in the standard mushroom design with the proper width of belt, half the distance between columns will amount to practically six- to seven-tenths of the efficiency of the direct belt, so it is evident that, if the diagonal reinforcement is to be eliminated, the side-belts must be increased very largely or to nearly double the cross-sectional area required for the four-way system. This increase is brought about not only by reason of the relation just pointed out, but for the further reason that with a four-way arrangement, the resistance to circumferential stress by the steel is more complete than with a two-way arrangement.

In a short paper of this kind, a complete discussion of all phases of the problem would be beyond its scope. To point out the fundamental difference between beam action and slab action and to offer a simple explanation thereof is the object which has been aimed at. Of the large amount of work which has been constructed giving perfect satisfaction, there is required some explanation more consistent and rational than to say that the uncertain and unreliable tensile strength of the concrete has brought about such satisfactory result. For those who are inclined to consider that the direct tensile strength of the concrete can be credited with these results, such experiments as the writer has made, in which the slab when loaded carries the load by concrete tension very well at first but in the course of a week or ten days failed completely under the load, would carry conviction to those who would take the time to investigate. The difficulty, as the writer views it, of arriving at a scientific analysis of the slab, has been the confusion of the properties of a composite material with those of a homogeneous elastic body.

Reinforced concrete is not a homogeneous material, but consists of radically different elements, steel and concrete. The properties of these materials are radically different. They work together only by virtue of the bond shear or shrinkage grip between the two, and it is the property of this connecting link or lateral efficiency thereof which has been successfully treated as Poisson's ratio by Dr. Eddy in his mathematical analysis of the continuous flat plate.

The Poisson ratio with which Dr. Eddy deals, as I understand it, is not a property of either concrete or steel, and has absolutely no relation to any property of the two materials, but is nothing more nor less than the coefficient of the lateral efficiency of the indirect stresses induced by bond shear in their coaction with each other, which coaction occurs in such manner that the direct tensile strength of the concrete is not overtaxed, as would be the case where dependence is placed upon the energy stored by indirect stress in a one-way reinforced beam.

The difference in operation of one-way and two-way structures as machines for storing up of the energy developed by the load in its descent during deflection of the slab, is of interest. In a newly cast beam, the deflection for small loads is much less than we would figure by the ordinary theory. The energy stored by the indirect stresses arising from bond shear in tension, however, is not stored in a stable manner, because the concrete soon becomes overtaxed or cracks, and energy thus stored leaks away and is dissipated. Further energy is developed by the load in its future descent through increased deflection, which is stored in turn by the steel. This phenomenon is sometimes incorrectly described as the concrete relieving itself of the stress and throwing it upon the steel. As a matter of fact, no such interchange occurs. The energy stored in the concrete is lost and dissipated and new energy is developed by the load in its descent through increased deflection, which energy is stored up in the steel in a dependable manner. In the slab, on the contrary, where energy is stored by the coaction of one set of indirect stresses with another, the storage is a dependable one, for the reason that these stresses are not cumulative, since they are merely transferred through one set of rods to the other through the concrete as a conductor, and do not have any cumulative effect on the structure, as in one-way reinforcement.

Certainly a theory such as that of Dr. Eddy, which enables us to compute deflections accurately, and which gives the steel stress in accord with experiment, cannot be lightly dismissed, no matter with what disfavor Poisson's ratio, the basis of the computation, may be viewed.

In conclusion, I believe that a clean-cut understanding of the nature of the fundamental relations which I have pointed out may help clear up some of the mystery with which slab design has been obscured, and that a more complete discussion of the fundamental laws of mechanics applicable thereto will eliminate the many errors and inconsistencies in its design into which those have fallen who have given the subject insufficient study. One of the gravest mistakes and the most common one, has been that of using too high a percentage of steel, with the confident belief that this excess of steel would add materially to the strength of the structure. The performance of the scientifically designed flat slab under test, places the burden of proof upon the critic, to show wherein the method of design is in error, and it would seem that thus far all criticism of the successful flat slab had been based upon the gratuitous assumption that reinforced concrete is such an anomalous mechanism that its operation as a machine is totally independent of the law of conservation of energy and the principles of least work. Further, our critics would have us believe that its innumerable manifestations of strength should cause us to lose all confidence in the dependence usually placed on the law of gravitation as a proper basis for load tests.

Treating the scientific flat slab as a machine on the theory of work, we can readily check up Dr. Eddy's conclusions regarding the performance of the machine in respect to its deflection. We have shown that the circumferential cantilever is four times as stiff as the linear cantilever. Now the successful flat slab is a continuous construction and it would be four times as stiff as the continuous beam. The continuous beam, in turn, is five times as stiff as the simple beam. Hence, the continuous flat plate is twenty times as stiff as the simple flat plate, but in order to build a flat slab supported on columns we have to have support of, generally, two-tenths of the span in diameter. This reduction of the span to eight-tenths would render the slab forty times as stiff as a simple slab on knife-edge supports, were it not for the fact that the resisting section grows smaller in a continuous slab on posts as the post is approached. This difference reduces the relation from forty to approximately thirty times for the above ratio of metal to span.

It seems to the writer that the average structural engineer in the consideration of his structures, is more inclined to feel that he is dealing with a mere problem of static equilibrium than to consider the structure as a true machine in which all of the elements are put in motion by every change of load.

Looking at it in the true light of its operation as a machine, or mechanism, the theoretical error of disregarding the vital elements or parts of the machine in treating its operation becomes apparent. We would not consider it practical to expect satisfactory operation of an engine with the connecting-rod left off, and why should we consider any theory as applicable to the operation of the flat slab in which the connecting link between the concrete and the steel is left out of consideration? Such a theory must evidently be as unsatisfactory in application as the engine with the connecting-rod removed.

Failure to consider the continuous flat slab as a mechanism accounts for the strange misconception of its character by the great majority of the engineering profession. They look at the commercially successful flat slab as one which is merely flat on top and bottom. Certainly the writer was not a pioneer in flat-slab construction of this ancient and useless variety.

In the construction of the reservoir at Bridgewater, Mass., a slab flat on top and bottom was used, and strips of expanded metal marked "lintels" on the working drawing were stretched from column to column in two directions and expanded metal was spread in the bottom layer. The operation of this structure as a machine, however, would not be the mode of operation which I have outlined by the preceding theory of work. It is a different mechanism entirely. No useful circumferential action could occur in the upper zone about the column, while the difference in rigidity of the expanded metal in the two directions, longitudinally and transversely, would prevent any material circumferential resistance in the bottom between columns. The performance of other slabs, flat in form as machines, may be referred to here.

Mr. George Hill, of New York, in the "Architectural Record" of September, 1902, described the construction of a warehouse with columns 16 feet centres, slab 11 inches thick, designed to carry 400 pounds working load, or 52 tons per panel. Failure occurred under approximately half this supposedly safe load, and the floor is now supported on alternate brick piers and concrete posts 8 feet centres, or nine times as many points of support per panel, 16 feet square about the column, as originally designed.

A reservoir roof on a similar plan was attempted, with columns about 22 feet centres, slab between seven and eight inches thick. Instead of seven posts it now rests securely on somewhat over forty posts.

The performance of these structures as machines when the thickness of the slab is reduced so that stability must depend on the slab action was unsatisfactory, for the reason that the general laws necessary to secure satisfactory results were not complied with. The type of flat slab outlined in Taylor and Thompson's work would come somewhat under the same category as regards width of belt and proper distribution of the material over the columns, to secure the most effective reduction of the radial moment by circumferential action. Its glaring defects in this respect the writer has noted with surprise, but they seem not to be generally appreciated by the profession at large.

To undertake in a short paper the discussion of wall panels, column flexure, and other more intricate phases of the flat slab problem, while as yet the simplest and most elementary form of the problem, the interior panel, is not generally understood, would be, as the writer views it, a waste of effort. When there is more general agreement on the simplest form of the problem, then the more complex and interesting phases of the question are in order for discussion.

OPPORTUNITIES FOR CANADIAN PRODUCTION.

The following is a partial list of articles not manufactured in Canada, but all of which are imported. It has been compiled by the Department of Trade and Commerce, Ottawa, and may serve as suggestions to manufacturers of engineering machinery and equipment.

Asbestos pipe coverings; carbons, electric light; copper tubing, seamless; galvanized wire netting, 14 x 15 gauge; galvanized wire netting, any gauge, ¾ mesh and smaller; miniature electric incandescent lamps; pipe coverings of cork for cold storage insulation; rolled edge steel plates; safety fuses, not metallic; seamless steel boiler tubes; oil engines; sheet copper and seamless copper tubing; sheets, Bessemer; slag trucks; sockets, incandescent for street lamps, 1½-inch inside diameter and over; steam steering engines for equipment of ships; steel squares; telephone carbon protector blocks, carbon discs and glass lenses used in manufacture of telephone; tubing, seamless steel.

PROPOSED EXHIBIT OF U.S. STEEL CORPORATION AT PANAMA PACIFIC INTERNATIONAL EXPOSITION, 1915.

The announcement is made that the United States Steel Corporation and subsidiary companies propose to have a comprehensive exhibit of their operations at the Panama-Pacific Exposition in San Francisco in the year 1915. It will begin with the ore fields and carry on an educational picture of operations in ore mining, rail and water transportation, dock operations, coal, coke and pig-iron production, steel manufacturing in its various lines, and will also present in a displayed way the processes of manufacturing many of the subsidiary companies' products, also how their by-products are utilized, and the display of many of the uses in which their general products are employed, typifying the advancement in the uses of this country's resources. In addition to the material exhibits before mentioned the corporation intend to illustrate in a comprehensive manner, by moving pictures, their operations throughout all departments, showing the ramifications of the processes of the corporation's operations. It is proposed as well to set forth to the world the work which the United States Steel Corporation has done towards the social welfare of its employees and dependants. The corporation will also exhibit many forms of safety devices that have been conceived by its officials and employees, and in the installation of which large sums have been and are being expended. In this social welfare department will also be shown the methods employed by the corporation in the aid and care for the injured, and the welfare of employees' conditions at work and the benefits that are aimed to be afforded to employees at their work and in their surroundings.

MATERIALS AND SUPPLIES FOR SOUTH AMERICA.

United States Consuls reporting on the immediate necessities of Latin countries state that there will be opportunities for the sale of the following: Para, Brazil=cement and manufactured iron; Rio de Janiero, Brazil=cement, hardware, iron and steel wire; Montevideo, Uruguay=cement; Lima, Peru=cement, steel rails, tools, machinery, explosives; Bogota, Colombia=machinery, railroad supplies, engines, cars, rails, bridges.

GRAPHICAL METHOD FOR BEAM DEFLECTION

PRACTICAL SOLUTIONS TO COMPLICATED PROBLEMS IN THE DEFLECTION OF BEAMS, OBTAINED BY THE APPLICATION OF THE FOLLOWING GRAPHICAL METHOD.

By I. F. MORRISON, S.B.,
Department of Structural Engineering, University of Alberta.

THE well-known formula for the deflection of a beam (due to the bending moment caused by the load), $\frac{d^2y}{dx^2} = \frac{M}{EI}$, where the values of x are horizontal and those of y vertical, M is the bending moment at any point, and E and I are the usual constants, affords a practical solution of such problems by a graphical method. Except for the simplest cases, the differential equation above is, at best, cumbersome to handle by the calculus, and, therefore, inefficient for practical purposes.

From this equation, $\frac{dy}{dx}$, which represents the slope of the elastic curve of the neutral axis at any point x, equals $\int \frac{Mdx}{EI}$, and y, which represents the vertical deflection at any point x, equals $\int\int \frac{Mdx^2}{EI}$. Also observe that $M = \int S\,dx$ and that $y = \int\int\int \frac{S\,dx^3}{EI}$, where S is the shearing force at x. If E and I are constant the following graphical method will be found valuable for complicated cases:—

Given a 6-in., 12.25-lb. I-beam, with the span and loading shown in Fig. 1, $E = 30{,}000{,}000$ lbs. per sq. in. $I = 21.8$ inches^4. Required the maximum deflection.

The method is as follows: The shearing force curve was first plotted as shown in Fig. 1, and from this the bending moment curve was obtained as follows: Vertical strips 1 foot wide to scale were taken and the middle ordinate of each strip was laid off on a vertical line at the right-hand end of the beam. The point P was chosen as a convenient pole, and the curve constructed in the same manner as an equilibrium polygon. Note that the edges of the strips were connected by the strings and not the middle ordinates.

Again, taking the middle ordinates of the bending moment curve, in the same way a new curve, the slope curve, is constructed. The ordinates to this curve give the slope at any point. Here, it is to be noted that to draw these curves in their proper position they must be made to conform to certain known conditions. The value of the bending moment is zero at the end of the beam; therefore, its curve must pass through zero at that point. The slope of the deflection curve is zero at the middle of the beam; therefore the slope curve must pass through zero at that point; and it has been so drawn. Finally, from the slope curve the deflection curve has been drawn in the same way, passing through zero at the ends of the beam, because the deflection here is known to be zero from the conditions of the problem.

Care must be taken with the scales, but there is no difficulty involved if they are put down as follows:—

First Scale: Horizontal, 1 in. = 2 ft.; vertical, 1 in. = 500 lbs.; pole distance = 6 ft.

For the Second Scale multiply the pole distance into the vertical scale of the First Scale.

Vertical, 1 in. = 3,000 foot-pounds.
Pole distance = 6 feet.

In the Third Scale the vertical is obtained in the same way.

Vertical, 1 in. = 18,000 pound-feet^2.
Pole distance = 6 feet.

For the Fourth Scale, the vertical scale,
1 in. = 108,000 pound-feet^3.

The deflection at any point is now obtained by scaling the vertical ordinate at the point to the deflection curve in inches (use a scale graduated to 100ths of an inch). Multiply this by 108,000 ft.-pds. and by 12 to obtain the deflection in inches. The product EI in the denominator must also be inserted.

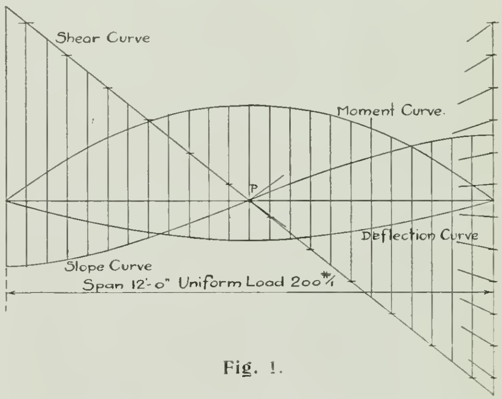

Fig. 1.

The results for this case are as follows:—

Scaled maximum ordinate on the deflection curve at centre = .50 inches.

$$\text{Deflection, } \frac{108{,}000. \times .50 \times 12^3}{30{,}000{,}000. \times 21.8} = .1427 \text{ inches.}$$

From the formula—

$$\text{Deflection, } \frac{5 \times 200. \times 12^4 \times 12^3}{384. \times 30{,}000{,}000. \times 21.8} = .1429 \text{ inches.}$$

Such extreme accuracy as this is due more to good fortune than to anything else, but it goes to show that the results so obtained are sufficiently accurate for practical purposes.

Let it be required to find the deflection of any point, "a," of the beam, with its loading, shown in Fig. 2. Fig. 3 shows the shearing force, bending moment, slope and deflection curves. The slope curve is not in its cor-

rect position, due to the fact that the constants of integration are determined by conditions imposed on the deflection curve, and, therefore, are not determined until this curve is drawn. These conditions are that the deflection curve shall pass through zero at each of the reactions. The slope curve could easily be shifted to its

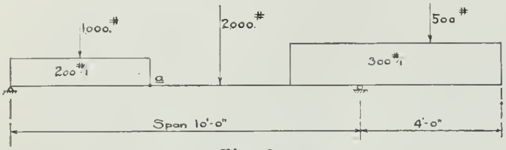

Fig. 2.

proper place, but that is hardly necessary, since the deflection curve is all that is desired in this instance. The deflection curve was made to pass through the required points by one of the several well-known methods for passing a polygon through two points. The choice of the last pole for this curve, therefore, was not wholly arbitrary and had to be scaled.

The scales work out as follows:—

First Scale: Horizontal, 1 in. = 2 ft.; vertical, 1 in. = 500 lbs.; pole distance, 4 ft.

Second Scale: Vertical, 1 in. = 2,000 foot-pounds. Pole distance, 4 feet.

Third Scale: Vertical, 1 in. = 8,000 pound-feet^2. Pole distance, 2.88 feet.

Fourth Scale: Vertical, 1 in. = 23,040 pound-feet^3.

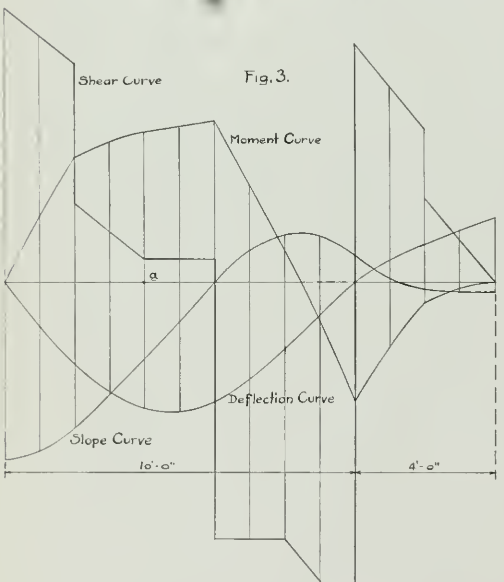

Fig. 3.

The scaled distance in inches to the deflection curve at "a" = 1.80 inches.

$$\text{Deflection, } \frac{23{,}040. \times 1.80 \times 12^3}{30{,}000{,}000. \times 21.8} = .1095 \text{ inches.}$$

Suppose that the beam shown in Fig. 2 is continuous over three supports and that the third support is at "a." To determine the reaction there it is required to find the single force which will cause a deflection at "a" of .1095 inches in the same beam. Substituting the numerical values in the formula for the deflection of a point on a beam with a single load and solving for the unknown load, it becomes in this case equal to 2,160 pounds. If this force of 2,160 pounds were to act upwards at point "a" in Fig. 2 it would deflect that point back to zero and the deflection curve for the beam over three supports would pass through zero.

In order to plot the deflection curve, plot first the deflection curve for the upward reaction in the same manner as demonstrated above. Observe that the same pole distances and the same scales should be used, so that the scale of this deflection curve will be the same as the previous one above. The final curve may be plotted by taking the algebraic sum of the ordinates of each curve at each point.

A fourth reaction might now be considered and treated in the same manner, but the solution would be much more complicated and laborious. It would require the drawing of a deflection curve for the beam over three supports and loaded with this fourth reaction. No new methods would be involved, however, and the work has, therefore, not been extended.

Besides being valuable as a practical application, those who are teaching the subject of the deflection of beams will find the above method very instructive. It shows graphically to the student the relations of the shearing force, bending moment, slope and deflection curves to one another.

TORONTO ELECTRIC DISTRIBUTION SYSTEM.

A quantity of underground work in connection with the Hydro-Electric distribution system has recently been under construction in Toronto. This consists of building a 15-duct run on the south side of King Street from John Street to Jarvis Street. Single 3-in clay ducts are laid three wide and five high, the top layer being square bore distributer duct. Several difficult channels have had to be made under car tracks—namely at York Street, Bay Street, Yonge Street, and Church Street. A single fibre duct of 3-in. diameter is used to connect run to all service boxes in the old run in the sidewalk. The ducts are encased in three inches of concrete and are laid with a minimum cover of 30 ins. from top of pavement.

In addition to the above work six large concrete transformer pits are being built. The dimensions of these pits are 9 ft. x 20 ft. deep, inside measurement. The pits will have 13-in. concrete walls and will be provided with special ventilation chambers. These pits are of sufficient size to take care of additional load in future years.

RAILWAY EXTENSION IN CHILE.

The Northern Longitudinal Railway of Chile is now in full operation, the work being entirely completed connecting Pisagua in the north of Chile with Valparaiso, Santiago, and Puerto Montt, well to the south of the country, a distance of about 1,960 miles. The new portion from Iquique to Calera, a distance of about 750 miles, has been constructed within the past three years; has cost about $40,000,000; and is to be operated for 50 years by the Chilean Northern Railway Company, Calera, Chile, an operating company organized by the Howard syndicate, which supplied the money under a guaranty from the Chilean Government. The gauge of this line is 3.28 feet, while the gauge of the old portion of the Longitudinal Railway is 5 feet 6 inches. A full description of this railway appeared in *The Canadian Engineer* for March 19th, 1914.

C. S. Cameron, secretary and treasurer of the Sydney Steel plant, has gone to England to investigate the opportunities for trade in the British market.

REINFORCED CONCRETE DOCK FAILURES.

THE subject of reinforced concrete dock construction has been given considerable study in these columns. In our issues of August 27th and October 1st, the extent of this form of dock construction was outlined as regards practice in England and America respectively. In reviewing what has been done thus with reinforced concrete, it is necessary to state that it has not withstood in every instance subjection to the action of sea water. For the results of an extensive investigation into the effect of alkali and sea water upon concrete structures, the reader is referred to an article on the subject in *The Canadian Engineer*, July 31, 1913, page 233. The following, which is a continuation of the subject of reinforced concrete dock construction, outlines the failures that have occurred, and it is to be noted that they are due chiefly to the above cause.

In discussing reinforced concrete docks, the fact that there have been failures among them must not be overlooked. In Massachusetts waters, north of Cape Cod, a number of serious cases of deterioration of concrete have been caused by the disintegrating effects of sea water, wave action, and frost, especially in Boston Harbor, where nearly all the concrete structures standing in sea water have been affected badly between high and low tide, the most notable instance of which is the concrete pier at the Charleston Navy Yard. Although that part of the pier which is constantly submerged has given but little trouble, the part exposed alternately to the sea and air has been seriously affected, many large pieces having broken completely away, making it self-evident that some other agent than the chemical action between cement and sea water was at work.

As is well known, winter temperatures on the whole eastern front of the New England Coast run far below zero. In Boston Harbor 12° below zero is not uncommon. In the same way that hard earth and porous rocks are broken up by frost action, permeable concrete in freezing water will gradually be destroyed between wind and sea, as the water which gets into the concrete simply exercises its natural expanding function in freezing, which *a priori* is detrimental to the concrete structure. It is generally admitted that the exterior concrete in these Boston structures, especially in the Navy Yard pier, has failed almost entirely from the effect of the alternate freezing and thawing with each tide during the winter, due to permeable concrete.

A number of failures similar to that already cited have occurred in Boston, the disintegration taking place in all cases between low and high tides. In the case of the Dover Street draw-bridge pier, built in 1894, the disintegration had extended 1.4 ft. into the pier at the end of 17 years, the greatest damage being just below high-tide level. The pier was built of 1 : 2 : 5 concrete, with a 1-in. plastered mortar facing. English Portland cement was used throughout. Whether the 1-in. facing mortar was expected to act as a waterproof shield to the interior concrete is not apparent. Evidently, it did not act thus, as might have been expected.

As all the concrete in these disastrous cases seems to have been placed in the wet, that is, the sea water was allowed to come in contact with the concrete before it had become thoroughly cured and hardened, such results are not to be wondered at, for one of the axioms of a successful use of concrete in sea water is that it must be kept from contact with sea water for such a period of time as to enable it to become thoroughly hardened, especially that part between tides in freezing climates.

In several cases in Boston Harbor where the concrete was placed inside of a coffer-dam, or used in the form of pre-moulded, driven, concrete piles, the concrete does not seem to have been affected as in the other cases cited. These successful cases go a long way toward substantiating the truism that concrete, to be used successfully in sea water, especially in freezing water, must be made impermeable in the process of making, with full consideration given to the brand of cement used, the mixture, the sand, and stone (or gravel), the skilled labor of placing, as well as keeping it from contact with sea water until it has set and hardened sufficiently. It is very apparent, from a study of the method used in placing the concrete in the disintegrated structures in Boston Harbor, that that method was far from possessing the essential features necessary for a successful solution of the problem, viewed in the light of present-day knowledge.

In comparison with these Boston failures, it is fitting to state that at Dundee, Scotland, where the climatic conditions are said to be worse than at Boston, and where there is a rise and fall of the tide of about 12 ft., the combined action of the sea, waves, and frost has had no ill effect on the concrete docks in that harbor, the concrete piles of which were allowed to harden for 30 days before being put in place.

Another noted case of the destruction of concrete by frost and sea action is the large concrete sea wall along the water front of Lynn, Mass.—a massive concrete sea wall exposed to the pounding of the winter storms and seas. The steps to the beach in the front of this wall were destroyed to such an extent as to be hardly recognizable as steps. It might be of interest to state that this wall and some of the damaged structures in Boston harbor have apparently been repaired effectively by the cemen gun process.

In reviewing these failures in Boston and vicinity, it is well to consider the results obtained in using concrete in another port subject to freezing and ice conditions, viz., New York Harbor. In addition to freezing conditions, New York Harbor has to contend with a strong tidal effect, which results in large solid ice floes and fields of broken ice moving back and forth with a tide of considerable velocity, ice floes of such size coming down the Hudson as at times practically to compel abandonment of all transfer traffic in that river. This is an effect from which Boston docks are perhaps free, as no large rivers flow into that harbor, the Charles being kept under control by the so-called Charles River Dam.

In discussing this additional handicap and destructive force at work on New York City's 8¼ miles of concrete sea walls, some of which have been in existence for 41 years, Charles W. Staniford, M. Am. Soc. C.E., Chief Engineer of the New York Department of Docks and Ferries, states:

"Up to the present time (August, 1911), no disintegration has been discovered that can be attributed to the existence of the structure in salt water. The concrete itself is in an admirable state of preservation, absolutely hard, and is undergoing no regular process of disintegration." * * * "this sea-wall which has been under construction * * * for 41 years, is at the present time an excellent piece of work and is subject to the same climatic conditions as all cities on the Northern Atlantic Coast with the attending ice, cold and rain characteristic of this latitude."

In many instances, parts of this wall above low water are faced with granite blocks. This is a noted example of what can be expected in the way of using mass concrete in sea water if properly made, though perhaps some repair work has been necessary in order to maintain the excellent condition of the wall.

In some of the earlier sections of this wall the concrete was placed "*en-mass*-in-site," but, since 1876, most of the wall has been built by the concrete block method. Only under specially favorable conditions is it possible to place concrete successfully *in situ* under (sea) water, as it becomes disintegrated "through the chemical action of the sulphate of magnesia on fresh concrete or through the resulting porosity of concrete due to the impossibility of tamping under water";* the viscosity and weight of the mass not being sufficient to produce such a dense material as obtained in block work.

To discuss an opposite case in New York Harbor, viz., Dry Dock No. 2, New York Navy Yard, originally built of timber in 1890, the history of which it is not necessary to relate here: In 1900 this dock was rebuilt, concrete being used very extensively. During 1913 a large sum was expended in repairing and replacing the concrete altars and floors. As it has been stated that the difficulties of using concrete in sea water have been so great at this yard as to indicate that this is not a permanent material for use in sea water structures, it would be of deep interest to learn the facts as to the chemical composition of the cement used, of the sand and stone, as to the mixture thereof, and the precautions taken in mixing and placing; also as to whether the dock is kept flooded when not in use, especially during the winter. If, as has been stated, the concrete "has deteriorated and disintegrated to such an extent that it was possible to use a pick and shovel in removing it," it is apparent that it was lacking in one or more of the essential features that are deemed absolutely necessary for a successful use of concrete in sea water structures.

Whether any of the concrete pile docks on the Great Lakes have shown any signs of deterioration due to frost action, the writer does not know, but trusts that some facts covering this question will be brought out in the discussion. As the water level is practically the same all through the winter, only a very short length of the pile would be affected, and not some 10 ft., as in Boston Harbor.

One of the first concrete docks built in San Francisco is said to have failed in part due to poor construction. The early method of building the concrete columns of San Francisco concrete docks was to use a wooden cylinder, strongly built, as a column form, into which, it has been stated, the concrete was poured, apparently without any attempt to pump out the cylinder. As long as the wooden cylindrical forms remained in place around the supposedly concrete column, the dock was pronounced a success. When the teredo had finally destroyed the forms, the columns began to collapse and the dock became a pronounced failure, because, in pouring the concrete, the heavier material—the stone or gravel—settled first, then the sand, and finally the cement. The result was that throughout the length of the concrete columns there were alternate layers of uncemented stone and sand, with the cement in between the sand of one batch and the stone of the following one. Concrete can be and is successfully dropped through a height of 50 ft.—and even up to 100 ft. in one noted case in Arizona—but, if the receptacle into which it is dropped is full of water, disaster alone awaits the unfortunate engineer.

In another of the San Francisco docks, where wooden piles supported the concrete columns, the concrete was not carried down below the mud line a sufficient distance to prevent the teredo from destroying the piles below the concrete.

The question has been raised: Has any deterioration taken place in concrete structures standing in sea water in the harbors of the Southern States, where frost action is unknown? The most prominent concrete structure thus situated is the famous viaduct across the Florida Keys, built of Alsen cement, imported from Germany. It is possible that some of the members of this society are in a position to give complete information regarding the action of salt water and the waves of the Gulf on this structure.

In order to guard against the disintegration (irrespective of its cause) of mass concrete placed *in situ* above low water, or to repair any damage that has been done, besides the cement gun process, various methods have been used, all based on the fundamental principle of using an impermeable material for the facing of the structure. Below low water, properly made block work has given most satisfactory results. Carefully made, fully cured pre-moulded concrete piles seem to resist the action of the sea and frost successfully. In Holland, hard, impermeable brick have been used to prevent any further damage to one of the breakwaters above low water. In England, the upper parts of massive breakwaters are mostly faced with granite or some other hard suitable stone. In Nova Scotia, both brick and pre-moulded blocks of concrete of small size were placed on the face of a concrete sea wall after the disintegrated concrete had been removed. A still more recent device is the use of hollow, vitrified, salt-glazed tile blocks filled with concrete after being put in place. Experiments thus far seem to have proved that:

"Vitrified salt-glazed tile is impervious to any deteriorating action of sea water, and has an effective structure against the battering of ice; it is so dense as to preclude the possibility of any water entering and freezing in it to the consequent destruction of the tile."

Though oiled concrete is being used as a waterproof material in certain cases, it is possible that the refuse, oil, gases, etc., discharged from certain classes of buildings, etc., might have a destructive effect on the concrete foundation piles or other parts of the building, especially in sea water heavily charged with sewage. It is a well-known fact that concrete sewers will not perform their duty properly for any length of time unless they have a brick lining invert, over which flows the heavy sludge. In time of flood the surface water is so great as to dilute the sewage and prevent injurious effects. The writer would be pleased to hear opinions on this point, as it is possible that a destructive effect might have been caused by sewage in connection with one of the most seriously affected cases in Boston.

Although poor results seem to have attended quite a number of the reinforced concrete structures standing in sea water in America, the opposite appears to have been true in foreign countries. Still, a few failures are on record as having occurred in England and Germany, due mostly to permeable concrete.

---

*This subject is discussed further by the writer in an article entitled "Chemistry of Salt Water Cement," Metallurgical and Chemical Engineering, January and February, 1914.

GERMANY ELIMINATED FROM THE IRON AND STEEL TRADE.

THE German export business in iron and steel and manufactures thereof is rapidly being distributed among other nations, chiefly Great Britain and the United States. How extensive this transformation is, and to what degree these two countries may be relied upon to adequately supply the demand occasioned by the suspension of German exports, appear from the following comparative figures. It is to be noted that the figures pertaining to Germany and the United States include not only iron and steel, but also manufactures thereof, such as machinery and hardware, whereas the British figures comprise iron and steel alone:

Year.	Germany. (in marks)	United States. $	Great Britain. Tons.	Great Britain. £
1912 ..	1,275,053,000	259,709,399	4,814,005	49,800,000
1911 ..	1,100,133,000	230,725,351	4,515,905	44,800,000
1910 ..	923,705,000	179,133,186	4,588,009	42,976,671
1909 ..	780,760,000	144,951,357	4,210,799	38,192,142
1908 ..	772,673,000	183,982,182	4,096,521	37,406,028
1907 ..	852,650,000	181,530,871	5,152,227	46,563,386
1906 ..	715,043,000	160,984,985	4,682,200	39,840,595
1905 ..	639,934,000	134,728,363	3,721,382	31,826,438
1904 ..	582,322,000	111,948,586	3,262,842	28,066,671
1903 ..	634,361,000	96,642,467	3,564,601	30,399,261
1902 ..	603,375,000	98,552,562	3,579,104	28,877,337
1901 ..	517,259,000	117,319,320	2,897,719	25,008,757
1900 ..	479,609,000	121,913,548	3,540,689	31,623,353
1896 ..	337,540,000	41,160,877	3,550,398	23,462,793

Because of the difference in classification methods, comparisons drawn from these figures are somewhat unfair to Great Britain in that British exports of iron and steel and manufactures thereof increase more rapidly than her exports of iron and steel alone. However, it is still true that Germany has been increasing her iron and steel export trade more rapidly than Great Britain, but less rapidly than the United States.

Since the panic of 1907 German exports have increased in value 65.01%, while those of the United States have grown 110.14%. British exports of steel and iron, in tons, meantime increased 17.51%. But if the British figures included manufactures of iron and steel, they would show a gain of about 30% or 35%. From 1907 to 1912 the gain in British exports of iron and steel alone, as measured in pounds sterling, was 33.15%, as compared with 64.81% in German exports likewise classified.

Great Britain, Germany and the United States are the world's great steel makers; and with Germany eliminated for an indefinite period there should be a large opportunity for her two great competitors. The value of her exports in 1912, when reduced to our money, was $303,462,600; and much of this foreign trade was in steel products and, therefore, competitive merchandise. The largest single item of steel and iron themselves was malleable iron bars, and next to this came steel rails, then rough bars and ingots, iron wire, plates and sheets, and angle iron. The other countries produce large quantities of all of these; and what is more to the point is that the plant capacity of their steel mills has been so vastly increased during the past few years that if allowed to do so they could probably supply all of Germany's foreign customers in these products, as well as their own.

Water-Bound Macadam is being used in the Panama-Pacific Exposition for most of the streets and driveways, the total wearing surface of which is about 144,000 sq. yds.

SOME TUNNELING COSTS.

(Continued from last week.)

Stilwell Tunnel.

Location: Telluride, Colo.

Purpose: Mine drainage and development.

Cross-section: Square, with ditch at side.

Size: 7 by 7 feet.

Length: 2,950 feet.

Character of rock penetrated: Conglomerate and andesite.

Type of power: Purchased electric current.

Ventilator: Fan.

Size of ventilating pipe: 10 inches.

Drills: Started with electric drills, finished with pneumatic piston drills, using 2 in the heading.

Mounting of drills: Vertical columns.

Number of holes per round: 16.

Average depth of round: 6 to 6½ feet.

Number of drillers and helpers per shift: 2 drillers and 2 helpers.

Number of drill shifts per day: 1.

Explosive: 40 per cent. gelatine dynamite.

Number of muckers per shift: 3.

Number of mucking shifts per day: 1.

Type of haulage: Horses.

Wages: Drillers $4.50, helpers $4, muckers and trammers $3.50, blacksmith $4.50.

Maximum progress in any calendar month: 170 feet, August, 1904.

Average monthly progress: 150 feet (last 10 months).

Cost of Driving.

	Feet.	Cost per foot of tunnel.
1901	12	$23.88
1901-2	490	22.98
1902-3	377	27.94
1903-4	702	21.69
1904-5	1,077	21.19
1905	292	30.37
Average for	2,950	$23.38

These costs include all labor, supplies, repairs, powder, fuse, caps, candles, tools, lubricants, and general expenses, and the total value of the electric-drill plant with which the tunnel was started, and the total value of the air-drill plant which succeeded it, together with tunnel buildings, pipe, rails, and the ventilator, with no credit for salvage on any of this permanent equipment.

The fiscal year dated from September 30.

The tunnel was driven in 1901-3 with electric drills, and the high cost for:

1905 .... 292 $30.37

Strawberry Tunnel.

Location: Utah and Wasatch Counties, Utah.

Purpose: Irrigation and reclamation.

Cross-section: Straight bottom and walls, with arched roof.

Size: 8 feet wide by 9½ feet high.

Length: 19,100 feet.

Character of rock penetrated: Limestone with interbedded sandstone, and sandstone with interbedded shale.

Type of power: Electric power generated in a hydraulic plant operated in connection with the tunnel. Dis-

tance of transmission from west portal to power house approximately 23 miles.

Ventilator: Pressure blower.

Size of ventilating pipe: 14 inches.

Drills: Piston pneumatic, usually 2 in the heading.

Mounting of drills: Vertical columns.

Number of holes per round: 16 to 18.

Number of drillers and helpers per shift: 2 drillers and 2 helpers.

Number of drill shifts per day: 3.

Explosive: 40 per cent. gelatine dynamite.

Number of muckers per shift: 6.

Number of mucking shifts per day: 3.

Type of haulage: Electric after first 2,000 feet.

Wages: Drillers $3.50, helpers $3.25, muckers $2.75, motormen $3.25, brakemen $2.75, blacksmiths $4, helpers $2.75.

Maximum progress in any calendar month: 500 feet, November, 1910.

Average monthly progress: 320 feet per heading.

Cost of Driving.

	Feet.	Cost per foot of tunnel.
West heading:		
Previous to 1909	1,613	$60.05
During 1909	3,892	33.58
During 1910	5,021	30.56
During 1911	3,491	41.52
January to July, 1912	2,382	36.79
East heading:		
October, 1911, to July, 1912	2,682	33.04
Average for	19,081	$36.78

Detailed Cost of Driving the West Heading for the Year 1909, 3,892 Feet.

	Cost per foot of tunnel.	
Labor:		
Engineering	$0.49	
Superintendence	.73	
Shift bosses	1.22	
Timekeepers	.36	
Drillmen and helpers	3.15	
Miners (for handwork, trimming, etc.)	.23	
Muckers	2.96	
Track and dumpmen	.74	
Mule drivers	.39	
Motormen and brakemen	.44	
Electricians and blower men	.07	
Disabled employees	.19	
Timbermen	.22	
Miscellaneous	.40	
		$11.59
Materials:		
Powder, fuse, caps, etc.	3.08	
Lumber	.29	
Oils, candles, etc.	.22	
Ventilating pipe	.64	
Track, including ties	.68	
Pressure air pipe	.40	
Drill repair parts (including hose)	.18	
Miscellaneous	.19	
		5.68
Repairs:		
Machine-shop expense (including labor and supplies)	.93	
Blacksmith-shop expense (including labor and supplies)	1.22	
		2.15
Power (all purposes)		7.65
Depreciation:		
Haulage equipment	.09	
General equipment	1.00	
		1.09
General expense	3.96	
Camp expense	1.21	
Corral expense	.25	
		5.42
Total		$33.58

"General expense" includes a proportionate charge for the expenses of the Provo office, such as salaries, stationery, telephone, and supplies; also a proportionate charge for the expenses of the Washington, the Chicago, and the supervising engineer's offices. The Provo office covers approximately 68 per cent. of this charge, the Washington office 23 per cent., the Chicago office 2 per cent., and the supervising engineer's office 7 per cent.

Gunnison Tunnel.

Location: Montrose, Colo.

Purpose: Irrigation and reclamation.

Shape of cross-section: Horseshoe.

Size: 10 feet wide at the bottom, 10 feet 6 inches wide at the spring line, 10 feet high at the spring line, 12 feet 4 inches high at the centre of the arch.

Length: 30,645 feet.

Character of rock penetrated: Chiefly metamorphosed granite with some water-bearing clay and gravel, some hard black shale, and a zone of faulted and broken rock.

Type of power: Steam.

Ventilator: Pressure blower.

Size of ventilating pipe: 17 inches.

Drills: At first, pneumatic hammer, 4 drills in the heading; afterwards, pneumatic piston, 4 drills in the heading.

Mounting of drills: Horizontal bar for the hammer drills, vertical columns for the piston drills.

Number of holes per round: 20 to 24 in the heading (approximately one-half of the tunnel).

Average depth of round: 6 to 7 feet.

Number of drillers and helpers per shift: 4 drillers and 2 helpers.

Number of drill shifts per day: 3.

Explosive: 60 per cent. gelatine dynamite, with some 40 per cent.

Number of muckers per shift: 5 to 8.

Number of mucking shifts per day: 3.

Type of haulage: Electric.

Wages: Drillers $3.50 and $4, helpers $3 and $3.50, muckers $2.50 and $3, blacksmiths $3.50 and $4, motormen $3, brakemen $2.50 and $3, power engineers $4.

Maximum progress in any calendar month: 449 feet.

Average monthly progress: 250 feet, approximately.

Cost of Driving.

	Cost per foot of tunnel.
10,019 feet driven by undercut heading and subsequent enlargement	$87.23
20,626 feet driven by top heading and bench	62.18
Average cost of excavation of entire tunnel	70.66

These costs include all labor, all materials, all repairs, all power, depreciation figured as 100 per cent. on all equipment, with a proportionate charge for general (supervisory) and miscellaneous expenses of the entire reclamation project.

LARAMIE-POUDRE TUNNEL.

Location: Home, Colo.

Purpose: Irrigation.

Cross-section: Rectangular.

Size: 9½ feet wide by 7½ feet high.

Length: 11,306 feet.

Character of rock penetrated: Close-grained red and gray granite.

Type of power: Hydraulic at the east end, electric at the west.

Ventilator: Pressure blower.

Size of ventilating pipe: 14 and 15 inches.

Drills: 3 pneumatic hammer.

Mounting of drills: Horizontal bar.

Number of holes per round: 21 to 23.

Average depth of round: 10 feet at first, 7 to 8 feet later.

Number of drillers and helpers per shift: 3 drillers, 2 helpers.

Number of drill shifts per day: 3.

Explosive: 60 per cent. gelatine dynamite, with some 100 per cent. in the cut holes.

Number of muckers per shift: 6.

Number of mucking shifts per day: 3.

Type of haulage: Mules.

Wages: Drillers $4.50, helpers $4, muckers $3.50, blacksmiths $5, drivers $4.50, dumpmen $3.50.

Maximum progress in any calendar month: 653 feet, March, 1911.

Average monthly progress: 509 feet (for the 16 months when complete plant operated).

Special feature: Inaccessibility; the tunnel was located about 60 miles from the nearest railroad siding, and the roads were mountainous and very steep in places.

Cost of Driving 11,306 Feet.

	Cost per foot of tunnel.
Superintendents and foremen	$1.50
Drilling	4.47
Mucking and loading	4.92
Tramming and dumping	4.63
Track and pipe	.47
Power house	.35
Blacksmithing	.84
Repairs	.47
Bonus to workmen	1.75
Maintenance of camps, buildings and fuel	.62
Machinery repairs	.12
Air drills and parts	1.33
Picks, shovels and steel	.84
Explosives	4.50
Lamps and candles	.42
Oil and waste	.38
Blacksmith supplies	.53
Liability insurance	.81
Office supplies, telephone and bookkeeping	.86
	$29.81
Permanent equipment (less approximately 10 per cent. salvage)	9.73
	$39.54

The permanent equipment included power plant, camp buildings and furnishings, pipes, rails, etc.

PRESERVATIVE TREATMENT OF POLES FOR LINE WIRES.

THE normal yearly production of poles in the United States is about 2,750,000, and to-day there are, approximately, over 50,000,000 poles supporting wires, either telephone, telegraph, light, or power. It is only of recent years that the pole user could be induced to take the precaution of preserving his timber.

In the last few years, prompted by their increased price, there is hardly a pole set without the owner's having some idea of preserving it. He begins to compare what he or his predecessor formerly paid for a pole with the present price, hence he begins to figure how to stop the expense of replacing rotten poles.

Since the records obtained in the past years show what ingredients remain in treated timbers the greatest period of time, it is natural to conclude that a good preservative should contain as great an amount of these ingredients as it is possible to obtain. The impregnating process, while one of the oldest methods known, is yet in its infancy. The records referred to, however, are based on timbers which had been treated with a tar oil under pressure. This method, if properly used, is frequently so expensive that the additional cost makes its use prohibitory.

It is the high boiling oils of coal tar which preserve timber, because that is what was obtained by subjecting the preserved timbers to dry distillation. The records do not show whether or not these high boiling oils originally contained any neutral, such as paraffin or similar oils, which have not as yet been proven germicidal.

The average tar oil obtainable, which is forced into timber under pressure, contains from 15 to 35 per cent. oil distilling above 300 degrees centigrade. Hence, if an oil that contained 35 per cent. distilling above 300 degrees centigrade, at most, which had been injected into the timber showed such excellent results, it is reasonable to suppose that a lesser amount of oil containing proportionally a greater per cent. of distillate above 300 degrees centigrade will bring good results when properly applied.

It is important for the one who supposes petroleum to be a preservative to exercise much care in the selection of the petroleum because it may prove an unwise form of economy, as it has repeatedly.

In 1900 the C-A-Wood-Preserver Company began directing attention to the value of high boiling tar oils as against the offered "secret" or "patented" process in connection with preservatives. Since scientific investigations by the government and others have substantiated these theories and arguments, some are attempting to use preservatives which are the high boiling portions of crude petroleum. These mislead the chemist unless he make the sulphonation test. The company mentioned, in 1886, sold one of the first barrels of coal tar distillate that came to America. This product, which was intended for the superficial method, distilled only 75 per cent. above 300 degrees centigrade. Eleven years afterward this was increased to 85 per cent. and during the summer of 1909 to 92 per cent. This was the highest mark reached so far and it required special machinery to produce it.

It is practically impossible to produce a successful oil distilling more than 92 per cent. above 300 degrees centigrade according to the United States Forest Service method of analysis, as it would solidify at normal temperature if it were free from petroleum residues or similar oils. Some tars will distill much more than 92 per cent.

above 300 degrees centigrade, but they are not free from the paraffin oils which have a high boiling point though they are nongermicidal.

While it has been less than a year since a strictly coal tar distillate containing as much as 92 per cent. liquid residue (oil) above 300 degrees centigrade (United States Forest Service method) has been manufactured and put on the market, it may be interesting to note a few records and illustrations of the methods of application and results derived from the use of that heretofore produced, or from the oil distilling 85 per cent. above 300 degrees centigrade.

After determining the quality of preservative, the pole user is interested in the method of application. The brush method is the simplest and most universally used. Next is the pouring system, which is done in two ways. One consists of a portable tank, while the other is stationary, the poles being conveyed to the treating tank.

Poles which are already erected and which have begun to show decay can be saved by a very simple method. By digging away the earth to a depth of about two feet around the pole, applying two coats of a good preservative with a brush and then replacing the earth, the pole is saved. Rot is caused by a germ and the preservative being a germicide or antiseptic kills those present when applied to the decaying parts and its presence in the wood prevents future decay as well. The manager of the Memphis (Tenn.) Telephone Company, in 1904, made this experiment on cypress poles and he reports them in perfect condition to-day with every evidence of lasting many years longer. The Austin (Texas) Electric Railway Company has likewise found this a most successful experiment on cedar poles.

Cross arms can be treated by the brush method, however, the complete dipping or immersion is the more favorable. The cost of treating a pole depends upon its size, character, condition, price of the preservative and the amount used—whether it be treated at the ground line only or the entire butt end. There is a variation from four cents to perhaps a dollar per pole and each user of poles knows best what he can afford to pay for the protection of his timber.

Last, but not the least important, it should be noted that under no circumstances should unseasoned or green timber be treated, regardless of the preservative used; it must be at least partly seasoned to allow penetration.—*Municipal Engineering.*

MILEAGE ON THE N.T.R.

The accompanying chart, denoting the mileage between principal points on the Eastern Division, (Moncton to Winnipeg), of the National Transcontinental Railway is self-explanatory. Special attention is called to it, however, in connection with the concise review of the construction of the N.T.R. appearing in *The Canadian Engineer* for September 17th, 1914. As stated there, the whole line is expected to be ready to cope with its share of the western wheat crop in the course of a few weeks, at which time ballasting, and erection of buildings, etc., will have been completed.

NATIONAL TRANSCONTINENTAL RAILWAY
EASTERN DIVISION

MILEAGE BETWEEN PRINCIPAL POINTS

A. O. Cook
Asst to Chief Engineer.

Editorial

A NEW PHASE OF WAR ENGINEERING.

The part played by engineering in the present European conflict is something for the details of which we may be obliged to wait a considerable length of time. The continual shifting of positions by the contending armies, however, impress us as sufficient to require a most remarkable manipulation of guns and supplies over rough country whose transportation routes have already been blocked and destroyed. This work falls naturally to the military engineers.

An outstanding feature of the methods of transportation and communication is the extensive use of the motor truck. It has brought about a revolution in transportation methods and has made possible the manoeuvring of millions of men and the required equipment of various classes of guns, ammunition, provisions, etc. These trucks are, for the most part, of ordinary type. This we know from the knowledge that Germany, France and England have systematically subsidized motor trucks during recent years on condition that they be available for governmental use in case of need. In Germany the subsidy amounted to $2,000, one-half of which was applied to the purchase price, and $250 of which was applied on upkeep yearly for four years. These trucks were to have a capacity of 6½ tons, to run 10 miles an hour with full load, to climb a 10% grade, and to haul one, or, if necessary, two trailers. At the beginning of 1912 over 800 trucks had been subsidized and the number has very greatly increased since that time, the government having power to requisition every motor vehicle in the German Empire.

In France a subsidy of $600 toward purchase, and $200 a year for three years toward upkeep, could be obtained from the government by owners of trucks of capacity of over three tons.

Great Britain allows a subsidy varying from $40 to $60 per vehicle and $75 a year for upkeep. Austria also subsidizes motor trucks and has a right to take possession in times of need.

The result is that motor trucks are brought into commission in almost every conceivable way for the rapid transportation of men and supplies. Artillery is, to a considerable extent, hauled by motors. This applies particularly to big motors such as constitute the heavy siege artillery. Many of these guns are known to weigh from 8 to 20 tons, while it is stated that there are larger pieces weighing 40 tons each, and at least as much more for the gun carriage. The projectile which such a gun uses weighs approximately a ton. It is evident that the transportation of these pieces of artillery, together with their ammunition supply, over stretches of country where there are no railroad facilities and whose bridges, etc., have been previously destroyed, is an engineering task that requires utmost skill, as the manipulation has to be prompt and absolutely reliable, since there may be depending upon the service armies of hundreds of thousands of men.

It is interesting to note that the Canadian expeditionary force at present on its way to Great Britain possesses an extensive motor equipment, including motors for mechanical transport, armoured cars with machine-guns, motor-drawn trucks, motor ambulances, touring cars for the officers and an armoured motor machine shop. This shop is very complete in itself with a full equipment of tools and lathes.

The problem of transportation is sufficiently gigantic of itself to evidence the dependence of military manoeuvres upon the engineering corps. There are other problems, such as those of entrenchments and fortifications, of water purification and sanitation—problems that are of an impromptu nature requiring immediate solution, thereby differing from the engineering that has already made itself evident in the design and construction of artillery pieces, ammunition, etc., while the world was yet at peace.

OPPORTUNITY FOR CANADIAN ELECTRICAL MANUFACTURERS.

Canadian exports of electrical apparatus amounted last year to $215,546. Imports, on the other hand, amounted to $9,098,736. At the present time there is a scarcity in England of electrical apparatus. It is only a few days ago that a newly established foreign trade commission in Pittsburgh, Pa., had a communication from a large engineering equipment house in London, England, stating that owing to the war its orders could not be filled and asking to be put in touch with Pittsburgh firms supplying all kinds of electrical equipment and machinery.

In view of the above figures of Canadian foreign trade in electrical apparatus, it is somewhat improbable for Canada to hope to export largely to Great Britain unless her productive capacity is materially increased. That Britain, whose supplies from Germany in this line amounted last year to £721,078 will have to look elsewhere should be an inducement of no small magnitude to Canadian manufacturers of electrical machinery and apparatus. The portion of the demand that might be supplied in this country is small, perhaps, in proportion to that which the United States is prepared to look after. Last year Great Britain's imports of these supplies from the United States attained a value of £437,906. Canadian manufacturers, however, should give the problem their very careful consideration at the present time. There is undoubtedly a market and that market is a country with which we are more closely associated than any other.

TRANSFER OF LOCOMOTIVE CONTRACTS.

Owing to the European war and the immediate cessation of trade relations with Germany the supply of railway locomotives and rolling stock, for which Germany has long been a keen contender, is rapidly undergoing a change in its source of manufacture. Before war broke out the leading German companies had in hand some enormous orders from British and overseas railways. One of the most important contracts comprises a large number of passenger carriages for the new electrified services around Buenos Ayres of the Central Argentine Railway Company. This contract was originally placed with a Hanover firm, but has now been awarded to the

Metropolitan Amalgamated Railway Carriage Company, of Birmingham.

South Africa and New Zealand had large orders for locomotives with the Maffic Company, of Munich. The Hanover company were also building thirty-four passenger carriages for the Union of South Africa railways.

Kersckel of Casel had orders for eighteen heavy main line engines for South Indian and some Argentine railways.

The Hanover Machine factory was building locomotives for the Bengal railway and Taff Vale railway, and the Hohenzollern works at Dusseldorff were building six powerful shunting locomotives for the Port of London authorities.

All these contracts now have been cancelled and shortly will be divided amongst British and American engineers.

AMERICAN ROAD BUILDERS' CONVENTION, CHICAGO.

The programme committee of the American Road Builders' Association reports that plans for the 11th Annual Convention to be held in Chicago, Dec. 14-18, are near completion. The general features of the programme have been decided upon, practically all of the subjects have been chosen and the assignment of speakers is now being made.

Registration will be carried on throughout Monday afternoon and evening. The forenoon of Tuesday, Dec. 15, will be devoted to the reception of delegates and visitors and to committee meetings, other preliminary business and the inspection of exhibits. At 2.30 p.m. the Congress will be formally called to order by President W. A. McLean, Provincial Highway Engineer of Ontario, and addresses of welcome will be given by officials of the city of Chicago, the state of Illinois, the Illinois Highway Commission, the University of Illinois, the Illinois Society of Civil Engineers and Surveyors, and the Illinois Highway Improvement Association.

The technical sessions will commence on Wednesday, and will be held each morning and afternoon until the close of the convention. On Wednesday evening, the Association will hold its annual dinner.

Essentially the same plan for the programme as that adopted at recent conventions of the Association will be followed. The various subjects to be treated have been so chosen as to cover the important phases of the three general divisions of the subject of highway work: Organization, Construction and Maintenance. Each topic will be introduced by a short paper presented by an authority especially selected for his knowledge of the subject on which he will speak. The discussion on that topic will then be opened by an especially selected speaker, who will be followed by other speakers, also selected because of their familiarity with the subject. The discussion will then be open for anyone who chooses to take part.

Among the topics to be treated are the following:—"Road and Pavement Dimensions—Widths, Depths and Crown;" "Road Foundations—Concrete, Telford, Gravel, etc.;" "Organization;" "Traffic—Present Tendencies, Probable Development and Regulation;" "Machinery for Construction and Maintenance;" "Brick Roads and Streets;" "Surface or Floors for Bridges;" "Bituminous Construction and Maintenance—Recent Practice;" "Concrete Roads;" "Recent Practice in the Construction of Wood and Granite Block Pavements;" "Earth and Gravel Road Construction;" "Street Paving in Small Cities;" "Convict Labor in Road Construction," and "Dust Prevention and Street Cleaning."

STEEL PRODUCTION IN CANADA, 1913.

PRODUCTION of all kinds of steel ingots and castings in Canada in 1913 amounted to 1,042,503 gross tons, an increase of 189,472 tons above 1912, according to the report issued by the American Iron and Steel Institute. Of the 1913 production, 1,006,149 tons were ingots and 36,354 tons were direct steel castings, being respective increases above 1912 of 185,357 and 4,115 tons.

The total productions of steel ingots and castings has increased rapidly in recent years, and the 1913 output was by far the largest in the history of Canada.

A table covering the production by both classes in gross tons, during the last ten years, follows:

Years.	Ingots.	Castings.
1913	1,006,149	36,354
1912	820,792	32,239
1911	768,559	22,312
1910	723,002	18,922
1909	664,789	13,962
1908	500,300	9,657
1907	629,026	17,728
1906	555,913	14,976
1905	394,955	9,394
1904	142,279	6,505

Plants Involved.—In 1913 there were sixteen steel works engaged in the manufacture of ingots or castings, compared with fourteen in 1912. There were four idle works in 1913, compared with three in 1912. In regard to processes, the production of Bessemer steel ingots and castings in 1913 was 273,391 tons, an increase of 65,822 above 1912. The output of open-hearth steel ingots and castings in 1913 amounted to 768,663 tons, which was 123,601 above 1912. Nearly all Bessemer steel made in the last two years was in the form of ingots. Of the 1913 open-hearth production, 736,562 tons was in ingots and 32,101 in castings.

The production of all kinds of finished rolled iron and steel in 1913 amounted to 967,097 tons, an increase of 105,873 tons, and also was the largest in the Dominion's history. Of last year's output about 95,881 tons were iron and 871,216 steel.

Finished Iron and Steel.—The production of all kinds of finished rolled iron and steel, in gross tons, by provinces, during a two-year period, follows:

Provinces.	1913.	1912.
Nova Scotia	380,488	337,466
Quebec	72,439	88,172
Ontario	504,900	418,346
New Brunswick, Alberta, Manitoba	9,270	17,240
Total	967,097	861,224

In 1913 there were twenty-one works engaged in rolling finished forms of iron and steel, and also the same number in the previous year. There were five idle rolling mills and steel works in 1913, compared with four in 1912. Three new steel plants were built in 1913, all equipped to make steel castings but not rolled iron or steel products. At the close of 1913 three additional similar plants were in course of being constructed.

Assurance comes from New York city that Tramways, Limited, the company which proposes to build the interurban line in the Edmonton district, announces that it is prepared to proceed with the project as soon as arrangements can be finally completed by the Edmonton city council for that construction.

Coast to Coast

Montreal, Que.—The taking over of the Montreal Water and Power Company is still a live question in the city of Montreal.

Sarnia, Ont.—Water from the new Sarnia waterworks plant on the lake shore is now flowing through the new mains into the city.

Peterborough, Ont.—On September 24, the distributing system of the Peterborough Light and Power Company passed into the possession of the city of Peterborough.

Fort William, Ont.—The net earnings of the Kaministiquia Power Company for the first 8 months of 1914 are announced as $185,295, with a surplus for the same period of $126,479.

Kingston, Ont.—What is said to be the most modern sewerage system in America has just been installed at the Rockwood Asylum for the Insane, Kingston. It was formally opened on September 19th by Dr. A. Amyot and J. A. Dallyn of the provincial department of public health.

Winnipeg, Man.—Though the contracts amounting to approximately $6,000,000 have just been awarded in connection with the Shoal Lake water supply project for Winnipeg, the work on the five various contracts totalling the stated amount will not be commenced until next May.

Selkirk, Man.—The public works under construction by the Dominion Government, which are being continued in spite of war conditions, are the new $100,000 drydock to accommodate the shipping on the Red river, and a $150,000 steel boat to serve as a fishing patrol on Lake Winnipeg, which is to be completed by June, 1915.

Winnipeg, Man.—The report of works completed thus far this year in the city of Winnipeg shows a long list of large paving works in asphalt No. 1, asphalt No. 2, concrete, and other pavements, sewers, walks, and various local works. The report further details important works yet under construction in sewers and pavements, as well as an extensive list of smaller works of all kinds throughout the city, either finished or now in the final stage of completion.

West Kildonan, Man.—Extensive public improvements have been conducted this year in West Kildonan. These include a 6-foot granolithic sidewalk on Main street from the city limits of Winnipeg to Kildonan Park; the laying of a portion of the two miles of 12-foot trunk sewer, which is to be completed from the river along Jefferson avenue by 1917; paving on North Main street for a distance of about 1½ miles; and a sewer to drain this 24-foot paved street which will be laid as soon as the paving is completed.

Prince Rupert, B.C.—It is expected that by the beginning of 1915 six of the great pontoons which are to be used in the construction of the G.T.P. floating dock at Prince Rupert, will have been completed. The first of these was launched about two weeks ago at the northern terminal. To build this 300,000 feet of lumber were used, besides tons of iron bars, bolts, nails and other fixtures required; and it is 130 feet in length. There will be 12 pontoons in all in this great dock, which will require 3,600,000 feet of lumber, not to speak of the many thousand extra feet will be necessary for the sides of the floating shipyard. The capacity of the new dock will be 20,000 tons, which means that it will be able to lift the largest warships or mercantile ships which ply the Pacific Ocean. The dock is so arranged that it can be used as three separate units or in any combination that is desired. The dock will probably be completed some time next year. Most of the piers in connection with the plant have been erected, and the buildings are now almost completed.

Toronto, Ont.—The work of dredging sewer outlets in Toronto harbor for the Toronto harbor commissioners, the contract for which was awarded to Mr. John E. Russell, has been about three-quarters completed. The work consists of dredging material which has been deposited in the slips along the waterfront through the sewers, and of conveying the matter dredged into the lake a distance of 10 miles and of dumping it there. The other work in connection with the harbor improvements being carried out this year by the commissioners, is making very substantial progress under the contractors, The Canadian Stewart Company. Both the ship channel, which is to serve the industrial district being created in the old Ashbridge's Bay, and the dock structures along the west face of this district, are well under way. Also work is being carried on rapidly from both the east and west ends and working towards the centre in the placing of cribs as a foundation for the seawall which is to protect the shore from the foot of Bathurst street west to the Humber river. Approximately $1,500,000 will be spent on this work during the year 1914.

Winnipeg, Man.—According to the recent progress report furnished to the meeting of the board of the Greater Winnipeg Water District, the field staff at work on the Shoal Lake water supply scheme was engaged in laying out and measuring up railway grade, track-laying, ballasting and drainage work. Up to August 31st, delivery had been taken of 266,879 railway ties, or 97 per cent. of the total order; telephone lines had been strung along a distance of 82.89 miles, leaving a balance of 11.89 miles to complete; 8,415½ long ton steel rails had been delivered, or 84 per cent. of the total tonnage required; 1,004,176 lbs. of splice bars had been delivered, completing the order pending an adjustment of the quantities shipped; 52 per cent. of the estimated total of necessary railway construction was under excavation; track-laying had been completed on 29.196 miles or on 29 per cent. of the estimated total; 12½ miles of the right-of-way had been fenced; 2,536 acres of the right-of-way had been cleared; division engineers' residences were practically completed; and 115,664 cubic yards of material were placed in the Falcon river dike, or 47 per cent. of the total required.

Winnipeg, Man.— An official announcement by the Greater Winnipeg Water District administration states that half of the Falcon river dyke at the Shoal Lake end of the water supply aqueduct, being constructed by Tomlinson and Flemming at a cost of $120,700, has been completed. This undertaking requires an embankment 5,070 feet long; and a channel 3,300 feet long, 35 feet wide, and 7 feet deep. For the former 170,000 cubic yards of sand and gravel, 12,000 cubic yards of riprap, and 5,000 feet of trestle will be used. For the latter 30,000 cubic yards of earth is to be removed. These operations are carried out to avoid the dark-colored water discharged by the river and to cut off the shallow flowage at the extreme westerly end of Indian Bay. The dyke is being built across the end of the bay, and a canal constructed therefrom to Snowshoe bay. It will be curved a mile long, and be a substantial embankment of sandy and gravelly material, raised 4 feet above the high-water level of the lake and protected on the exposed side with a heavy facing of riprap. A gate and screen chamber on the shore will be built; and to protect the intake from material drifting along the shore, piers will be constructed 150 feet out into the lake at each end of the receiving hole. A submerged conduit is also planned to bring the water from a point at least 150 feet from the shore. The gate and screens have been designed with liberal areas for sluice-gate openings and for screens, so as to cause as little fall of the water from the bay to the aqueduct as possible. There will be at least two sluice-gates, not less than 5 feet wide, and 6 feet high; and the screens will have a total length of not less than 50 feet, and a height extending from the bottom of the aqueduct

to the surface of the water. At the Falcon river crossing, a pile foundation for 600 feet is to be constructed; and for 150 feet of this length it will be necessary to depress the aqueduct, so that its top will be low enough to permit the passage of water of the river and light-draft boats. The depressed portion will be reinforced with steel, and the concrete will be much thicker than under usual circumstances.

PERSONAL.

Hon. Dr. J. O. REAUME, Minister of Public Works in the Ontario Cabinet, has resigned.

Hon. FINLAY G. MACDIARMID has succeeded Hon. Dr. Reaume as Minister of Public Works for the Province of Ontario.

R. O. WYNNE-ROBERTS, consulting engineer, Regina, Sask., is on a trip east, visiting Toronto, Ottawa, Montreal and New York.

Hon. W. H. HEARST, Minister of Lands Forests and Mines for the Province, has been chosen to succeed the late Sir James Whitney as Premier of Ontario.

E. L. HORWOOD, Ottawa, has been appointed chief architect of the Department of Public Works. Mr. David Ewart, who for about forty years has been acting in that capacity, will be consulting architect.

H. C. GROUT, St. John, N.B., has been appointed general superintendent of the Atlantic Division of the C.P.R., succeeding Mr. Wm. Downie, resigned. Mr. Grout has been in the company's service since 1898.

Hon. Sir ADAM BECK, chairman of the Hydro-Electric Power Commission of Ontario, has retired from the Ontario Cabinet. It is understood that his desire is to devote as much time as possible to the affairs of the Commission.

H. A. WOODS, of Montreal, is acting as chief engineer of the Grand Trunk Pacific Railway Co., at Winnipeg, since the resignation of Mr. B. B. Kelliher. (See *The Canadian Engineer*, Sept. 10th, 1914.) The directors have decided not to appoint a successor at present.

Hon. I. B. LUCAS, Provincial Treasurer of Ontario, has been appointed a member of the Hydro-Electric Power Commission of Ontario, to succeed Lieut.-Col. Hon. J. S. Hendrie, whose appointment to the Lieutenant-Governorship of the Province left a vacancy on the Hydro Board.

Dr. T. KENNARD THOMSON, consulting engineer, New York City, has been appointed by Gov. Glynn, of New York State, a member of the Atlantic Deeper Waterways Commission. This commission, of which Hon. J. Hampton Moore is President, has under investigation a system of canals to extend from Florida to Maine, with a total length of between seven and eight hundred miles and at a probable cost of $35,000,000.

CANADIAN SOCIETY OF CIVIL ENGINEERS.

The Council of the Canadian Society of Civil Engineers have announced that their fees for the year will be remitted to all members of the Society who have volunteered for service with the allied armies.

At its meeting on Sept. 9th the Council also resolved to establish a fund to be applied in aid of dependent members of families of Society members who have volunteered for active service in the army.

Premier McBride says that public works in the province will not be stopped, that construction will proceed on the railways in different sections, and that every effort will be made to sustain that confidence which has generally marked the people of British Columbia.

IRRIGATION PUMPS FOR EGYPT.

Some particulars have been recently made public regarding the pumps which are being supplied from England in connection with the irrigation work now being carried out in the Behira district.

The pumps are of the Humphrey pattern, similar to those at the Metropolitan Water Board's reservoir at Chingford, but incorporating some novel ideas. The valves, for example, are of a unique design, which permits them to shut fairly close even when a large obstruction fouls the seating. The pumps will be eight in number, with a total capacity of 792,000,000 gallons per 24 hours, and the lift to be provided for is from 19 ft. to 20 ft. The maximum internal diameter of the combustion chamber will be 8 ft. 8 in., and it will be about 14 ft. in height. The water valve box, which will be 7 ft. in height, will be 8 ft. 8 in. in diameter.

The gas for the pumps will be produced by an anthracite Mond plant, gasifying 44 tons per day, the plant consisting of nine producers, one of which is a spare. The plant is being supplied under a guaranteed consumption of 1.15 lb. of coal per water horsepower.

COMING MEETINGS.

MOTOR TRUCK CLUB OF AMERICA.—Annual Convention, Detroit, Mich., October 7th to 9th. President, George H. Duck, New York City.

GULF AND INTEROCEAN NATIONAL HIGHWAY ASSOCIATION.—October 8th, 9th, 10th; conference to be held at New Orleans, La. Secretary, Jno. B. Kent, Lake Charles, La.

INTERNATIONAL ASSOCIATION OF FIRE ENGINEERS.—Annual Convention, Grunewald Hotel, New Orleans, La. October 20th to 23rd. Secretary, Mr. McFall, Roanoke, Va.

ALABAMA GOOD ROADS ASSOCIATION.—Nineteenth Annual Convention will be held from October 21st to 23rd at Montgomery, Ala. Secretary, J. A. Rountree, 1021 Brown Marx Building, Birmingham, Ala.

NORTHWESTERN ROAD CONGRESS.—Annual Convention, to be held at Milwaukee, Wis., October 28th to 31st. Secretary, J. P. Keenan, Milwaukee.

AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—Charles Carroll Brown, Secretary, Indianapolis, Ind. Meets at Somerset Hotel, Boston, Mass., October 21st, 22nd and 23rd.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

WASHINGTON STATE GOOD ROADS ASSOCIATION.—Convention to be held at Spokane, Wash., November 18th, 19th, and 20th. Secretary, M. D. Lechey, Alaska Building, Seattle, Wash.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

TRANSMISSION LINE CHARACTERISTICS

MECHANICAL CHARACTERISTICS OF COPPER AND ALUMINUM WIRES FOR ELECTRICAL TRANSMISSION LINES—SOME USEFUL TABLES, FORMULAS AND CHARTS.

By E. MAERKER, A.Sc.,
Designing Structural Engineer, Toronto.

VARIOUS tables and charts pertaining to electric transmission line wires have been compiled by different authors from time to time. These tables and charts enable the engineer in the field, when stringing the wire, to allow a certain tension at the prevailing temperature in order that the tension may not become excessive at some lower temperature and maximum loading; and on the other hand, to prevent the sag from becoming too great at some high temperature, which might reduce the clearance from ground to lowest point of wire beyond the specified limit.

In order to obtain a clear picture of how different temperatures and various loadings affect the tension and sag in the wire, Charts I. and II. have been constructed, the former for copper wire and the latter for aluminum.

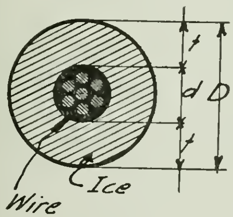

Fig. 1.

These diagrams are easily constructed and the values are read off directly, eliminating all shifting about on the paper with straight-edges, as would be the case with parallel-scale types and others. The following diagrams are based on the parabolic law, as no appreciable error is introduced by doing so, providing the span is within reasonable limits.

The loading on the wire depends, of course, on the climatic conditions. However, in temperate zones an ice loading of ½ inch in thickness at 0° F. in conjunction with a wind pressure of 8 lbs. per square foot of projected area of the wire, corresponding to a 70-mile indicated wind velocity, or 55.2 actual, is usually recommended as maximum loading.

To obtain the weight of ice per foot of wire, the author has derived the following formula, which will undoubtedly be of some value.

Taking the ice as 57.3 lbs. per cu. ft., we have for W, the weight of ice per foot of wire:

$$W = \frac{\frac{D^2\pi}{4} - \frac{d^2\pi}{4}}{144} \cdot 57 \cdot 3 = \frac{57 \cdot 3 \cdot \pi}{4 \cdot 144} (D^2 - d^2)$$

Substituting $d + 2t = D$, we have:

$$W = \frac{57 \cdot 3 \cdot \pi}{144} \cdot (dt + t^2) = \frac{5}{4}\, t\, (d + t) \qquad (1)$$

where t denotes the thickness of the ice coating, and d the diameter of the wire; all values being in inches.

Combining the weight of the wire plus the ice with the wind, the resultant force acting on the wire is thus obtained, which forms the basis to all further calculation.

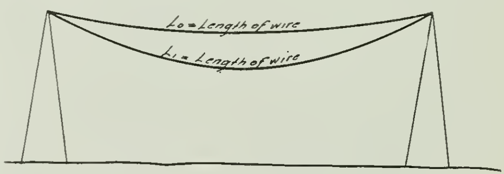

Fig. 2.

Development of Equations.

Let a denote the area of the wire in square inches.
w_0 " the resultant force per foot of wire under maximum loading at 0° F., in lbs.
$w_1 w_2 w_3$ " the resultant force per foot of wire under different loading, in lbs.
l " the span in feet.
S_0 " the sag at midspan under maximum loading at 0° F., in feet.
S_1 " the sag at midspan under different loading, in feet.
P_0 " the pull or tension in the wire under maximum loading at 0° F., in lbs.
P_1 " the pull or tension in the wire under any loading or at any temperature, in lbs.
L_0 " length of wire at maximum loading at 0° F., in feet.
L_1 " length of wire at any other loading and other temperature.
α " coefficient of linear expansion.
t " temperature in degrees of Fahrenheit.
E " Modulus of elasticity in lbs. per sq. in.

Fig. 2 shows two rigid supports and a wire suspended between these supports. Let L_0 represent the length of the wire under maximum loading; *i.e.*, under a loading equal to the resultant of the dead load of the wire plus the weight of ½ inch of ice and a wind pressure of 8 lbs. per square foot of projected area of ice-covered wire at a temperature of 0° F.

Evidently this wire is undergoing a change in length at some other temperature and different loading. A simultaneous change of temperature and loading is more complicated, but by letting the loading remain constant for the time being, calculating the change in length due to the temperature only and finally combining this with the change due to the different loading, the total change in the length is easily found.

Let L_1 (Fig. 2) be this changed length of the wire. The effect of the temperature is always partly counterbalanced by the effect of the change in tension. A higher temperature will stretch the wire and increase the sag. This increased sag in turn will diminish the tension and cause a shortening in the length. The algebraic sum of these changes will be the actual change in the length. The author has seen several charts which do not take account of this change due to the tension, caused by the change of temperature. This factor is quite an appreciable one, even with moderate spans.

Let $L_0 \alpha t$ be the linear expansion due to the rise in temperature t, then $L_0 (1 + \alpha t)$ would be the total length of the wire, providing the tension would remain the same. Since, however, the tension becomes less with the increase in length, the shortening has to be added algebraically to the above value $L (1 + \alpha t)$, and the actual length is thus found. In order to derive an expression for this shortening in the length, we have to employ following fundamental formula:

$$\text{Modulus of elasticity } E = \frac{\text{unit stress}}{\text{unit strain}} = \frac{P_0/a}{e_0/L_0} = \frac{P_1/a}{e_1/L}$$

and by transposing $e_0 = \dfrac{P_0 L_0}{a E}$ and $e_1 = \dfrac{P_1 L_1}{a E}$ where e_0 and e_1 represent the linear deformation due to the tension P_0 and P_1 respectively.

The total difference is

$$L_1 - L_0 = L_0 \alpha t + e_1 - e_0; \text{ or,}$$

$$L_1 - L_0 = L_0 \alpha t + \frac{P_1 L_1 - P_0 L_0}{a E} \qquad (2)$$

Transposing: $P_1 L_1 = L_1 a E - L_0 a E - L_0 \alpha t a E + P_0 L_0$

Dividing by L_1; $P_1 = a E - \dfrac{L_0}{L_1} aE - \dfrac{L_0}{L_1} \alpha t a E + \dfrac{L_0}{L_1} P_0$;

$$\text{or, } P_1 = \frac{L_0}{L_1} [P_0 - a E (1 + \alpha t)] + a E$$

The general expression for the length of the wire in terms of the sag is $L = l + \dfrac{8 S^2}{3 l} = \dfrac{3 l^2 + 8 S^2}{3 l}$, and substituting for L_0 and L_1 we have

$$P_1 = \frac{3 l^2 + 8 S_0^2}{3 l^2 + 8 S_1^2} [P_0 - aE (1 + \alpha t)] + a E \qquad (3)$$

which is the formula used for compiling Table II. Here we notice that three variables are involved in this equation, P_1, S_1 and t. By giving t a certain value and assume different values for S_1, we obtain corresponding values for P_1 which can be plotted. The P_1 values are plotted on the vertical axis and the S_1 values on the horizontal axis. By repeating this operation and assigning another certain value for t, we obtain a family of curves. This operation renders t a variable parameter.

Since we have two variables now and only one equation, we have to establish some other relation between P_1 and S_1. This is accomplished by using the well-known formula

$$P_1 = \frac{w l^2}{8 S_1} \qquad (4)$$

The value w represents the variable parameter.

Table I. has been worked out for a copper wire of 250,000 C.M. and a span of 600 feet. The values are taken from the reports of the National Electric Light Association, 36th convention:

Table I.—Stranded Hard-drawn Copper Wire of 250,000 C.M.

Area in circular mills	250,000 or a = .19635 sq. ins.
Elastic limit	35,000 lbs. per square inch.
Elastic limit	6,870 lbs. per wire.
Allowable tension...	30,000 lbs. per square inch.
Allowable tension...	P_0 = 5,900 lbs. per wire.
Ultimate strength ..	60,000 lbs. per square inch.
Ultimate strength ..	11,790 lbs. per wire.
Modulus of elasticity	$E = 16 \times 10^6$ lbs. per sq. in.
Coefficient of linear expansion	$\alpha = 96 \times 10^{-7}$
Weight per ft. of wire plus ½ in. ice and 8 lbs. wind.........	w_0 = 1.788 lbs.
Weight per ft. of wire, no ice, no wind....	w_1 = .762 lbs.
Weight per ft. of wire, no ice, 15 lbs. wind	w_2 = 1.061 lbs.
Weight per ft. of wire, ½ in. ice, no wind	w_3 = 1.440 lbs.

Above values are substituted in equation (3).

$$P_1 = \frac{3 l^2 + 8 S_0^2}{3 l^2 + 8 S_1^2} [P_0 - a E (1 + \alpha t)] + a E$$

$$l = 600; \ 3 l^2 = 1{,}080{,}000$$

$$S_0 = \frac{w_0 l^2}{8 P_0} = \frac{1.788.360000}{8.5900} = 13.637; \ 8 S_0^2 = 1{,}487.75$$

$$3 l^2 + 8 S_0^2 = 1{,}080{,}000 + 1{,}487.75 = 1{,}081{,}488$$

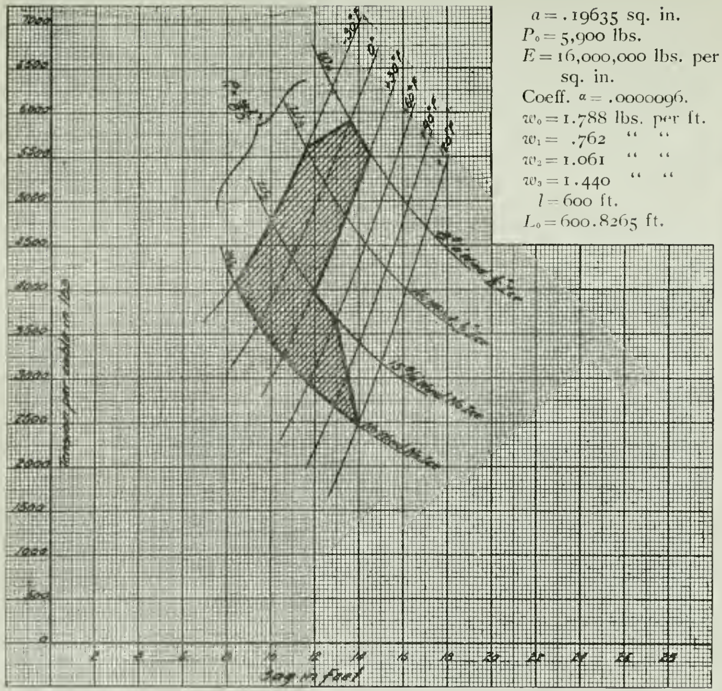
$$a E = .19635 \times 16{,}000{,}000 = 3{,}141{,}600$$

Table II. gives values for P_1 and S_1 which can be plotted now.

In order to plot equation 4, which furnishes points of intersections with above curves, Table III. has been compiled.

Having plotted all these values for P_1 and S_1, we obtain an exact picture of the behavior of the wire at various temperatures and under different loadings. It will be noticed that equation (3) is rather lengthy and cumbersome. By making a slight change in this equation the whole computation is materially shortened without affecting the results appreciably. This is accomplished by substituting L_0 for L_1 in equation (2) on the right side only, as shown $L_1 - L_0 = L_0 \alpha t + \dfrac{P_1 - P_0}{a E} L_0$

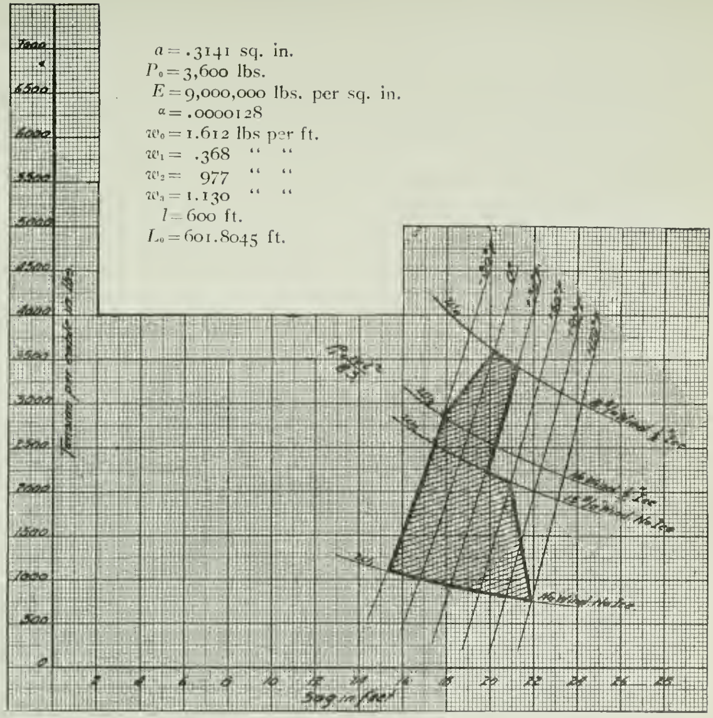
Solving for P_1 we get $P_1 = P_0 + a E \left[\dfrac{L_1}{L_0} - 1 - \alpha t\right]$



$a = .19635$ sq. in.
$P_0 = 5{,}900$ lbs.
$E = 16{,}000{,}000$ lbs. per sq. in.
Coeff. $\alpha = .0000096$.
$w_0 = 1.788$ lbs. per ft.
$w_1 = .762$ " "
$w_2 = 1.061$ " "
$w_3 = 1.440$ " "
$l = 600$ ft.
$L_0 = 600.8265$ ft.

Chart I.—Showing Tension and Sag of 250,000 C.M. Hard-drawn Copper Cable at Various Temperatures and Under Different Loading; 600-ft. Span.

$$P_1 = P_0 + a E \left[\frac{8 S_1^2}{3 l L_0} + \frac{l}{L_0} - 1 - \alpha t^\circ\right]$$



$a = .3141$ sq. in.
$P_0 = 3{,}600$ lbs.
$E = 9{,}000{,}000$ lbs. per sq. in.
$\alpha = .0000128$
$w_0 = 1.612$ lbs per ft.
$w_1 = .368$ " "
$w_2 = 977$ " "
$w_3 = 1.130$ " "
$l = 600$ ft.
$L_0 = 601.8045$ ft.

Chart II.—Showing Tension and Sag of 400,000 C.M. Aluminum Cable at Various Temperatures and Under Different Loading; 600-ft. Span.

$$P_1 = P_0 + a E \left[\frac{8 S_1^2}{3 l L_0} + \frac{l}{L_0} - 1 - \alpha t^\circ\right]$$

Table II.

Table VI.—Aluminum Wire.

$$P_1 = \frac{w l^2}{8 S_1}$$

Sag S_1 in feet.

			12	14	16	18	20	22	24	26
Tension P_1 in lbs.	$w_0 = 1.612$	8 lb. wind; ½″ ice	6,045	5,180	4,540	4,030	3,627	3,300	3,020	2,790
	$w_1 = .368$	No wind; no ice..	1,380	1,182	1,035	920	823	753	690	637
	$w_2 = .977$	15 lb. wind; no ice	3,664	3,140	2,748	2,440	2,198	1,997	1,830	1,690
	$w_3 = 1.130$	No wind; ½″ ice.	4,238	3,632	3,180	2,825	2,543	2,310	2,117	1,955

and substitute $l + \dfrac{8 S_1^2}{3 l}$ for L_1 we have

$$P_1 = P_0 + a E \left[\frac{8 S_1^2}{3 l L_0} + \frac{l}{L_0} - 1 - \alpha t\right] \quad - \quad - \quad (5)$$

which is the equation used for Charts I. and II. Chart I. is for copper wire and Chart II. for aluminum. Substituting the numerical values in above equation and letting $L_0 = l + \dfrac{8 S_0^2}{3 l}$, we obtain

$$P_1 = 5{,}900 + 23.239 S_1^2 - 4{,}321 - 30.16 t$$

or $$P_1 = 23.239 S_1^2 + 1{,}580 - 30.16 t$$

Chart I. is constructed from Tables III. and IV., and Chart II. from Tables V. and VI., using equations 4 and 5.

Comparing results of equations 3 and 5, it is seen that no appreciable error is introduced by adopting equation 5.

Tables V. and VI. are for aluminum wire. Size, weight, etc., are printed on Chart II.

The boundaries of the shaded area are the limitations to which the sag and the tension are confined. Since max. loading is specified at 0° F., the curve w_0 could not extend further to the left of the temperature curve of 0°, accounting for the edge chipped off in the left-hand upper corner. The ice limit at 32° F. shows the ice loading curves running outside along the 30° curve down to the w_2 loading curve. From there it runs along the latter curve to 60°, where a maximum wind of 15 lbs. is liable to occur. From here the line runs to the intersection of the w_1 curve with the 120° curve, *i.e.*, highest temperature with no ice and wind.

It is to be noticed from Chart I. that the maximum sag does not occur at the highest temperature, but at 30° with a maximum loading. These curves show very plainly what effect the temperature and the loading has upon the tension and the sag of the wire.

In Chart I. it is seen that a change in loading affects the tension more than the sag, while a temperature change has an equal effect on tension and sag. In Chart II. a change in loading is affecting the tension far more than the sag and a change in temperature has a greater effect upon the sag than the tension, especially noticeable with the w_1 curve.

[This article deals with spans of 600 feet only; in a later article Mr. Maerker will extend the information to include spans ranging from 200 to 1,000 feet.—EDITOR.]

NORTHERN WATER-POWERS.

The statement is sometimes made by the uninitiated that the water powers north of the settled parts of our Dominion are of little value. The existence of numerous falls and rapids in these parts is not denied, but the argument is advanced that the temperature and other climatic conditions existing where these falls and rapids are situated will prevent their utilization. As a direct contradiction to the above assertion, we need only turn to Norway, the latitude of which is about the same as that of the Yukon and where climatic conditions are similar to those of northern Canada. In size, Norway is only slightly larger than our Maritime Provinces, and yet we find their water-power plants with a total capacity of over 1,500,000 h.p., either in actual operation or in course of construction. Hydro-electric stations of considerable size have been constructed in different parts of that country. Many of the smaller ones have been erected for municipal use; but the larger ones are for the electrochemical industry, in which a main factor of success is cheap and plentified electric power.

AMERICAN PIG-IRON, ROLLED IRON AND STEEL.

The official statistics of American pig-iron production in the first half of 1914 make the following comparisons, in tons of 2,240 lbs.:—

	First half.	Second half.	Year.
1911	11,666,996	11,952,551	23,649,547
1912	14,072,274	15,654,623	29,726,937
1913	16,488,602	14,477,550	30,966,152
1914	12,536,094	....	....

Thus there was a decrease of 24 per cent. from the tonnage in the best half-year—the first half of 1913. An interesting feature in the statistics is that while the total production greatly decreased, the production of foundry iron was larger in the first half of this year than in the second half of last year. The explanation probably is that too much foundry iron was made in the first half of last year, while in the second half the stocks were liquidated, with unusually light production, and production this year returned to normal.

The production of rolled iron and steel in 1913 has just been officially reported, and we include in the table below the production of steel ingots, already reported for 1913:—

	Total rolled. Tons.	Rolled iron. Tons.	Rolled steel. Tons.	Steel ingots. Tons.
1911	19,039,171	1,460,615	17,578,556	23,029,479
1912	24,656,841	1,637,582	23,019,259	30,284,682
1913	24,791,243	1,678,257	23,112,986	30,280,130

The rolled material is reported in the form in which it suffered its last hot rolling, the material of course being sheared or cropped thereafter. Thus no billets or sheet bars are included, except those exported, plus rolled forging billets, while rods and skelp are returned as such, and blackplates rather than tinplates are included.

In the past two years the difference between steel ingots and rolled steel has averaged about 7,200,000 tons. A small part of this difference was absolutely lost, but the great bulk of the difference represented new scrap. In addition, there is new scrap produced in fabrication. A small tonnage of sheet mill scrap is used in charcoal forges, but in general there is indicated a supply of about 7,500,000 tons annually, which went to the open-hearth steel works, thus constituting 35 per cent. of the production of 21,599,931 tons of open-hearth steel ingots and castings. The production of basic pig-iron in 1913 was 12,500,000 tons, while there was perhaps 750,000 tons of Bessemer and low-phosphorus iron used in the acid open-hearth steel process. With these figures available, it is evident that the consumption of old scrap in the open-hearth process is really not large.

It is stated by Mr. J. H. Plummer, president of the Dominion Steel Works at Sydney, N.S., that indications point to a speedy resumption of operations of some of the mills of the works. Orders have already been received from England for 2,000 tons of nails and 2,000 tons of wire rods, and negotiations are pending regarding an order for rails.

Although the production of coal in North Dakota in 1913 was only 495,320 short tons, valued at $750,652, some interesting facts regarding the possibilities of the vast deposits which underlie the state are shown in a statement by E. W. Parker just made public by the United States Geological Survey. All the present mineral fuel produced in North Dakota is brown coal, or lignite. Considerable areas of sub-bituminous coal of usable quality and workable thickness are believed to underlie portions of the lignite areas, but no attempt to exploit the sub-bituminous coals has been made. At present the lignite is used chiefly for domestic purposes, but with proper equipment it can be used with satisfaction as a boiler fuel. A convincing example of what may be accomplished with lignite for such use is presented by the irrigation plant of the United States reclamation service at Williston. The lignite used here is taken from the only coal mine owned and operated by the Government. As the gas-producer and internal-combustion engines in large units come into more general use in the West, as they are rapidly doing in the East, the lignites of North Dakota will be recognized as possessing great potentialities in the settlement and economic development of the state. Experiments also show that lignite can be successfully briquetted, after which it stands transportation well and its heat value is increased 50 to 70 per cent.

MODERN FIXED AND INTERLOCKING RAILROAD SIGNALS.

RAILROAD signalling is the art of conveying information as to the occupancy or condition of the track ahead to an engineman or conductor in charge of a train so that he may move his train safely and expeditiously. It is obviously necessary for the train crew to have this information whenever more than one train is operated over the line at the same time. The means of conveying it are numerous, and include the time card, dispatcher's orders, precedence of one class of train over another, hand or lamp signals, and fixed signals.

A discussion of fixed signals, and the interlocking and other devices connected therewith is contained in a paper on railroad signalling read by H. J. Pfeifer, engineer maintenance of way, Terminal Railroad Association of St. Louis, before the Engineers' Club of St. Louis. From it the following notes are taken.

The end sought by all railroads, signal engineers, and the manufacturers of signal appliances is "Safety First." To be successful, however, in these times of dense traffic at high speeds, increased expense and low rates, a signal installation must have other qualities in addition, among which are facility, reliability, and economy.

In the early stages, attempts to secure safety and facility were more or less compromises between the two with sacrifices on the part of each. The advance of the art, however, has been so rapid of late years that less and less sacrifice is necessary. To secure safety and facility the signal mechanism must be reliable in operation; *i.e.*, subject to the minimum of failure.

True economy is not confined to the cost of installation, or even of maintenance and operation, but takes into account the entire conduct of the railroad and that system is the best in each case, which results in the safe movement of the traffic at the least gross expense, and in the shortest time, even though the signalling system is elaborate and costly in itself.

Fixed signals may be divided into two general classes, block and interlocking. The first are for the purpose of maintaining a proper space interval between trains on a given stretch of track, and the second for controlling the movement of trains at crossings, junctions and terminal points.

Block Signals.—Probably the simplest form of block signal is the train order board or simple manual block at a station which is under the control of an operator or agent. Information as to the condition of the line is transmitted to him by telegraph, and in recent years by the telephone. Ordinarily this board gives three indications, "Stop," "Proceed cautiously" because of train in block moving in same direction, (this order is usually given to freight trains only) and "Proceed," block is clear. The manipulation of the signal is entirely in the control of the operator, there being no connection between adjoining stations, except for the transmission of information. You will note that in the use of this system, collision or accident may result, through the unchecked action of at least three men or agencies: First, the operator at the station in advance, having overlooked the train in the block, may give false information; second, the operator may make a mistake and give a clear signal with a train in the block ahead, and third, the engineman may fail to obey a stop signal.

The danger of this lack of control over the operators resulted in the development of the controlled manual block. In this system the signal is locked in the stop position and cannot be cleared until released by the operator at the station in advance. After the passage of the train the signal automatically returns to the stop position. This system increases safety because a clear signal cannot be given, except by the concurrent action of two operators. There is nothing about it, however, reducing the danger resulting from the failure of the engineman to obey a stop signal.

An additional safeguard on single track lines is the electric train staff. In this system there are interlocked receptacles at each station containing staffs for delivery to the engineman. Not more than one staff can be taken out at one time, which is an assurance that there can be only one train in the block, as no train is permitted to enter unless the engineman has a staff. The staff is placed in a frame, adjacent to the track, similar to a mail catcher, out of which the engineman can take it if moving at a reasonably low rate of speed. As the train passes the advance block the staff is thrown off by the engineman and placed in its receptacle by the operator, after which it is again possible to withdraw a staff at either one end or the other. In addition to the main staff, provision is made for permissive staffs, which can be issued to following trains, and grant the right to enter the block under control and with the advice that block is already occupied. This gives great additional safety, because the key for unlocking the system is on the train itself and cannot be used until the train has cleared at either end. In this system also there is no mechanical device to check the engineman in case he fails to obey the signal.

The St. Louis tunnel, as an example, is operated on on an absolute controlled block, with a modified staff system added for eastbound freight trains only. On account of the smoke and darkness it is essential that not more than one train is on each track at one time.

The system consists of an interlocking machine at the west end of the tunnel, known as "X" office, and another at the east end known as "MS" office. They are a little more than a mile apart.

The two machines are connected by a system of electric locking which compels the co-operation of the operators at both ends before signals can be given which will permit a train to enter the tunnel. These signals, by means of track circuits, are automatically returned to the stop position behind the train accepting the proceed signal and entering the tunnel. The track circuit is in two sections of about 240 feet, one at each end of the tunnel. The signal automatically restored to the stop position and the signal governing in the opposite direction cannot again be cleared until the train has passed out of the tunnel. As an additional precaution there must be a red light on the rear end of each train. The operator at the outlet station must see this light and then record on his train sheet the hour and minute during which the train passed his station. There is a heavy grade eastward through the tunnel and it is possible that an eastbound freight train may break in two, and leave cars standing between the track circuits, without being noticed by either the engineman or the operator. As the forward part of the train would release the track circuit control, it is within the bounds of possibility for the operator to make a mistake, say, that he saw the red light on the rear end of the train, when he actually did not, and release the tunnel entrance signal at the west end for another train. The disastrous possibilities of the resulting collision with the cars in the tunnel led to the adoption, a few years ago, of the following device:

Before entering the tunnel the rear switchman on every freight train, who is compelled under the rules to ride on the rear end of the last car, is given a numbered leather disk by the yardmaster. This number is communicated to the dispatcher or operator at the west end of the tunnel. As the train passes "MS" office at the east end the rear switchman delivers this disk to the operator, who reports its number to the dispatcher at "X" office. Unless the number reported by the yardmaster and operator agree, no train is permitted to enter the tunnel until it has been found clear by a light engine feeling its way through.

Another form of block signal is the automatic, which is defined as follows in the Signal Dictionary:

"A block signal, worked by electric or pneumatic agency, which is controlled by the passage of a train into, through and out of the block section to which the signal is connected. The entrance of a train sets the home signal at stop, and the clearing of the block section by the passage of the train out of it sets that signal clear. The apparatus is so arranged that the misplacement of a switch or the accidental entrance of a car from a side track will set the signal at stop."

This result is accomplished by the use of the track circuit defined as follows in the same volume:

"An electric current flowing through the rails of a railroad track. In a typical track circuit, the current flows from the battery to the nearest rail of the track, thence to the other end of the track circuit section; thence by wire to the track relay (controlling a signal) back by a wire to the farther rail, and by that rail back to the battery. Each rail is made electrically continuous from one end of the track-circuit section to the other by metallic bonds at the joints, and at the ends of the section insulated joints are used."

Automatic signals have been in use in this country since 1871 with "track instruments" and since 1879 with "track circuits."

The first form of automatic signal was the enclosed disk or banjo type which is still used on some of the largest railroads. The day indications are given by the color or position of circular disks, and the night indications by the usual colored lenses.

Of late years the disk signal has been almost entirely superseded by the semaphore; defined as follows:

"A type of signal introduced on railroads in England about 1841 and now in almost universal use for both block and interlocking signals. It consists of an arm about 4 ft. long and 10 in. wide, mounted on a post usually 24 to 30 ft. high at one side of the tracks; or on a shorter post supported by a bridge or other structure above the track. Day indications are given by the position of the arm horizontal, inclined or vertical, and night indications by a light. The pivot of the arm is combined with a spectacle casting holding colored glass disks, which, as the position of the arm is changed, move in front of a lamp mounted on the post."

By far the largest portion of all automatic semaphore block signals are electric, although there are some electro-pneumatic and electro-gas signals.

In some of the earlier automatic installations, the signal indicated the condition of the track for one block section only. It was found particularly in mountainous regions, where the view of the track ahead is obscured, that this was not sufficient, if a reasonable speed was to be maintained. Three general methods have been used to supply the engineman with additional information.

(1) By the overlap, which is an extension of the track circuit one or two thousand feet beyond the advance signal. The effect of this is to encourage an engineman to pass a signal at danger, by giving him the assurance that the track for a considerable distance beyond it is clear. As there is a large element of danger in this, the use of the overlap as outlined is not considered good practice.

(2) By the use of the distant signal which, when clear, indicates that the home or main signal is clear, and when blocked tells the engineman that he must be prepared to stop at the home signal. The distant signal is frequently placed on the same mast with the preceding home signal, and by this means the condition of the track for the two blocks ahead is indicated.

(3) By the use of the three-position signal, which indicates the condition of the track for two blocks ahead as follows:

Blade horizontal, first block occupied.

Blade inclined at an angle of forty-five degrees, first block clear, second block occupied.

Blade vertical, both blocks clear.

Automatic block signals are usually operated on the permissive system as follows: If a signal is in the stop position, the train must come to a full stop for one minute, after which it may enter the block under control prepared to stop in case of danger without any additional signal or warning.

The number and location of automatic block signals varies with the nature of the service. On lines of heavy traffic they must be placed as close together as possible, so as to get the maximum operating capacity out of the line. In no event should they be placed any closer than the distance required by the fastest and heaviest train to come to a full stop.

The automatic block signal is superior as a safety device to any of the manual block systems, because in addition to making known the presence of a train in the block, it also gives an indication of track obstructions, such as cars on sidings fouling the main line, broken rails or other defects destroying the continuity of the track.

The automatic block, like the manual, does not and cannot guard against the failure of the engineman to obey signals. The only manner in which the engineman can be controlled is by some system of automatic speed control or train stop, which would shut off the steam supply and set the brakes on the locomotive. There has been considerable talk about these devices but so far nothing practical for general use has been developed, and we must therefore depend on the care and watchfulness of the man at the throttle. After all, in spite of the multiplicity of automatic devices, we must always in the last analysis depend on a man or men for our safety.

One of the latest developments in automatic block signals is the use of alternating current signals. An installation of this kind was recently completed on the Southern Railroad between Denim, N.C., and Charlotte, N.C., a stretch of 100 miles. The line had been previously operated under the manual block system with 19 stations. When the new system was installed 15 of the 19 operators were no longer needed and were sent to other parts of the line. The power-house was installed at about the middle of the system and the current, which was also used for lighting stations and other buildings along the right-of-way, was transmitted at 4,400 volts. There are 118 signals in the system and the total energy required for the signals, track circuits and lights in the signals, is less than 10 kw.

There are at present more than 35,000 miles of automatic block signals in use on American railroads, and the mileage is rapidly increasing. Their installation in many instances is an economy, because aside from the greater safety secured they increase the traffic-carrying capacity of the line to such an extent that the construction of an additional track, entailing a much larger expense, may frequently be indefinitely postponed.

Interlocking.—This has been defined as "An arrangement of switch, lock and signal appliances so interconnected that their movements must succeed each other in a predetermined order." The term includes the cabin, the machine, switches and signals and all the connections and appurtenances.

Patents for manually operated interlocking devices were first granted in England in the year 1856, and in 1873 the system had been so generally adopted in England that the London & Northwestern Railway alone employed 13,000 interlocking levers. The first experimental interlocking installation was made in the United States at Spuyter Duyvil Junction, New York City, in 1874. The first important installation on a commercial basis was made by the Manhattan elevated lines in New York City in 1877-78.

Interlocking resulted from the desire on the part of English railways to save labor by concentrating in a single frame the levers operating a number of widely separated switches and signals. After this it was a short and simple step to so lock these levers one with the other that a clear signal could not be given unless the route was properly set up, and so that signals for conflicting movements could not be given. As the cost of labor is higher in the United States than in England there was a demand in this country for an interlocking that would permit of the operation of switches and signals over greater distances and with fewer operators. This resulted in the development of a hydro-pneumatic interlocking, which was first installed in 1884 at Bound Brook, N.J., at the crossing of the Philadelphia & Reading and Lehigh Valley Railroads. From 1884 to 1891 eighteen of these plants, having 482 levers, were installed on six railways. As the system developed many serious defects were found, and its inventors devised the electro-pneumatic system in 1891, which is still in general use, particularly in large installations.

The first interlocking in the St. Louis territory was installed in 1883-84 to control switches and signals at both ends of the tunnel, and at about the same time the crossings, switches and signals at the east end of the east approach to the Eads bridge were also interlocked. The levers of these machines were made to operate special valves which controlled the hydraulic pressure used to operate the switches and signals. Pipes were laid from the ports of the valves to the switch and signal-operating mechanism in which the pressure was maintained by a system of pumps and accumulators or hydraulic rams.

It is here noted that this was one of the first interlocking plants using other than manual power installed in this or any other country. This type of machine, although it developed many defects, was continued in service with some modifications until 1899, when the present electro-pneumatic plant was installed at the tunnel entrances.

Interlocking development has easily kept pace with that in other fields.

The principal types of machines now in use in this country are the mechanical, the electro-pneumatic, the pneumatic and the all-electric.

Mechanical.—A mechanical interlocking plant consists of a frame of levers in a tower, which are connected by means of pipe and wire-runs to switches and signals which are moved by manual power applied to the levers in the tower. Where the distances are not too great, the switch layout comparatively simple and traffic light, this type of plant is both cheap and efficient. With the present tendency toward the control of trains by the block system, most modern mechanical plants are equipped with a number of electric safeguards, such as power distant signals, track circuits, electric route locking, etc. These trimmings in some instances have cost more than the mechanical interlocking itself.

Electro-Pneumatic.—Electro-pneumatic interlocking was first placed on the market in 1891 by the Union Switch and Signal Company. It was found to be particularly advantageous for use in large, complicated installations. The original St. Louis Union Station interlocker, built in 1891-92, was one of the first large installations of this system. This was followed a year or two later by the South Boston station interlocker, and since that time the system has been installed in some of the largest plants in the country, including the St. Louis Union Station as remodeled in 1903-1904.

Electro-pneumatic interlocking is described as follows: Compressed air at a pressure of about 85 lbs. is stored in a reservoir at or near the signal tower and is conveyed in pipe laid underground to cylinders, one at each switch and signal, in which the pressure by means of a piston, moves the switch or signal. The admission of air to a cylinder is controlled by an electric magnet fixed at its side, and the circuit of this magnet is controlled by a miniature lever in the cabin, the wires being run from the switch or signal to the cabin. These little levers are suitably interlocked the same as the large levers in a manual machine. The movement of a lever to work a switch does not, however, actuate the interlocking which releases the lever to be moved next; for the lever movement does not insure that the switch has actually been moved, it only closes the circuit. The next lever is held locked until by an electric current, the circuit of which is closed by the switch rails themselves, after their movement is completed, the "indication" of such completion is sent back to the cabin permitting the unlocking of the next lever.

Electro-pneumatic, in common with other forms of power interlocking, has many advantages over mechanical or manual, particularly in large complicated installations in which the installation of manual interlocking is practically impossible on account of the size of machine required and the great number of pipe-runs. The same amount of interlocking can be accomplished by power with fewer levers and each lever occupies about one-third as much space in the machine. A manually operated machine to operate the Union Station layout, if it were possible to properly lock it, would be at least two hundred feet long; and the pipe-runs would be so numerous and bulky that it would be difficult, if not impossible, to find space for them and the tracks too.

Pneumatic.—Another form of machine is the pneumatic or low-pressure air which has been used to a limited extent within the past 12 or 14 years. This machine acts more slowly than the electro-pneumatic or all-electric. In this system the pressure in the cylinders, moving switches and signals is 15 lbs., and in the small pipes leading to the diaphragm valves it is only 7 lbs. per square inch. The signalman's work consists in opening and closing these valves. The interlocking is the same as in other machines.

All-Electric.—The all-electric interlocking was developed by J. D. Taylor about 1900. A switch is moved by a one horse-power electric motor fixed to the ties and worked by an electric current conveyed by wires from a dynamo or storage battery in the cabin; and a signal by a motor of 1/6 horse-power, fixed to the signal post. The storage battery is usually charged by a generator run by a gasoline engine; and the amount of electric power used is so small that a small engine need be run but a few hours daily.

The machine in the cabin consists of a frame supporting horizontal sliding bars or levers, each movement closing a circuit to a switch or signal. The levers are interlocked as in other machines, and as in other power machines the interlocking is controlled by an indication sent to the machine from a switch after it has actually completed its movement. This "indication" current is generated by the momentum of the switch motor, which is converted into a generator for a fraction of a second after it has completed its work of moving the switch. The movement of a switch requires a current of only seven amperes.

All-electric interlocking has been manufactured since its development by the General Railway Signal Company.

Among the large all-electric installations may be mentioned the new Grand Central Terminal at New York, and the Chicago & Northwestern Terminal at Chicago. The latter is one of the most recent and up-to-date installations, so that a short description of it may be interesting. The Lake Street or main plant controls the entrance to 16 station tracks, which converge into six main lines. The semaphore signals are all of the three-position upper quadrant types and the dwarf signals are also three-position. The signal blades when horizontal mean stop; when inclined at an angle of 45°, proceed, stop at next signal; and when vertical, proceed.

In place of mechanical detector bars, which are usually installed at all interlocked switches to prevent the throwing of the switch under a train, electric track circuit locking is substituted. Miniature lights are placed on switch levers to indicate the presence or absence of trains on the switches and illuminated track diagrams are employed to give information to levermen as to occupied or unoccupied condition of all tracks.

An elaborate system of route and release locking is installed at this point, which by means of track circuits, controlling lever locks in the interlocking machine, prevent the movement of switches in a given route after a clear signal has been given to and accepted by a train over such route, even though the governing signal has been restored to normal or stop position. An ingenious feature of this "Route and Release" locking system is that while it is impossible to change the position of switches ahead of a train moving over the route, it is possible to move switches immediately after it has passed, thus permitting a new route to be lined up for a following train. In the older methods of track circuit route locking, the train must pass over all the switches in the circuit before any of them can be moved. The former scheme greatly facilitates train movement, while retaining all of the safety features of the latter.

There has been in late years a good deal of discussion as to the proper signal aspects for both day and night. While practice is not uniform the consensus of opinion is that a semaphore signal at the right side of the track or above it, with the semaphore blade to the right of the mast and working through the upper quadrant is the best practice. In this type of signal the blade horizontal means stop; inclined upward at an angle of 45°, proceed cautiously; and inclined upward at an angle of 90°, proceed.

At night the stop signal is a red light, the caution a yellow and the proceed a green light. Formerly, a white light or an ordinary flame seen through an uncolored lens was the clear indication, but on account of the danger of confusing this light with others in the vicinity, and the fact that the breaking of a red lens might cause a light to appear white when it should be red, the green light was adopted for the clear indication.

At interlocked railroad crossings it is the general practice, and in most States the law requires the installation of derails and distant signals. The derail on high-speed tracks is placed about 500 feet from the crossing and will throw a train off the track if the stop signal is not obeyed by the engineman.

The distant signal is placed about 2,000 feet ahead of the derail and warns the engineman that he is approaching an interlocking plant. The distant signal gives two indications—one that the home signal is clear and that he may proceed over the crossing without stopping, and the other that he must approach the home signal prepared to stop.

It is customary in modern installations to have a track circuit route locking which will prevent the moving of any switch or signal on the route after a train has accepted and passed a clear distant signal and until it has passed the home signal or through the entire plant.

RAILWAY ELECTRIFICATION IN ENGLAND.

A brief description has recently been published on the electrification by the London and North Western Railway Company of some 80 miles of single track, the first section of which was placed in operation on May 1st. of the present year. In all, about 7½ miles of single track have been equipped to date. High tension cables will, as far as possible be carried on short posts along the railway. The low tension cables will be laid underground. The conductor rails are all of a special low carbon soft steel having a weight of 105 lb. per yard; and the electrical resistance is approximately 6½ times that of copper. The rails are supported on porcelain insulators attached to the sleepers by malleable iron clips.

Trains, such as it is proposed to operate on these lines, will consist each of three cars having a total length of 179 feet. End doors are used with through communication, and both cross and longitudinal seats are provided. The electrical control gear will be supplied by the Siemens companies. Every motor car will be fitted with four motors of 250 h.p. each.

The generating equipment will consist of 5 turbo-generators of 5,000 kw. each, three-phase, 11,000 volts, 25-cycles; and transformers and rotary converters will be used to reduce the current to 600 volts d.c. Storage batteries will also be installed for peak and emergency service.

The transformers are being manufactured by the British Electric Transformer Company; sub-station plants, by the British Thompson-Houston Company; and the electrical apparatus of the trains, by the Maschinenfabric Oerlikon. Owing to the war, however, it is almost certain that all contracts with the German company have been cancelled.

The state of Texas mined 2,429,144 short tons of coal in 1913, valued at $4,288,920, according to E. W. Parker, of the United States Geological Survey. This production was nearly evenly divided between lignite and bituminous coal, with the balance slightly in favor of the latter. Both classes of coal showed increases in production in 1913, and both made their record output. The total production in 1913 exceeded that of 1912 by 240,532 short tons, or 11 per cent in quantity, and by $633,176, or 17 per cent., in value.

ECONOMICS OF WATER WASTE IN CITIES.

By R. O. Wynne-Roberts, M.Inst.C.E., M.Can.Soc.C.E., F.R.San.Inst.
Consulting Engineer, Regina, Sask.

A PERUSAL of the technical press and of the papers and discussion at the various conventions of engineers will indicate that the subject of water consumption and waste is one of considerable importance.

That water is being wasted in cities is recognized by engineers, and that it cannot be completely eliminated is admitted by all. But the quantity which is used or wasted in *excess* of allowable or unpreventable waste plus that actually consumed for all legitimate purposes, represents a tangible and potential source of wealth. The means by which such wealth can be conserved is dependent on the method adopted and the manner in which it is organized.

The influences which affect the consumption of water are the nature of the industries, the wealth and habits of the people, the extent to which water is used for fountains or other ornamental objects, watering of lawns, street sprinkling and other public purposes. Climate has also a very considerable influence especially as to the amount used for sprinkling purposes, and that which is wasted in winter to prevent freezing. It is probable, however, that the most important factors in determining the consumption of water is the degree of care taken to detect leakage and other waste, and the fact as to whether the water is sold by measure or otherwise. (1)

It will be assumed that the actual consumption of water on the North American continent is on a more generous scale, and that the climate, as a rule, is less humid and consequently the gardens and streets receive more watering than in Europe. This, however, cannot account for the great difference in the average consumption per capita.

Whilst it is not always a sure method of comparison to consider the consumption in any one city with that of another, owing to the different conditions which obtain, yet when several cities are compared, the above statement loses some of its force.

The following is a list of a few Canadian and American cities selected at random from references in various papers and reports:

City.	U.S. gals. per capita.	Population.	Source of information.
St. John, N.B.	250	42,500	Commission of Conservation
Vancouver, B.C. ...	164	120,000	Commission of Conservation
Halifax, N.S.	260	46,600	Commission of Conservation
Quebec, Que.	161	78,200	Commission of Conservation
Hamilton, Ont.	148	81,000	Commission of Conservation
Ottawa, Ont.	220	87,000	Special Report
Toronto, Ont.	120	450,000	Commission of Conservation
Montreal, Que.	130	555,000	Hering&Fuller Report, 1910
New York City, N.Y.	111	4,800,000	(2)
Buffalo, N.Y.	321	425,000	(2)
Chicago, Ill.	235	2,200,000	(2)
Philadelphia, Pa. ...	203	1,600,000	(2)
Milwaukee, Wis. ...	115	410,000	1913 Report
Kansas City, Mo. ...	126	300,000	1913 Report
Cincinnati, O.	131	392,000	1913 Sewerage Report
Pittsburgh, Pa.	197	550,000	(2)
St. Louis, Mo.	109	687,000	(2)
Cleveland, O.	102	560,000	Toronto 1912 Report
Detroit, Mich.	173	466,000	(2)
Baltimore, Md.	115	560,000	(2)
St. Paul, Minn.	61	210,000	
New Orleans, La. ..	53	370,000	1913 Report
Boston, Mass.	108	733,000	1913 Report
Albany, N.Y.	242	101,000	Engr. Record, Aug. 3, 1912
Salt Lake City, Utah	400	......	Engr. Record, July 25, 1913

The following are the statistics of a few European cities:—

City.	U.S. gals. per capita.	Population.	Source of information.
Vienna, Austria	15	1,800,000	(3)
Aachen, Germany	25	....	(4)
Frankfort-on-Maine, Germany	46	400,000	(5)
Wiesbaden, Germany.	28	100,000	(3)
Hamburg, Germany..	44	757,000	(3)
Munich, Germany ...	45	524,000	(3)
Berlin, Germany	22	2,100,000	(3)
Basel, Switzerland ...	42	....	(4)
Copenhagen, Denmark	27	....	(4)
London, England ...	43	6,721,207	1913-14 Report
Liverpool, England ..	36	960,000	(6)
Newcastle-on-Tyne, England	36	590,000	(6)
Hull, England	49	250,000	(6)
Manchester, England.	42	1,200,000	(6)
Devonport, England..	51	75,000	(6)
Glasgow, Scotland ...	72	1,150,000	(6)
Nuneaton, England ..	21	37,000	(7)
Stirling, Scotland	64	28,000	(7)
Plymouth, England ..	47	152,500	(8)
Sydney, Australia ...	48	668,000	(9)
Riga, Russia	25	....	(4)
Weardale and Consett, England	22	400,000	Letter

Chicago has about the same population as Vienna but the quantity of water consumed is over 15 times as great; Ottawa is about the same size city as Devonport but uses about 4½ times as much water; Montreal and Newcastle-on-Tyne are nearly similar in size but Montreal uses 3½ times the volume of water used in Newcastle; Milwaukee and Frankfort-on-the-Maine have approxi-

mately the same number of inhabitants, yet the former uses three times the quantity as the latter; Basel in Switzerland and Buffalo in New York State are nearly alike in population, but Basel uses only one-eighth as much water; New York City, the greatest city of the west, requires 2½ times the quantity needed in London, England. The reader who will continue the comparisons will find material for thought and investigation. There are, of course, certain conditions in Europe which tend to keep the consumption low, and these should be studied so as to arrive at a reasonable comparison. Such conditions are the number of faucets fixed on services, types of dwelling, methods of living, density of population in certain quarters and so on, but space will not permit discussing them at present.

In Germany an allowance of 100 litres per capita per day is ordinarily considered as ample for all city uses—this is equal to 27 U.S. gallons. Mr. Edward S. Coles, in a paper read before the American Waterworks Association in 1912, held in Louisville, Kentucky, presented a list of British cities, the average domestic consumption in which was 29.8 U.S. gallons and the average trade consumption was 13.6 gallons, or a total of 43.4 gallons daily per capita.

Even granting that the actual use of water for ablutionary and other purposes is more generous here than in European cities, it is palpable that the excess will not be great.

An American authority (10) estimates that the daily average would be:

For domestic purposes ..	25	gallons per capita
For commercial purposes	20	" " "
For public purposes.....	5	" " "
Loss	20	" " "
Total	75	" " "

There are many cities in the United States and Canada that are thriving on a smaller average. Domestic allowance of 25 gallons daily per capita is more than ample, and when it is borne in mind that a large number of industries, railways, etc., do not use city water, as a perusal of Cincinnati Sewerage and other reports clearly shows, an allowance of 20 gallons per head per day for industrial consumption is high. The loss of 20 gallons is excessive, whilst the preceding allowances evidently include waste also.

The average of the European cities cited is about 40 gallons per head per day. If this figure is increased by 25 per cent. it will represent a reasonable quantity and includes unpreventable waste, which occurs in all cities.

The writer will, for the purposes of this article, assume two hypothetical cities, each of 250,000 inhabitants. One city will consume 50 gallons per capita daily, and the other 150 gallons. Approximate estimates, based on published statements which will be quoted, will be submitted to show the economics of waste. The water is supposed to be filtered, chlorinated and pumped 200 feet high or equivalent in pressure, and distributed. The sewage will be collected on the separate system and treated bacteriologically.

There is ordinarily one ratepaying consumer in every six inhabitants, so that in each city of 250,000 population there will be about 42,000 water consumers.

The daily consumption of water will average: 250,000 × 50 = 12,500,000 gallons; 250,000 × 150 = 37,500,000 gallons, and to these figures must, of course, be added an allowance in capacities of mains, pumps, etc., to meet the fluctuating hourly flows.

(10) Water Supplies, Turneaure and Russell, page 22.

The waterworks of the six largest cities in Wisconsin (11) supplying an average of 81 gallons per head daily, cost about $187.25 per consumer, but eliminating one city, where the cost exceeded the average by nearly 100 per cent., the mean of five cities was $151.42 per consumer. Accepting this as the basis of cost, the waterworks system for a city of 250,000 inhabitants or 42,000 consumers will be about $6,360,000. It is therefore reasonable to estimate that for 50 gallons per head daily the cost will be about $6,000,000 and for 150 gallons per head $7,000,000. The extra $1,000,000 will annually cost 5 per cent. for interest and, say, 2½ per cent. for depreciation, a total of $75,000 per annum.

The cost of pumping water will be about six cents per million foot-gallons (12); so that 12.5 million gallons raised 200 feet will cost about $54,750, whereas 37.5 millions raised to the same height will cost $153,250, an extra cost of $109,500 per annum. The average cost in 21 cities in Wisconsin in 1911 was $16.70 per million gallons pumped and on this basis the annual cost would be $76,000 and $228,000 respectively.

Filtration and sterilization will cost about $3.37 per million gallons (13), to which is added the cost of pumping into filters, making a total of $3.50. So that, in the first city, this work will cost about $16,000 and in the second $48,000, a difference of about $32,000 per year.

The distributing mains, sufficient for domestic, industrial and fire purposes, should satisfy the National Board of Fire Underwriters' (1910) standard and also allow for the usual maximum fluctuations in consumption.

The National Board of Fire Underwriters' general requirements may be expressed by the following equation:

$$Y = 1020 \sqrt{X} (1 - 0.01 \sqrt{X})$$

Y = gallons per minute.

X = population in thousands.

The cities under consideration have about 250 thousands population, so that to satisfy the above requirements

$$Y = 1020 \sqrt{250} (1 - 0.01 \sqrt{250}) = 13,570 \text{ gals. per min.}$$

The consumption of 12,500,000 gallons per day is equal to an average of 8,700 gallons per minute and 37,500,000 gallons daily represents an average of 26,000 gallons per minute, but the maximum rate will probably be about 150 per cent. of the average. Therefore, the relative requirements of the two cities will be as follows:

	No. 1 City.	No. 2 City.
Fire purposes	13,570	13,570
Domestic and industrial purposes.	8,700	26,000
Add 50% for max. hourly demand	4,350	13,000
Total gallons per minute	26,620	52,570

In other words, the capacity of the mains in the city No. 1 will be only one-half of that in No. 2.

According to published statistics (14), distributing mains absorb about 64 per cent. of the total capita expenditure. There are other published figures which conflict with this percentage, but as the above result was evidently obtained by careful analysis of at least 22 dif-

(11) Wisconsin Railroad Commission Report, 1911, page 453.

(12) Wisconsin Railroad Commission Report, 1911, page 453.

(13) Fuller, Baltimore Works, Engineering Record, May 9th, 1914.

(14) Proceedings, American Waterworks Association, 1911, page 75.

ferent city waterworks, it may be taken for granted that it is reliable. The cost of the distributing mains in No. 1 city will therefore be about $3,840,000 and in No. 2 about $4,480,000 and additional expenditure of about $640,000. The cost of operating distribution works may be estimated at $2.50 per million gallons pumped (15) which in the first city would amount to about $11,400 and in the second about $34,200, a difference of $22,800 per annum.

After having distributed the water to the people, the city must also provide sewers to drain it away after use or misuse. The lateral sewers are, of course, designed for flows which normally will only partially fill the pipes. The trunk sewers must be calculated so as to be ample to accommodate the districts served.

Supposing that it was necessary to provide one main conduit to the outfall works, that the grade was 1 in 5,000 and that no ground water was admitted, the diameter of such a sewer to convey 12.5 million gallons per day would have to be about 54 inches and for 37.5 million gallons 82 inches, this does not take into account the hourly fluctuations, otherwise the diameter would have in each case to be larger. Accepting Cincinnati prices (16) the cost of these conduits would be:

54-in. Diameter Sewer—

Trenching 8 yds. @ $1.25	$16.00
Concrete, 1.38 yds. @ $15	20.70
Cost per foot run	$30.70

82-in. Diameter Sewer—

Trenching 11.3 yds. @ $1.25	$13.95
Concrete, 2.24 yds. @ $15	33.60
Cost per foot run	$47.55

That is, to convey three times as much sewage as would be required economically, the ratepayer would have to pay about 60 per cent. more in capital expenditure (and of course in annual taxes for interest and maintenance) on such trunk sewers. When the cost of vitrified pipe sewers are analyzed, it will be found that the extra cost for sewers laid to carry, say, 1,200 gallons per minute and 3,600 gallons per minute will be in the following ratio:

15-inch Pipe, Grade 1/600—

Vitrified pipes	$ .75
Trenching 10 feet deep	.70
Total per foot run	$1.45

24-inch Pipe, Grade 1/800—

Vitrified pipes	$2.00
Trenching 10 feet deep	.70
Total per foot run	$2.70

Extra cost 86 per cent., so that the additional cost to convey three times a given volume of sewage increases as the diameter of the sewers diminishes. The cost of sewering a city is probably about the same as to provide water mains, perhaps more, because water mains operate under pressure and sewers by gravity; the former are always full, whilst the latter are generally only partially full and consequently larger in diameter or dimensions. Many of the lateral sewers could not be reduced in size even if the water consumed was maintained at 50 gallons per capita, but many of the larger sewers could, and the saving in capital expenditure would be tangible.

(15) Wisconsin Railroad Commission Report, 1911, page 445.

(16) Report on a Plan of Sewerage, Cincinnati, 1913, page 252.

The next item of expenditure is for sewage disposal works. Whilst to some degree it is true that an extravagant use of water does not necessarily entail the construction of works to treat sewage, in proportion to the flow or volume, it nevertheless means works of a greater capacity than would be necessary in the case of economical water consumption, for tanks and pumps must be in some relation to the hourly quantity of sewage. The capacity of the pumps (if any) must be more than equal to the maximum hourly flow of sewage, with reserve pumps and power as well, in case of breakdowns or other contingencies, common to such plant. The velocity of the flow of sewage through the tanks must not for long periods exceed a critical limit. To attain this condition it is evident that tanks capable of treating 37.5 million gallons daily will be much larger than would be necessary for a discharge of one-third that volume.

Mr. George H. Wisner, in his report (17) supplies an interesting table of costs which is copied below:

Type of tank.	Nominal period of settling.	Gallons per capita.	Cost per capita.
Emscher	3 hours	200	$1.44
Dortmund	4 hours	200	.84
Straight flow	8 hours	200	.77
Straight flow	6 hours	200	.58

As Emscher or two-story tanks are now prominently before us, its estimated cost per capita will be provisionally accepted. To maintain the same velocity for 150 gallons per capita daily, the cost will be $\$1.44 \times \frac{150}{200} =$ $1.08 and for 50 gallons per day $\$1.44 \times \frac{50}{200} = \$0.36$. The writer does not contend that the cost of these tanks will be in strict proportion to the flow of sewage, as there are items of expenditure which are not proportionate; still, taken as an entity, the cost will not seriously exceed the above. Mr. Clark, when discussing a plant in course of construction in Baltimore, stated that the detention period with Emscher tanks would be two hours (18)—which is the ordinary standard detention period—consequently, to maintain this detention period as closely as possible, the number or sizes of the tanks must, in the cases under present discussion, be approximately in the same ratio as to dimension and cost. But to allow for contingencies, assume that the cost would be $1.10 and 40 cents respectively per capita, then, 250,000 × $1.10 = $275,000, and 250,000 × 40 cents = $100,000, a difference of $175,000 which, at 5 per cent. interest and 2 per cent. maintenance, etc., means $12,250 per annum.

Perco filters, again, are designed to deal with about 2,000,000 gallons per acre daily. Columbus filters were designed for this rating. Mr. George W. Fuller states in his book that his practice has been to specify for average conditions a 6-foot filter at an average rate of two million gallons per acre per day (19). This would be for a sewage flow of separate sewers approximately 100 gallons per capita daily. It is contended that perco filters will deal with approximately the same quantity of organic matter per acre per day, regardless of the degree of dilution. In other words, the organic matter from a residential city will, in the aggregate, roughly amount to the same

(17) Report on Sewage Disposal, Sanitary District of Chicago, 1911.

(18) Engineering Record, July 4th, 1914.

(19) Sewage Disposal, George W. Fuller, 1912, page 697.

quantity whether it is contained in a large or small volume of water. The British Government (Local Government Board) ordinarily requires in the case where there is no land for subsequent treatment or a large river for effective dilution, a filter 6 feet deep and one acre in area for each million gallons of sewage (dry weather flow) but when, as is the practice in America, a river is available for the ultimate oxidation of the filtrate, then the area is about one-half. It is, therefore, reasonable to postulate that for a consumption of 50 gallons per capita daily the area of filter will be about one acre per million gallons and for 150 gallons per day an area of one acre for each two million gallons, on which basis the respective areas will be about 12½ and 18¾ acres. A reserve must be added, say, ten per cent., which will increase the areas to 13.75 and 20.625 acres. Mr. Wisner estimates the cost of perco filters at about $28,000, whilst, according to the experience of other cities the average was about $38,000 (20). Basing the cost at $30,000 per acre, then, the first case will require an expenditure of $412,500 and the second $618,750, a difference of $206,250, which, at 5 per cent. interest, is equivalent to an annual burden of $10,312. The cost of operating and maintaining these filters may be placed at $2 per million gallons (21). This will amount to $12.5 \times 365 \times 2 = \$9,125$ and $37.5 \times 365 \times 2 = \$27,375$.

Sterilization of the filtrate by hypochlorite of lime costs about $1.67 per million gallons treated (22), when 4½ parts of available chlorine per million parts are applied. This for the first case would mean $7,620 and in the second case $22,860.

Summarizing the items already mentioned in the foregoing observations, the following results are obtained:

	No. 1 city. Consumption, 50 gals. per capita daily.	No. 2 city. Consumption, 150 gals. per capita daily.
Interest and depreciation on total capital on waterworks, per annum	$450,000	$525,000
Annual cost of pumping	54,750	153,250
Annual cost of filtration and sterilization	16,000	48,000
Annual cost of distribution works	11,400	34,200
Total on waterworks	$532,150	$760,450
Annual cost of sewers	.....	.....
Annual cost of operating sewage tanks, plus interest	$ 7,000	$ 19,250
Annual cost of operating perco-filters, plus interest	29,750	58,312
Sterilization of filtrate	7,620	22,860
Total	$ 44,370	$100,420

Adding the two expenditures together we arrive at a rough idea of what it means to the ratepayers:

	No. 1 City.	No. 2 City.
Waterworks	$532,150	$760,450
Sewage works	44,370	100,420
Total cost	$576,520	$860,870

The difference of $284,350, capitalized at 5 per cent., will represent a decent sum of $5,687,000.

The writer has advisedly adopted published figures and in doing so has quoted the authorities, but it is manifest that the above estimates serve only as indications, and therefore each city must be considered separately, although the foregoing statistics answer as direction posts to those who will carefully analyze the financial results to be obtained in their own cities. The foregoing will afford sufficiently safe basis to warrant a close scrutiny into the relative cost to the ratepayers of an economical versus an extravagant consumption of water. Furthermore, in those cities where the water supply is controlled by companies, the foregoing observations will suffice to show what waste means to them, and to their customers. The dividend-producing power of any franchise depends on an efficient management and this in its turn means the stoppage of all preventable waste.

(20) and (21) Engineering Record, 22nd August, 1914.

(22) Report on Plan of Sewerage, Cincinnati, 1913, page 567.

CEMENT PRODUCTION IN UNITED STATES, 1913.

A report on the cement output last year in the United States shows an increasing share of the rapidly growing consumption of cement in the United States being supplied by the domestic industry, production having risen from 8,000,000 barrels in 1890 to 93,000,000 in 1913; while imports of cement have fallen from 2,250,000 barrels in 1890 to 95,827 barrels in the fiscal year 1914; which is, with one exception, the lowest total reported in many years. The United States, according to the latest information received by the Bureau of Foreign and Domestic Commerce, Washington, leads the world in the production of cement, its output being approximately four times as much as that of England and nearly three times that of Germany.

The total quantity of Portland, natural, and puzzolan cement produced in the United States last year was the greatest in the history of the cement industry, according to a recent government report. The total amount was 92,949,102 barrels, valued at $93,001,169, compared with 83,351,191 barrels valued at $67,461,513 in 1912.

The total production of Portland cement in 1913, as reported to the Geological Survey, was 92,097,131 barrels, valued at $92,557,617; the production for 1912 was 82,438,096 barrels, valued at $67,016,928.

Of the 113 producing plants in the United States in 1913, 23 were in the State of Pennsylvania, whose output was 28,701,845 barrels of Portland cement, the largest quantity produced by any one state. The second greatest production came from Indiana, with 10,872,574 barrels, and California was third, with 6,159,182 barrels.

The natural cement produced in the United States in 1913 amounted to 744,658 barrels of 265 lbs. each, valued at $345,889, compared with an output of 821,231 barrels, valued at $367,222, in 1912. Puzzolan cement was manufactured in 1913 at three plants in the United States, in Alabama, Ohio, and Pennsylvania. The output of puzzolan and Collos cements in 1913 was 107,313 barrels valued at $97,663, compared with 91,864 barrels, valued at $77,363 in 1912.

The United States has a comparatively small export trade in cement. In 1913 the total quantity exported was only 2,964,358 barrels, most of which was Portland cement, valued at $4,270,666, compared with 4,215,232 barrels, valued at $6,160,341, in 1912.

In 16 years the United States office of public roads constructed 343 object-lesson and experimental roads. The cost has been borne by the localities, and the work of the engineers sent out has proven effective in spreading information. State-aid laws had passed in only 4 states 16 years ago, but 40 states have now adopted the state-aid principle.

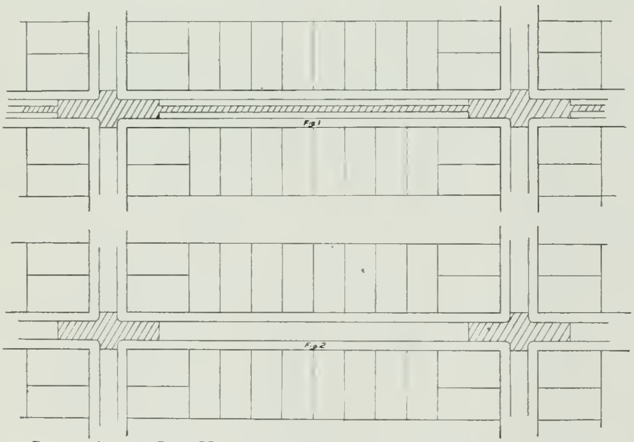
PAVEMENT AND ROADWAY WORK IN OTTAWA, ONTARIO.

By L. McLaren Hunter, A.M.Inst.M.C.E.
City Engineer's Department, Ottawa.

LOCAL Improvement pavements are either petitioned for, by property owners, or initiated under Sec. 9, Chap. 58 of the Municipal Act by the City Council on the advice of the city engineer. If the pavement is petitioned for, the act requires that there must be on the petition the signature of half the property owners representing two-thirds the assessed value of the property—if this is not complied with the petition will be of no use. Supposing, however, the city engineer decides that a pavement on this street is a necessity, then he may advise council to initiate the pavement under Sec. 9. Under these circumstances no petition against the work by the property owners will avail. The work must thereafter be proceeded with.

A Local Improvement report is then prepared by the roadway engineer. This report includes a sketch plan to a scale of 100 ft. = 1 in. showing the location of the work with the lots abutting on it. This L. I. report embraces also the report of the Board of Control and city engineer. The engineer's report contains a detailed statement of the estimated cost of the work.

The cost of the pavements up to July of last year was proportioned as follows: Property owners paid ⅓ the cost of the work opposite their respective lots; the city at large paid the extra third and also all street intersections and the cost of the surface drainage. The city had to pay, also, half the cost of the work opposite any flankage lots, if there were any on the street. It often happened that the city had to pay ¾ the cost of the pavement, so the Council decided to change the by-law and pass another, so that, under the new regulation, the property owners have to pay the cost of all work opposite their property, the city paying the street intersections and half the flankage lots as under the old by-law. Fig. 1 and Fig. 2 show the proportion of costs before and as now regulated. Although pessimists declared at the time the new by-law was passed that it would practically stop all improvements to streets, this happily has not been the case. On the contrary, petitions are now being sent to the city hall in larger numbers than heretofore, and at the time of writing over 200,000 yds. of permanent pavements have been constructed by the council.



Proportion of Cost Under Old (Fig. 1) and New (Fig. 2) By-laws. Shading Denotes Part Payable by City.

When the L.I. report is passed by the board of control and city council, detailed surveys are made and cross-sections taken, by the roadway department. The surveys are plotted to a scale of 40 ft. = 1 in. On the plan a profile of the centre of the road is shown, and also a section

Fig. 3.—Part of Working Profile.

of the type of roadway to be constructed. These are the contract plans, and from them the quantities are calculated for the contractors to tender.

The working profile from which the grades are given is plotted to a horizontal scale of 25 ft. = 1 in. and a vertical scale of 2 ft. = 1 in. The sidewalks on this profile are shown by lines of different colors, and on it are placed the crown of the new roadway in red, and the gutter grades, showing the locations of the various catch-basins and summits. Fig. 3 shows a part of a working profile.

The surface drainage is all done by day labor, and 6 months must elapse after it is completed before the construction of the pavement starts, thus giving time for the loose excavation to become properly consolidated again. At the beginning of the 1913 season the city engineer recommended that all lots not built upon should have sewer services constructed by the city and charged to the owners of the lots along with the first payment on the pavement. The council adopted his recommendation and all the pavements constructed last year had these services put in. In addition to this, all water and gas services are constructed into the building line of the street. This has saved the cutting and disfigurement of the pavements, in more than 50 instances. No more will the city officials have to complain that they are always "digging of it up and putting of it down."

A new system in calling for tenders is being tried this year. Instead of having bulk tenders for each street several streets have been let on the unit principle. A schedule has been added to the specifications upon which the approximate quantities of asphalt, gutter, curb and gutter, etc., etc., have been placed. The contractor fills in his price per sq. yd. or lin. ft., as the case may be, the total charge being placed on a blank form. When the work is finished it is measured by the engineer and charged at the schedule rates. This is the method in practice in Great Britain.

The type of catchbasin and cover used in Ottawa is shown in Fig. 4. It is constructed of concrete with a 6-inch outlet leading to the sewer. The cover is of cast iron and has a very neat appearance on the street.

Asphalt Pavements.—Fig. 5 shows a typical cross-section of an asphalt pavement as it is laid on the resi-

dential streets of Ottawa. There is a 6-inch concrete foundation of a 1:3:6 mixture; ¾ inch of binder, and 2-inch layer of asphalt.

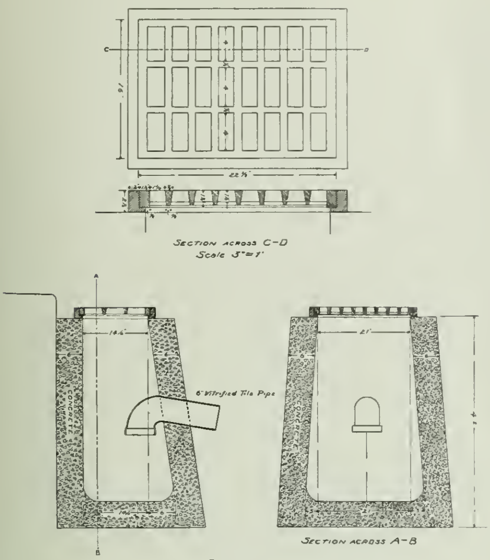


Fig. 4.—Catchbasin Details.

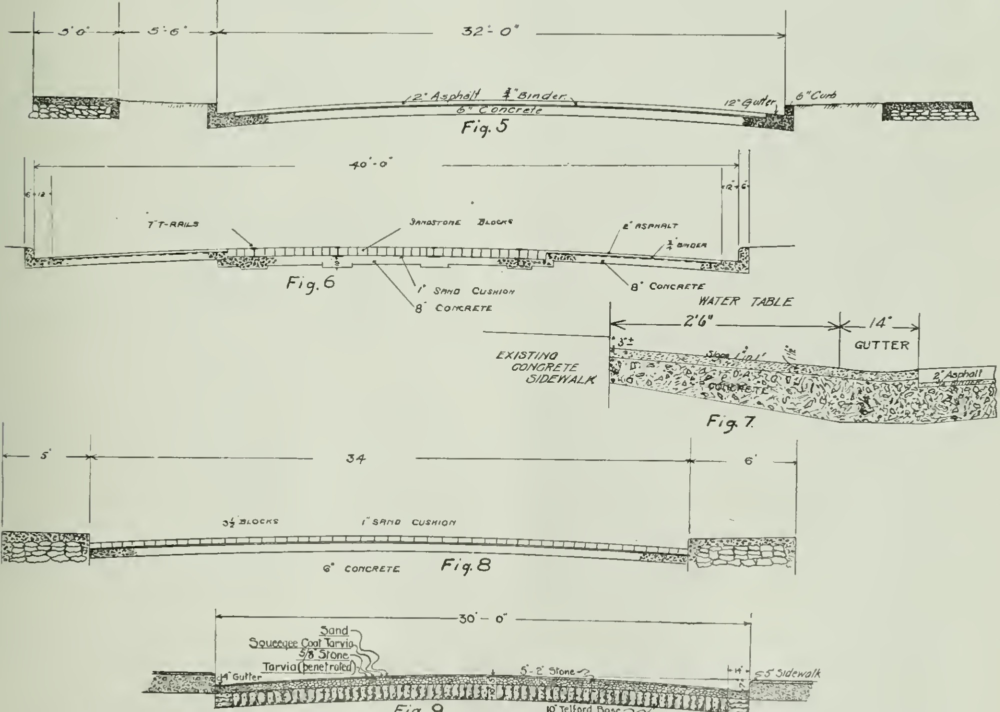
Fig. 6 shows a cross-section of a business thoroughfare, where the street railway operates; 8 inches of concrete is usually laid (especially if there is very heavy traffic) with the same thickness of binder and asphalt. If there happens to be a large number of telegraph poles outside the sidewalk, more so on a business street, a water table is constructed as shown on Fig. 7. This allows an unobstructed run of the water to the catchbasin and also eliminates the necessity for a curb and gutter, which would form a boulevard. In the business section this would be unsightly as the grass between the curb and the sidewalk would be trampled under foot and worn entirely bare.

The asphalts permitted to be used in Ottawa are, Trinidad, Pitch Lake, Bermuda, Mexican, and Californian, and, to show the exact locality from which it comes, the contractors have to furnish the city engineer with proper certificates of shipment.

The matrix or asphaltic cement is made of a mixture of the refined asphalt and flux, proportioned to show the presence of about 22% asphaltine.

The refined asphalt is heated to about 300° F., so that it may be properly agitated by the forced introduction of air. When it is thoroughly melted the flux is introduced and well mixed with the refined asphalt. This is the asphaltic cement that is used for making the binder, and the wearing surface for painting gutters, and, when necessary, for pouring joints.

The wearing surface is formed of the asphaltic cement described above, along with clean gravel and sand or crushed stone. The proportion of each is regulated



Some Typical Cross-sections: Fig. 5, Asphalt; Fig. 6, Asphalt and Stone Block (business street with car tracks); Fig. 7, Detail of Water Table; Fig. 8, Creosoted Wood Block; Fig. 9, Tarvia Macadam Roadway.

according to the kind and shape of the gravel and stone which will pass through a ⅜-inch mesh and be held by a 1-inch mesh. The sand or crushed stone is specified to pass through a ⅛-inch mesh and be held by a 1/50-inch mesh. The stone and sand are heated to about 300° F. by passing through revolving heaters. After all the moisture is driven off and all vegetable matter destroyed, while they are still hot, the asphaltic cement is added.

The proportion of each allowed in Ottawa is as follows (regulated so as to contain from 9% to 11% of bitumen in the wearing surface): Gravel and stone, size ⅜ to ⅛ inch, 25 to 25 parts; sand and stone, size ⅛ to 1/50 inch, 23 to 30 parts; sand, smaller than 1/50 inch, 35 to 35 parts; and asphaltic cement, 17 to 10 parts. These have to be thoroughly mixed and delivered on the work at not less than 250° F.

Two companies operate in the construction of asphalt pavements in Ottawa, namely, The Ottawa Construction Co. (John Foley, managing-director), and the Union Construction Co. (Pat. O'Leary, managing-director).

Creosoted Wood Block Pavements.—About 20,000 yds. of this class of pavement have been laid in Ottawa during the present season, by the Canada Creosoting Co., Toronto. A Norway pine block 3½ inches in depth is being used, laid on a 6-inch concrete foundation, with a 1-inch sand cushion. The blocks are treated with oil to the extent of 16 lbs. to each cu. ft. and are set with the fibre of the wood vertical, in straight parallel courses, at right angles to the curb, except that one row of blocks is placed parallel with the curb, about 1½ to 2 inches therefrom. This is filled with a bituminous filler (two of asphalt to one of pitch). Every 100 ft. a cross expansion joint is made, about 2 inches in width and filled in the same manner as the longitudinal one along the curb. The blocks are laid loosely together on the cushion coat, joints being never more than ⅛ in. in width. After they are laid they are rolled with a light steam roller, until the surface becomes smooth. Then water-washed sand is spread over and allowed to percolate into the joints. This is brushed off after the traffic has been allowed on it for about a week.

The first effect of traffic on the wood block is to broom the edges of the wood slightly, thus closing the joints and making them practically invisible, except near the curb where there is less wear.

Concrete gutters are only laid where the grade of street is less than .5%, otherwise no gutter is used.

Tarvia Macadam Roadways.—This type of roadway is becoming popular in the residential districts of Ottawa. It is laid on a Telford base, being stones about 10 inches thick, laid on edge. On this base is spread a layer of fine stone dust which serves to keep the Tarvia from penetrating into the foundation. The wearing course of evenly crushed 2-inch stone is then spread to a depth of 4 inches and dry rolled. The Tarvia is then spread on, after it has been heated to a temperature of not less than 200° F. Two gal. of Tarvia is used to the sq. yd. in this course. Over it is spread a coat of ⅝-inch stone which is rolled well in to fill up and cover any vein in the surface. A squeegee coat is then applied, about ½ gal. to the sq. yd. being used. Then clean sharp sand is spread on top and well rolled until thoroughly compacted.

Each year these roads are recoated with a coating of Tarvia "B," which adds greatly to the life of the road and also keeps down the dust. Fig. 9 shows a section of Tarvia macadam roadway as laid down in Ottawa.

DISTRIBUTION OF COST OF CONCRETE ROAD CONSTRUCTION.

Some interesting diagrams showing the relative costs of different items entering into the construction of concrete roads is printed in the report of Committee 12 on "The Cost of Constructing Concrete Roads," printed in the proceedings of the National Conference on Concrete Road Building, which has recently been issued.

Three diagrams showing actual costs are reproduced. The first shows the distribution of cost on seven Michigan roads, built 1909-1912, taken from a report by State Highway Commissioner Frank F. Rogers; the second shows similar data on eight sections of concrete road in Wayne County, Mich., built 1912-1913; and the third shows similar data for construction in 1903 reported by the Illinois Highway Commission. The accompanying table shows the percentages of the total for each of the several items in the three cases.

Table Showing Distribution of Cost in Concrete Road Construction—in Percentages.

Item.	Seven Michigan roads.	Eight Wayne Co. (Mich.) roads.	Illinois roads.
Labor:			
Mixing and placing	....	....	11.6
Unloading and laying ..	....	....	13.1
Shaping roadbed and trimming shoulders ..	....	....	6.8
Superintendence and miscellaneous labor	....	....	7.0
Total	43.0	46.0	38.5
Materials:			
Aggregate	29.0	27.0	25.2
Cement	22.7	19.9	31.7
Miscellaneous supplies..	5.3	7.1	2.3
Expansion joints	....	....	2.3
Total	57.0	54.0	61.5

In addition to these three diagrams, another is presented which is designated as a "weighted mean," covering data shown on the other three diagrams. On this diagram labor is given as 44.3 per cent. of the total and material as 55.7 per cent. The item of material is made up of aggregate 27.7 per cent., cement 21.6 per cent., and expansion joints and miscellaneous supplies 6.4 per cent.

Kaministiquia Power Company, which is so closely associated with the upbuilding of the twin cities of Fort William and Port Arthur, Ontario, continues to report good earnings. The net income for June was $22,697. After all fixed charges the surplus amounted to $15,042 for the month. For eight months the company's net earnings total $185,295 and the surplus for the same period amounts to $126,479.

The sources, respective quantities and percentages of the world's production of crude petroleum are shown in the following table:—

Country:	1912, short tons.	Percentage of total.
United States	32,897,060	62.16
Russia	10,174,560	19.23
Mexico	2,910,000	5.50
Roumania	1,987,360	3.76
Dutch East Indies	1,672,000	3.16
Galicia	1,298,620	2.45
India	1,101,450	2.08
Canada	38,750	0.073
Other countries	841,250	1.59

GENERAL CONSIDERATIONS AND COSTS OF REINFORCED CONCRETE DOCKS.

FOLLOWING up the articles that have recently appeared in these columns relating to the application of reinforced concrete in the construction of docks, the available data respecting cost of construction are such that full confidence cannot be placed in them owing to a certain danger of unreliability. Some figures are presented herewith, however, that cover the cost of docks as outlined in articles appearing in *The Canadian Engineer* for August 27th and October 1st, 1914. The data in Table I. have been collected from various publications by Harrison S. Taft and presented in his paper on the subject read before the American Society of Civil Engineers on May 20, 1914. The table gives the cost per square foot of construction.

Maintenance Cost.—A few figures covering the cost of maintenance of reinforced concrete docks in England are noted. In addition to what has already been said on the maintenance question,* the cold storage wharf at Southampton is reported to have cost nothing to date for maintenance. On the other hand, the widened dock and the coal jetties are said to have shown considerable deterioration due to rusting of the steel, it having been improperly placed in these structures. It has been stated authoritatively that "while six to seven years is perhaps a rather short time in which to form any definite conclusions, the maintenance cost (of the above described Port Talbot docks) has been practically nothing"

The annual repair charges on the Purfleet coaling jetty (exclusive of the damage done at the time of the collision) for the first 9 years of its existence are stated to have been but $50 per annum, which, based on its cost, $60,000, is less than one-tenth of 1 per cent.

Table II., from data published by the Chief Engineer of the Mersey Dock and Harbor Board in 1910, gives some very interesting results as respects the cost of annual repairs to six of the reinforced concrete docks at Southampton.

*See *The Canadian Engineer* Aug. 27, 1914.

If the results in Table II. are true, it is no wonder that the English engineers report that their reinforced concrete docks cost nothing for annual repairs.

General Considerations.

Opinions of Foreign Experts.—Although failures have accompanied the use of concrete in sea water and in the construction of reinforced concrete docks, it must be admitted that, if the Engineering Profession did not meet with a failure now and then, it would never acquire anything new, as it is through failures that it gains the most vital knowledge of engineering.

(*a*) In discussing the question of concrete docks, a prominent New York engineer has stated that, of the large number of concrete docks which have come under his observation, the majority have been a success, though here and there he reports a failure due to poor construction and material, and not to defects in the design. It is authentically stated that the reinforced concrete docks at Southampton have shown no deterioration due to salt water action, except at the Southampton coal jetty. The engineers of the Liverpool Docks have been using concrete in connection with their work since 1872, apparently with great success. It has been stated on the best authority that in England the alternation of "dryness and wetness and fluctuations in temperature" does not appear to have affected reinforced concrete sea water structures adversely.

Mr. Henry Hunter, Chief Engineer of the Manchester Canal, England, states that "the concrete in the concrete lock built at Eastham is in better condition at the present date than the day it was deposited," and adds that, covering an experience of more than 30 years of placing concrete in salt water, he has known no failures in such work where the concrete has been properly mixed and deposited.

In discussing the concrete docks of the Port Talbot Dock Company, Mr. William Cleaver has stated that:

"While reinforced concrete requires extreme care, both in the choice of material and in the supervision of the workmanship, the results justify the extensive adoption of the material for dock work."

Table I.—Cost of Concrete Docks.

Location.	Type.	Cost per square foot.
Pier No. 8, Puget Sound Navy Yard	Concrete columns Steel deck-beams. Concrete deck-slab.	$3.11
Naval Station, Philippines	Concrete columns. Steel deck-beams. Concrete deck-slab.	2.60
Balboa, Panama Canal	Concrete columns. Concrete beams. Concrete deck-slab.	3.28
Oakland, Cal.	Concrete piles. Concrete beams. Concrete deck-slab.	3.27
Brunswick, Ga.	Concrete piles. Wooden deck system.	1.40
Charleston Navy Yard, S.C.	Concrete piles. Wooden decking.	2.60
United Fruit Company, Panama	Concrete-protected wooden piles. Concrete deck-beams. Concrete slab.	2.13
Brooklyn, average of two docks	Wooden piles. Wooden caps. Concrete deck-slab.	0.90

The exceptionally experienced dock engineer, Mr. Francis E. Wentworth-Shields, of the London and South-western Railway Company, has stated that "if great care is exercised in making and placing concrete, an impermeable material will be obtained which can withstand the action of salt water." Mr. Shields has also said, "while many engineers were nervous about the life of reinforced concrete (for sea structures), he had observed that maintenance engineers were not so nervous as construction engineers." He is inclined to feel that there is nothing special to be feared respecting the life of reinforced concrete when used in marine work. Although, under certain circumstances, it is likely to deteriorate, he does not think it will do so from simply standing in sea water. He says that though in some cases deterioration has taken place at Southampton above low water, it has not done so below low water; that a 10-year-old reinforced concrete structure standing in sea water at Southampton is in perfect condition at the present date; and that, during the whole experience at Southampton, sea water does not seem to have produced any chemical or other deleterious action on the concrete.

Experiments by Mr. Baldwin-Weisman, in 1907, in England, on the permeability of concrete, show that, if it is well made, it is one of the most water-tight materials known, and that it rapidly becomes less and less porous when water is forced through it.

Mr. V. De Blocq von Keuffeler, in summing up the experience in using concrete for salt water structures in Holland, says:

"A suitable mixture, very carefully manufactured, the use of a good brand of cement with trass, and setting in a moist atmosphere, are the most efficient means of ensuring the preservation of reinforced concrete in sea water."

Mr. I. Ho, one of Japan's expert harbor engineers, who used more than 1,200 mass-concrete blocks in one instance, none of which during a period of 10 years has shown the slightest signs of failure, states, "that whereas a good and proper cement is of consideration, the most important factor is the mode of fabrication."

In reviewing the successful experiences of some of England's leading authorities, the question of the chemical composition of the cement used does not appear to be given. Such information would be of great value, in order that engineers may know whether they use a cement especially manufactured for sea water concrete or simply the ordinary Portland cement, with or without puzzolana, trass, etc.

(*b*) In discussing the deterioration of steel in reinforced concrete, by the action of sea water on ferro-concrete, provided the latter is properly made, Mr. C. S. Meiks, a prominent concrete engineer of England, says that such deterioration "is a negligible quantity." In support of this contention he cites the experience at Southampton, stating "that the exposed steelwork on a pile end that had been in the sea for 8 years was much corroded," whereas the bars in the body of the concrete, on being cut open, were found to be quite free from any rust and as fresh as the day they were put into the pile.

In connection with the building of some of the earlier concrete dock structures at Southampton, it appears that parts or the whole of piles not used were allowed to remain on the beach or shore, exposed to sea water, for some 7 years. At the end of this period the exposed steel had been badly rusted and deteriorated, whereas the part which was embedded in concrete was found to be in fine condition, practically as good as the day it was placed in the concrete. Still, concrete piles lying on the beach are not in the same position as concrete piles subjected to shocks in a dock.

Though the first jetties, built 11 years ago in Southampton water, are in excellent condition at present, the steel in another jetty at the same location has deteriorated, due to electrolytic action.

It is generally accepted by all English authorities that no deterioration takes place in steel when well embedded in the concrete.

(*c*) In speaking of reinforced concrete when used in marine work, Mr. Wentworth-Shields says "it will stand a wonderful amount of shock, and bending due to shocks, if a wooden fender is interposed." At a more recent date, Mr. Shields remarked: "On the other hand, reinforced concrete would not bear being knocked about by heavy ships, and where a structure was subjected to severe blows of that sort it was not easy to find anything better than timber, * * * but, when used at the right time and in the right place, reinforced concrete was a valuable material to dock engineers." From the leading position Mr. Shields occupies among the dock engineers of England, it would be of interest to know just what distinction there is between "a wonderful amount of shock" and "subjected to severe blows."

As an axiom: whatever system or design is adopted for a reinforced concrete dock, in no manner whatsoever should a vessel be allowed to rub against the main piling of the dock. The dock should always be protected by a system of fender-piles.

(*d*) As respects the resistance of a concrete pier or dock, when under such treatment as the Purfleet pier was at the time it was rammed, in 1904, Mr. Meiks, engineer in charge of its construction, states that "the vibration

Table II.—Annual Repairs, Southampton Docks.

Dock.	Erected.	Cost.	Cost of repairs to date.	Average per year.	Annual percentage based on original cost.	Remarks.
A	1899-1900	$24,000	$800	$80	0.0033	Deck for Cattle Wharf, Prince's Jetty (wood piles).
B	1904-06	63,500	375	75	0.0012	Floor or deck on Hennebique piles, Prince's Dock, West Quay.
C	1900	13,800	80	8	0.0005	Floor for wharf, Coburg Quay.
D	1901	3,700	25	3	0.0008	Floor for wharf, etc., Brunswick Half Tide Dock.
E	1908	17,500	....	...	......	Floor for wharf, etc., North Quay, Brocklebank Dock.
F	1908	163,500	....	...	......	Treble-story shed, South Quay, Sandon Dock.

Dock *A*. Subject to the effect of moist air arising from water below it.
Dock *B*. Subject to effect of moist air. Piles more or less submerged, according to water level.
Dock *C*. Complete reinforced shed and pile foundation; not sufficient time to form any conclusion.

was so great at the time of the collision that they thought the entire pier would collapse, but that its elasticity was most satisfactory, due no doubt to its horizontal concrete decking." Mr. Meiks also says that the vibration of a concrete pier supported on piles is nearly as great as in a pier made of timber piling; but this has no particular effect on the structure, judging by the experience gained with the Purfleet pier at the time it was rammed.

In speaking of the Port Talbot docks, Mr. A. E. Carey has stated:

"If the structure (reinforced concrete dock) was properly designed and built, its stability and life were assured, the only serious drawback being the difficulty of repairing damage due to collision."

But how often do collisions happen?

The Chief Engineer of the Port of London, Mr. Bryson Cunningham, recently stated that the art of building reinforced concrete docks in England has attained a degree of perfection greatly in advance of early experimental work. If their early experimental docks are still doing good service, will not their more recent docks become structures of an engineering and commercial success, thus justifying the American engineer in recommending concrete docks as long as they are built in a manner to guarantee impermeability and non-deterioration of the concrete?

Concrete Breakwaters.—As the application of reinforced concrete to dock construction has been developed almost entirely since 1900, some of the most conservative engineers may not feel that sufficient time has elapsed to judge correctly as to the merits of using cement and placing concrete structures in sea water, and as to the advisability of adopting reinforced concrete as a coming type of dock structure. As respects the first point, the prolonged and successful use of mass concrete by foreign countries in breakwater, tidal, and graving dock work would in itself appear to be sufficient answer to all such skepticism.

Though an extensive treatise might be written on concrete breakwaters and their construction, including shore protection, those phases of the use of concrete in sea water are supplementary to the principal subject of this paper. There is apparently hardly a leading seaport or a maritime nation outside of the United States that has not made a wide, extensive and successful use of mass and reinforced concrete in the development of harbor and shipping facilities.

Surprising as it may seem, a number of large concrete breakwaters have been in existence in Japan for more than 18 years. As a matter of fact, the use of concrete in the harbor work of Japan is far in advance of American practice, being apparently on the same high level as in England and other European countries.

Mass concrete has been used very extensively in Belgium and Holland for sea water structures for years, and has given the best of results. In fact, some of the concrete sea walls in the latter country, built in 1867-77 and earlier, are so old as to be called ancient, and have as yet shown no signs of being affected by the action of sea water. Perhaps such a statement needs to be qualified, because some of the principal harbors of Holland are some distance from the sea, and are in fresh or brackish water.

Concrete was used by the Romans and Carthagenians in ancient times. Though it fell into disuse for many centuries, it came into use again in 1840-50. To this day, sea walls built of puzzolana and lime cement by the Romans are in existence in Italy.

The Italian engineers report that Portland cement concrete with an addition of one-eighth to one-tenth by volume of puzzolana gave no signs of disintegration in salt water, even after an exposure of 30 years in the harbors of Genoa, Civita Vecchia, Naples, etc.

At several places on the Italian coast concrete-faced breakwaters have been in existence since 1880, in most exposed positions, costing but little for repairs and maintenance, though subject to the high seas and heavy blows of the Mediterranean.

English engineers were using mass concrete in their tide locks and in the construction of massive breakwaters along the coast of England as far back as 1871, if not earlier. The fact that they have continued to use it more extensively each year, even to building vast reinforced concrete structures standing in sea water during the past 15 years, would appear, in spite of some failures, to be sufficient answer to any doubts the American engineer may entertain on the subject.

At Colombo, India, a concrete breakwater, finished in 1885, showed no failures above or below water at the end of 22 years. As stated above, some of the massive concrete breakwaters of the world have a hard stone facing, or are built of concrete blocks, with or without a stone facing.

The reasons that enable the foreign engineers to accomplish such lasting results with concrete is no doubt due to the fact that they, together with the foreign chemists and cement manufacturers, long ago learned the secret and acquired the art of manufacturing and using concrete in sea water structures. Though the American engineer excels the foreign engineer in certain lines of his profession, it must be admitted that, so far as using cement, and hence concrete, in sea water structures, the engineers of the leading European countries and of certain parts of South America are many years in advance. The American cement manufacturer, the chemist, and the harbor development engineer cannot long remain in such a position without reflecting on their ability as experts in their respective lines of work in the minds of their foreign contemporaries.

In view of the marked success obtained by foreign engineers in the use of concrete for sea water structures, when the execution of such undertakings has been placed in the hands of intelligent, skilful, and experienced men, the American engineer who denies the possibility of making a successful use of concrete for structures standing in sea water puts himself in a questionable position. He thereby confesses either his lack of a world-wide knowledge on the subject, or his inability to carry out properly such classes of construction work to the same successful conclusions as his foreign contemporaries have been doing for years past. Such a confession would seem to indicate a lack of foresight and ultra-conservatism as respects the use of cement subject to sea water conditions, on the part of the American cement manufacturer, chemist, and concrete engineer.

The American engineer who assumes a skeptical attitude toward the practicability and commercial success of reinforced concrete docks has standing before him as silent testimony of their worth and practicability such a vast number of foreign reinforced concrete docks—several about 20 years old and yet in excellent condition, with still more massive structures being built each year, some of them costing less than wooden docks, if reports are true, and most of them saving their owners large sums annually on account of their low cost of maintenance and repairs, with no rebuilding, as with our 15-year creosoted

wooden pile docks—that the grounds on which he stands become somewhat untenable. It is true that all American cements are not as yet wholly suitable for sea water purposes, and perhaps equally true that each and every American concrete engineer has not hitherto insisted on the proper placing of concrete in salt water structures, not fully realizing the importance of the fundamental principles of the use of concrete in sea water, due to the hitherto limited call for such types of structures in America, lumber having been so plentiful and cheap.

Though reinforced concrete docks have been in existence for more than 15 years, and operated successfully, the same old theorems are still put forth in opposition to them and to the practical experience gained during this period. Possibly these same theories will continue to be advanced against the use of concrete in dock work and other sea structures by the most conservative of our leading engineers, though others, guided and profiting by the experience already gained in such uses of concrete, will continue to expend large sums of money in the further development of such structures.

From a prolonged study of reinforced concrete dock construction, as carried out in foreign countries, it would appear that, in spite of early doubts and skepticism, the success in the use of reinforced concrete in dock work obtained by foreign engineers has swept away all such doubts and skepticism. If these are not facts, why are foreign countries and certain ports in America, including the United States Government, expending vast sums of money in building reinforced concrete docks and in other uses of concrete in harbor development and sea protection work; all "in spite of prejudices which leading engineers (psychologically) have against any new type of construction?"

Although the average American contractor may look upon concrete as just so much cement, sand, and stone, or gravel, to be thrown together and dumped into the forms in the quickest possible time, without any regard for the fundamental principles underlying reinforced concrete construction, a commercial proposition purely, such an application of reinforced concrete to dock work will most certainly spell disaster long before the structure is completed.

In spite of its apparent simplicity on dry land, the use of reinforced concrete in dock work calls for more than mere brawn and muscle. It is a class of construction work especially adapted to the broad knowledge, experience, and deep study of the trained engineer in association with an organization well skilled in the handling of concrete in sea water structures—"a field of engineering in which reinforced concrete will prove to be the most permanent and economical, as it has in the building of bridges, etc."

ST. JOHN VALLEY RAILWAY NEARING COMPLETION.

Before the end of the present month the St. John and Quebec Railway Company expect to have the St. John Valley Railway from Gagetown to Centreville, N.B., ready to be taken over by the Intercolonial. Arrangements are being made for the construction of a connecting link from this line to Fredericton. The proposed route through the city was recently laid before the city council by Mr. S. B. Wass, chief engineer of the St. John and Quebec Railway, and who is in charge of the work. Surveys have been under way for a short time past. The city council has just approved of the contemplated route.

CANADIAN MANUFACTURE OF SHRAPNEL SHELLS.

The Canadian Engineer is informed by Colonel A. Bertram that contracts are being let to various manufacturers in Canada to supply 15 and 18-lb. shrapnel shells and component parts for same. Subsequent inquiries by *The Canadian Engineer* show that these orders are being very widely placed. Among the companies which have received them are the Canadian Locomotive Company, the Canada Foundry Company, the Nova Scotia Steel Company, the Canada Forge Company, and the Canadian Billings and Spencer, Limited. The latter are subsidiaries of the Canada Foundries and Forgings, Limited.

The orders are generally for large quantities and will keep various departments of the companies in full operation during the winter.

Mr. T. J. Dillon, president of the Canada Forge Company, Limited, Welland, states that the shells are forged under their new modern hydraulic forging presses, which are equal in power and efficiency to any on this continent or in Europe.

These two plants are fully equipped to produce any size or class of shells or projectiles which may at any time be required by the government Militia or Navy Department, and it is at the Canadian Billings and Spencer Plant where all the forged steel parts for the Ross rifles are made.

To handle these orders on behalf of the Dominion government, acting for the Imperial government, a shell committee has been appointed with headquarters in Montreal. The members of the committee are: Col. A. Bertram, chairman; Thomas Cantley, George W. Watts, E. Carnegie, Col. T. Benson, Lieut.-Col. F. D. Lafferty, and Lieut.-Col. G. Harston.

INVESTIGATION INTO THE IRON MINING INDUSTRY.

Pursuant to a request made to the Dominion government for the granting of some measure of assistance toward the development of iron ore mining in Canada, and in accordance with the statement of the Hon. Minister of Finance in his budget speech during the 1913-14 session of Parliament, that the iron mining industry would be investigated, a committee has been appointed to enquire into the situation and to report the facts to the government. This committee consists of Messrs. O. E. LeRoy, G. C. Mackenzie, E. Lindeman and John McLeish, secretary.

Every owner or operator of an iron ore property in Canada should be interested in facilitating this enquiry and should communicate with the Deputy Minister of Mines at Ottawa, or the secretary of the committee, who will furnish a schedule of questions covering the information required by the committee.

OUR PUMP IMPORTS.

According to a pamphlet recently issued by the Commercial Intelligence Branch of the Board of Trade of Great Britain, the German trade in hand pumps with Canada, prior to the outbreak of the war, was more than 8 times that of Great Britain. That of the United States with Canada was over 51 times that of Great Britain.

Editorial

USE OF CANADIAN-MADE GOODS.

A recapitulation of Canada's import trade shows that during the fiscal year ended March 31st, 1914, we paid $14,686,069 to Germany, $1,787,473 to Austria, and $601,855,332 to other countries, for their products.

A few weeks ago the Council of the Toronto Board of Trade adopted the following resolution with reference to the use of Canadian-made goods by governments, municipalities, architects and engineers in all works under their control:

"Resolved that, in view of the state of unemployment existing, and of the large importation of goods into Canada, much of which could be supplied by Canadian manufacturers, the Council of the Board of Trade of the City of Toronto make representations to the Ontario Government, the City Council, the University of Toronto, the Board of Education, and the societies of engineers and architects, requesting them, where possible, to use Canadian-made goods for all works under their control."

Copies of the resolution were forwarded to the Boards of Trade throughout Canada asking them also to take similar action with governmental and municipal authorities, architects and engineers in their districts.

Realizing that the Trades and Labor Council's estimate of 20,000 unemployed in Toronto at the present time bespeaks similar conditions of a more or less acute nature in other cities, an effort at the development of every possible Canadian resource would undoubtedly result in the employment of the majority of these unfortunate laborers, the building up of Canada's revenue, and the strengthening of her credit as well.

It must not be forgotten that the incoming flood of foreign-made goods has been checked by the manufacturers themselves owing to lack of assurance of early payment, as much as by the consumers who have been obliged to bear the brunt of the financial stringency. The demands for manufactured goods have fallen off, not from a declining desire on the part of the municipalities, etc., to go ahead with their work but from a necessity owing to the unavailability of foreign capital. Under these circumstances the manufacturers of foreign-made goods should feel it no reflection upon themselves or their products that a widespread movement is under way in the Dominion to bring prosperity out of depression by the advocation of home-made goods for every possible service. There are many important works, small and large, that cannot be delayed for a lengthy period. Among them are certain works that demand goods impossible of adequate and successful manufacture, commercially, in Canada. For these we must look to our close friends and neighbors, the United States and Great Britain, who can supply practically every need of this nature.

The Toronto Board of Trade suggests that every manufacturer and merchant lay down the policy for his purchasing department of demanding Canadian-made products; that architects, builders, and contractors keep thousands of Canadian workmen employed by calling for Canadian-made materials in their building specifications; that government and municipal authorities have it in their hands to create a tremendous volume of business in Canadian factories, and that it would be wise for them, as well as patriotic, to give our own workmen the employment so that they will not become a charge upon the country.

THE CANADIAN MUNICIPALITY AND THE BANK.

A letter comes from a reader of *The Canadian Engineer* stating that a certain municipal contract had not been awarded "owing to concerted actions of the Canadian banks." Our correspondent adds that "towns and cities urgently require public improvements and are willing to pay for them in the only possible way of a new country," and hints that "the bankers are taking advantage of the war to squeeze the municipalities."

This view, we think, is held by many people in Canada, but when the position is closely analyzed it is found to be scarcely the correct one. The Dominion is a heavy borrower and to date has obtained £500,000,000, or about $2,500,000,000 of capital from Great Britain. This has been used largely in constructive work, such as the building of railroads, steam and electric; power developments; water and sewerage systems, and various other improvements of public utility or industrial nature. The country was building not only for the present but also for the future. Looking back now, we realize what a tremendous amount of construction work has been done in the past few years.

Dr. Adam Shortt, discussing the situation in a public address at Toronto the other day, stated that, generally speaking, we have in Canada enough constructive machinery and that what is necessary now is more production from the plant which has been installed. This is largely true. Our development has been very rapid and practically all upon British and foreign capital. The supply of capital is now stopped on account of the war. We cannot ask the Canadian banks to take its place. That is not their function, besides which it would be bad business for national credit. A curtailment of expenditure was due anyway, as the country had come to the end of an unusually active period of construction, and the beginning of a period of what it is hoped will be heavy production. The transition of the one to the other is involving some hardships. It means the transfer of labor to some extent, of economy in expenditures and of efforts to direct capital into some new and productive channel. The municipality to-day is trying to do what the individual and governments must do—economize to a reasonable and necessary extent.

The banks' chief duty is to see that they are prepared against all contingencies. Discussing the position of the banks in the present crisis, Dr. Shortt referred to the popular cry in certain quarters for them to come to the rescue just now and provide money to maintain the city and railway construction which had been going on and had been supported by British capital. "That would be perverting the function of the banks," said he, "which was simply the facilitating of exchange. You cannot," he continued, "by adjusting the banking system create one more mouthful of food. The money-lenders abroad must be paid by bills of exchange or counter goods, and not by Dominion notes."

Mr. J. W. Flavelle in a recent public speech said: "Let us bear in mind this is not the banks' trouble. A great number of us seem to have the impression that the only reason that we are unable to borrow all the money we need is because the banks are unreasonable and won't lend it. After all, the amount of resources which we have liquid in this country is comparatively limited. What do our friends the bankers have to do? They are trustees to hold these liquid resources of this country available for the need of this country, distributing them as best they may over the largest surface possible to accomplish the best result."

The same point was made in an interview recently given by Mr. G. B. Schofield, general manager of the Standard Bank of Canada. After stating that the Canadian banks would still stand in most intimate relationship with the manufacturing, agricultural and commercial life of Canada, he added: "Now, the role so long played cannot be cast aside, even if the banks wished to do so; which, as I need not say, they have no desire to do. At the same time, the banks must of necessity be very careful what they do with the people's deposits at this trying time. We must, above all, see to it that we keep our assets liquid. While every aid will be given to legitimate business enterprise, we must be doubly careful to see that such funds as are advanced are not placed in fixed capital forms. Now, as never before, it is necessary to keep our resources in a fluid form."

The Canadian banks have on loan to municipalities throughout Canada at the present time more than $40,000,000. Since 1905, Canadian municipalities have borrowed over $200,000,000, while they have raised also large sums in Canada and the United States. It is not contended that municipal development has ceased in this country, but owing to the economic depression and the advent of the war, much of that development is suspended temporarily.

At the same time *The Canadian Engineer* reiterates its opinion that governments, federal, provincial and municipal in times of extreme trade depression, should spend money on public work so far as proper economy dictates. So long as there is a sound method of financing such works, the banks will probably be found willing to take the necessary action. In a time such as the present, and in view of the fact that the theatre of war is not actually on Canadian soil, the Dominion Government well might employ fairly substantial sums upon certain public works, consistent with economy. Private borrowers will hesitate considerably at present because Canada's chief lender (Great Britain) has a bigger job on hand now than loaning money to its overseas dominions. Indeed, private borrowers, in which are included corporations, are almost helpless, except for funds in hand and for the possibility of borrowing elsewhere than in Great Britain.

It is reported that timber limits extending over 115 square miles along the foreshore of Seymour Inlet and adjacent waters in British Columbia, including 3,000,000,000 feet of high-grade cedar, were recently transferred to a syndicate of capitalists from the United States. It is said to be the intention of the purchasers to begin logging operations on the limits in the near future, and the plans contemplate placing several sawmills on the property. The scarcity of cedar and the increasing price of high-grade timber in the United States have caused American millmen to turn their attention to British Columbia, which has the largest compact area of merchantable timber on the continent. The abolition of the duty on Canadian shingles and other forest products has encouraged and given impetus to the shingle industry, which has made great progress in the province recently.

DEEPENING OF BURNETTE RIVER, B.C.

A very interesting drainage project is being carried out by the Vancouver and Districts Joint Sewerage and Drainage Board. The Burnette River is being deepened between Burnaby Lake and the eastern boundary of the municipality of that name. The new channel will regulate the size of Burnaby Lake. It forms a part of the sewerage scheme reported upon by Mr. R. S. Lee, consulting engineer, Montreal, and adopted by the municipalities. The scheme divides the Burrard Peninsula into several areas according to the bodies of water into which each drains. One of these is the watershed emptying into Burnaby Lake. The report, taking cognizance of the fact that the lake could hold a very limited amount of domestic sewage, but almost unlimited natural drainage, provided that an intercepting sewer be ultimately built around the south shore of the lake; but that for the present, and until the district had become more densely populated (the domestic sewage now being almost negligible), surface water might be allowed to flow into the lake.

The rise in the lake each spring is considerable, owing to the nature of the country surrounding it and also to a ledge of rock at the outlet into Burnette River which prevents more than a certain flow. The lake is thereby rendered more or less stagnant. The Joint Sewerage Commission, therefore, started during the summer on the task of deepening the river. A mile or more at the eastern end of the municipality has been dredged and cleared of boulders and logs which impeded the stream flow. Further up the stream the rock bed has been blasted out to a uniform depth of 6 or 7 ft. lower than the original depth. This cut, about 7 ft. in width and a mile or more in length, conforms to the old bed of the river. A temporary diverting flume is used to deviate the stream from the site of operations.

The Sewerage Board expects to continue the work well into the coming winter. This will necessitate a different method of flow control. It is proposed to dam back the flow a short distance from the outlet of the lake and to curtail it during the 8 hours of each working day, allowing the accumulated water to run off during the intervening 16 hours.

The work will result in a uniform depth, during summer and winter, of Burnaby Lake. It will greatly facilitate the drainage scheme and will permit the reclamation of a considerable area previously subject to floods in the rainy season. Eventually the level of the lake will be lowered several feet and approximately 150 acres more land will be thereby reclaimed. The Provincial Government has been approached with a proposal to convert the lake and its surroundings into a park.

The "Vita" the third of three similar steamers, which are being built at the Neptune Works of Swan, Hunter and Wigham Richardson, Limited, for the British Indian Steam Navigation Co., Limited, for the service of that company between India and the Persian Gulf, was launched on August 24. She is a twin screw steamer, 390 ft. in length by 53 ft. beam by 26¼ ft. in depth, and has accommodation for first and second-class passengers, together with space for a large number of native passengers. The propelling machinery is being built by Swan, Hunter and Wigham Richardson, Limited, at their Neptune Works, and consists of two sets of triple expansion engines with six large boilers of sufficient power for a speed of 16 knots. The auxiliary machinery is very complete and includes 8 steam winches, steam warping winch, steam steering gear, steam capstan, steam windlass, electric light and ventilation, wireless telegraphy, refrigerating machinery, etc.

AMERICAN ROAD CONGRESS, ATLANTA, GA.

"Overtopping all other road problems in its importance is that of maintenance," says Logan Waller Page, Director of the United States Office of Public Roads and President of the American Highway Association. "The destructive agencies of traffic and the elements are unceasing in their activities and it is idle to talk of permanent roads any more than to speak of a house, a fence, or a railroad ties as permanent.

"The public roads to-day, by reason of the exceptionally destructive traffic conditions, are more costly in construction and this is continually increasing with the advance in the prices of labor and material. It is criminally wasteful, therefore, to invest large sums of public money in building the highways demanded by traffic, unless the investment is conserved by adequate maintenance. Without such adequate maintenance a road costing anywhere from $5,000 to $15,000 per mile may go to ruin in a year or two, thus involving a permanent loss of considerable magnitude.

"When it is considered that the aggregate expenditure on roads in the United States is well over $200,000,000 annually, the seriousness of the question is apparent. I look to the conference of highway officials which will be held during the Fourth American Road Congress, which meets in Atlanta, Georgia, on November 9, to devote much attention to road maintenance, and that the accumulative moral effect of their findings will go far towards bringing legislatures and county boards to a realization of the necessity for prompt and efficient action. The roads should be classified and suitable maintenance, in organization and money, provided according to the importance of the representative classes of roads."

One of the questions which the Congress will discuss is that relating to the revision of road laws. A complete compilation of the road laws of all the states will be available for the session devoted to legislation and it is expected that in outlining bases for revision, maintenance will be given particular attention.

OPPORTUNITY FOR CANADA IN PAPER INDUSTRY.

A report from the European continent announces a dearth of sulphite pulp. Quotations on wood pulp have advanced from 92 to 145 shillings per ton in England. On the outbreak of the war 30,000 tons of paper consigned to the United States were on the sea. Of this amount, 20,000 tons had been sold, and the remainder not yet disposed of. The United States annually imports 350,000 tons.

France and Great Britain are beginning to suffer, as the greater part of their paper comes from Germany and Scandinavia. With Germany eliminated, Scandinavia is left to supply both countries. As the Baltic sea is normally open to commerce only between May and November, importers customarily lay in sufficient supply in the later part of the summer to last for the year. The present is the season of lowest supply.

With the Baltic blocked on account of the hostile fleets and with little hope of its being opened shortly, the shortage is being felt more and more each day. Some of the English publishers have already cut down the size of their papers. South American publishers are feeling the stress too, as they also procure paper from Europe. This leaves Canada as the only producer that is not affected which has any surplus paper.

Coast to Coast

Winnipeg, Man.—The engineers of the administration board of the Greater Winnipeg Water District have announced that, while the original estimates for the Shoal Lake scheme totalled $13,045,000, the outlay will be $1,200,000 less than that amount. Total disbursements on the entire project up to September 25 were $946,431.82; and the bank overdraft, $340,354.34.

Calgary, Alta.—Good progress is reported upon the work being supervised by Engineer Winter on the new east-end tunnel, which is to convey the Calgary sewerage system under the Bow River at Fifteenth Street East for the accommodation of Tuxedo Park and other parts of the North Hill. Of a total approximately 900 feet, 285 feet of the tunnel have been constructed, and it is stated that it will take until midwinter to complete the work.

Montreal, Que.—Outstanding features of the work which has been accomplished by the C.P.R. during 1914 are a new machine and erecting shop at McAdam Junction, as well as over one mile of new storage tracks to the yard at that centre; at West St. John, a fireproof elevator with a capacity of 1,000,000 bushels together with an up-to-date power house, also extensive improvements to terminal facilities in that city; at Windsor Station, Montreal, improvements to the passenger and freight terminals, the train shed just completed being one of the most modern and one of the largest now known; at Place Viger, Montreal, the completion of the improvements which have been in progress for three years, and which comprise a station, an hotel and trackage, the erection of which has cost nearly $5,000,000; and the commencement of the Union Station at Quebec. Throughout the year, also, there was completed the double track bridge at Lachine costing nearly $3,000,000 and the new Lake Shore line opened for traffic in June. The commencement of the new station and viaduct at Toronto has been authorized, and is being delayed only temporarily. Other works authorized and now assuming various stages of completion are: the extension of the Kippewa branch line 10 miles in a northerly direction; a 30-mile extension from Expanse to a junction with the Weyburn-Sterling branch of the C.P.R., which will be completed this fall; the line between Swift Current and Empress, a distance of 112 miles, which will be completed this year; the main line cut off from Swift Current to Bassano, of which 150 miles are completed; the 78 miles of the C.P.R. branch from Lacombe to Kerrobert, a new extension; the Alberta-Central Railway to Lochern, a distance of 65 miles from Red Deer; the great tunnel at Roger's Pass, of which one mile of the Pioneer tunnel has been completed; the C.P.R. depot and terminal offices at Vancouver; the Kootenay Central which is now open for traffic, from Golden, 60 miles south, and the work on which is being pushed vigorously between Golden and Colvalli; and the Esquimalt and Nanaimo line from Parksville Junction to Courtenay. Further, the C.P.R. is interested in the Kettle Valley Railway, and in connection with the same it is building a line from Midway to Penticton—a distance of 134 miles, 76 of which are already open for traffic. A line from Penticton to Osprey, 41 miles in length, has been completed; and work has been commenced on a new line between Osprey Lake and Princeton. The Kettle Valley Railway is also building a line 54 miles in length between Hope and Otter Summit; and a part of the track has already been laid. In addition to all this, the C.P.R. has continued its policy of double tracking.

PERSONAL.

W. P. HINTON has been appointed Assistant Passenger Agent of the Grand Trunk Railway with head-quarters in Montreal.

W. S. DAVIS, of Oakville, has been appointed to the Toronto-Hamilton Highway Commission, to succeed C. G. Marlatt, resigned.

C. L. CANTLEY, assistant general manager of the Nova Scotia Steel and Coal Company, is with the Canadian contingent as a lieutenant in the 5th Royal Scots, 13th Battalion.

MAURICE KERNOH, chief engineer of the Australian State Railways, is in Canada, investigating the government ownership, construction and management of railways and canals.

THOMAS ADAMS, of the Local Government Board of Great Britain, has been retained by the Commission of Conservation, Ottawa, to act as adviser in the work of encouraging town planning in towns and cities in Canada.

FRANK W. SKINNER, M.Am.Soc.C.E., has opened consulting offices at 45 Broadway, New York, and in the Crabtree Annex, St. George, Staten Island, and is associated with Mr. C. E. Fowler, C.E., Seattle, Wash. Mr. Skinner will continue in the field of bridge and structural steelwork, foundation and general civil engineering field construction methods, operations and plant with which he has long been intimately and extensively identified, and will also specialize in the preparation of engineering cases for litigation, expert witness research and testimony, preparation and mediation of cases in controversy.

EN ROUTE FOR THE FRONT.

A partial list has been compiled of the University of Toronto men who are now in England with the first Canadian expeditionary force. This contains the following names of students and graduates of the Faculty of Applied Science and Engineering:—L. C. M. Baldwin '14, P. G. C. Campbell (4th year), E. S. Foulds '11, G. G. Blackstock (4th year), B. H. Hughes (3rd year), G. H. Marani (3rd year), H. A. M. Grassett (3rd year), H. F. H. Hertzberg '07 (Chief Engineer, Canadian Bridge Co., Walkerville), H. A. Heaton '14, R. W. Hains (2nd year), T. S. Glover (2nd year), F. L. Erdley-Wilmot (2nd year), D. H. Storms (4th year) and C. H. Mitchell, C.E., '92 (Consulting Engineer, Toronto). Major C. H. Mitchell received an appointment to the post of general staff officer on the headquarters staff of the Canadian division.

ONTARIO CANALS UNDER INSPECTION.

Hon. John A. Bensel, New York State engineer, and the Board of Consulting Engineers of the New York State barge canal, consisting of M. G. Barnes, Wm. H. Burr, Geo. S. Greene, Jr., Joseph Ripley and T. Kennard Thomson are on a tour of inspection of the canals of Ontario.

NAME OMITTED.

In *The Canadian Engineer* for September 10th, 1914, omission was inadvertantly made of the name of the manufacturer of the large combined gas and steam engine unit which formed the subject of the article on Page 413. The engine was built and installed for the Ford Motor Company by the Hoover, Owens and Rentschler Co., Hamilton, Ohio.

NEW CANADIAN MEMBERS, AM. SOC. C.E.

Recent elections to the American Society of Civil Engineers include that of W. Chace Thomson, consulting engineer, Montreal. Mr. Kay Alexander, of Grant, Smith and Co., and McDonnell, Limited, Revelstoke, B.C., was transferred from associate member to member.

The list of elections to associate membership includes W. C. Bodycomb, superintendent, Victoria, B.C., branch of Westinghouse, Church, Kerr and Co.; J. B. Challies, superintendent, Water Power Branch, Department of the Interior, Ottawa; H. Osborne, resident engineer, Kettle Valley Ry. Co., Hope, B.C.; and J. C. K. Stuart, first assistant engineer, Mount Royal Tunnel and Terminal Co., Montreal.

EDMONTON BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

The Edmonton branch of the Canadian Society of Civil Engineers held its first general meeting since the organization was affected, at its headquarters in the University of Alberta, on October 1st. The meeting was largely attended by local engineers, and a programme was arranged to be carried out during the coming season. The chairman of the branch is Professor W. Muir Edwards, University of Alberta, and the secretary-treasurer is Mr. L. B. Elliot, Box 957, Edmonton.

COMING MEETINGS.

INTERNATIONAL ASSOCIATION OF FIRE ENGINEERS.—Annual Convention, Grunewald Hotel, New Orleans, La. October 20th to 23rd. Secretary, Mr. McFall, Roanoke, Va.

ALABAMA GOOD ROADS ASSOCIATION. — Nineteenth Annual Convention will be held from October 21st to 23rd at Montgomery, Ala. Secretary, J. A. Rountree, 1021 Brown Marx Building, Birmingham, Ala.

NORTHWESTERN ROAD CONGRESS.—Annual Convention, to be held at Milwaukee, Wis., October 28th to 31st. Secretary, J. P. Keenan, Milwaukee.

AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—Charles Carroll Brown, Secretary, Indianapolis, Ind. Meets at Somerset Hotel, Boston, Mass., October 21st, 22nd and 23rd.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

WASHINGTON STATE GOOD ROADS ASSOCIATION.—Convention to be held at Spokane, Wash., November 18th, 19th, and 20th. Secretary, M. D. Lechey, Alaska Building, Seattle, Wash.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

AMERICAN ROAD BUILDERS' ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

Volume 27. Toronto, October 22, 1914 Contents of this issue on page 3

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

LARGE HYDRO DEVELOPMENT ON THE ST. MAURICE RIVER

PRELIMINARY WORK ON THE 180,000-H.P. HYDRO-ELECTRIC DEVELOPMENT OF THE LAURENTIDE COMPANY AT GRAND MERE, QUE. — SOME DETAILS OF THE CONTRACTOR'S PLANT.

THE Laurentide Company has under construction at Grand Mere, on the St. Maurice River, a hydro-electric power plant, the ultimate capacity of which will place the company among the largest power producers in Canada. The new development is designed for an installation of 9 units, developing 20,000 h.p. each. Of this amount only 120,000 h.p. will be developed at the present time. It was expected that 3 units, developing 60,000 h.p., would be ready for operation early in November of the present year, but the temporary curtailment of operations, due to the European war, will prevent such substantial completion this year.

The St. Maurice River is one of the largest tributaries of the St. Lawrence. It takes its rise in the watershed dividing the St. Lawrence slope from that of Hudson Bay. It flows from west to east, about 350 miles, through a mountainous region, and is broken frequently by a series of cascades. The more important of these are the Shawinigan, La Tuque, Grand Mere and the Rapids des Hetres, nearly all of which are utilized by large industrial concerns. Grand Mere is situated about 90 miles north-east of Montreal, where the river drains an area of about 17,000 square miles. The point at which the development is being conducted is between two islands, one of them Grand Mere, which bears a rock with a remarkable resemblance of an aged woman, whereby the name was originally derived. The other is a triangular shaped, rocky island, about 600 ft. in width.

Fig. 1.—View of the Laurentide Co.'s Plant at Grand Mere. Inset Shows Channel and Grand Mere Rock.

The work was commenced in January, 1913. For years previous to this the Laurentide Company, manufacturers of pulp and paper, operated a dam and power house on the west shore of the river, the main channel remaining practically unharnessed. Fig. 1 is a view of the plant, while the inset shows at closer range the old

channel where the first development took place. The river here is 1,100 ft. in width with a bay on the eastern side. Power was obtained by utilizing a head of 45 ft., acquired by the construction at different times of three dams of 250 ft., 75 ft., and 350 ft. length respectively.

In the present project for utilizing the entire flow of the river the erection is involved of a power house 457 ft. in length x 137 ft. in width, to extend diagonally across the west channel of the river at a point about 200 ft. farther downstream than the old site. A concrete spillway dam 1,700 ft. in length is to extend from the channel corner of the power house, through the island, across the east channel to the shore side of Bee Island, where it deflects at a sharp angle to the shore above. Its height varies from 65 ft. at the deepest point, near the power house, to 4 ft., at the shallowest, which is on the site of the large island. The construction of this dam for utilizing the entire flow of the river has necessitated cutting this island of Grand Mere down to water level in order to provide a sufficient length of spillway to control the water level above the falls during spring floods. A triangular area 400 ft. x 300 ft. with considerable depth, and constituting a mass of approximately 600 tons of solid rock, is being removed. The rugged pinnacle which gave the island its name is being carefully cut and conveyed to mainland, where it will be re-erected.

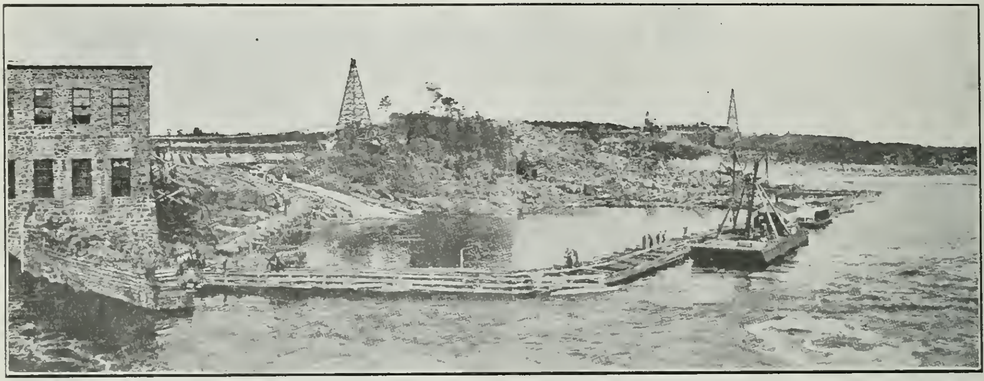


Fig. 2.—General View, Showing Present Power House and Dam, One of the Cable Towers, Cofferdam Under Construction, Main Island, Crushing and Mixing Plant, and the Main Channel of the St. Maurice.

In the new development the natural fall of 45 ft. will be raised to a total effective head of 77 ft. When the cofferdam, which is now diverting the river during the construction of the power house, is removed, the water will be backed up the river for a distance of about 15 miles.

In addition to the dam and power house construction, a tract of land, previously used by the company as storage yards for logs, had to be raised through a height of 10 to 15 ft. in preparation for the new water level.

The consulting engineers for the company are the Geo. F. Hardy Company, New York, and the contractors, the H. E. Talbott Construction Company. Operations were commenced immediately after signing the contract in January, 1913. Preliminary work by the contractors included the organization of force and equipment, together with preparatory operations in connection with the cofferdam below the falls. This could not be built until after the spring floods. The early part of the season saw the completion and pumping out of the cofferdams. The first was built on top of an old wooden crib dam previously constructed by the company, and dewatered the power house site from above. Considerable difficulty was experienced, however, in the construction of the lower cofferdam which extended across the tailrace at an average depth of about 20 ft. of water for a distance of about 600 ft. Wooden cribs, about 20 x 12 ft. in dimension, were filled with stone and sheeted with piling and canvas, thereby rendered watertight. These supported the dam. The placing of the cribs necessitated

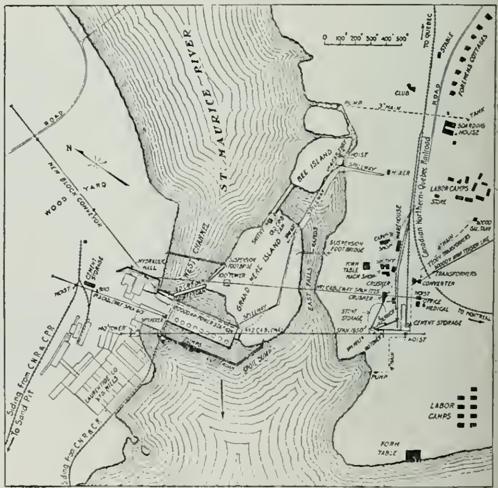

Fig. 3.—Contractor's Construction Camp, and Layout of Present and Proposed Development at Grand Mere.*

considerable dredging as the rock-bottom was covered with layers of debris, including bark, timbers, boulders, etc. In addition the rock surface was very irregular Fig. 2 shows the cofferdam under construction. It also

*By courtesy of *Engineering News*.

shows the present power house, the main island and channel.

Cofferdamming in the west channel was completed in August, 1913, and was immediately followed by excavation work for the tailrace and power house in addition to the erection of more extensive construction camps.

Fig. 4.—(Right) Power House Excavation With Draft Tubes, nearing Completion. (Left) Closer View of Completed Draft Tube.

These camps and their equipment have many distinctive features. They are located on the east side of the river, opposite the present mill site, as shown in Fig. 3, and are fully equipped with crushers, carpenter and blacksmith's shops, material bins, etc., in addition to the housing quarters for laborers. The need for a judicious arrangement of camp for the rapid and economical conveying and placing of material and supplies may be gained from the following: Over 2,000 carloads of lumber, cement, etc., are required for the work. The excavation will approximate 150,000 cu. yds. of rock and 250,000 cu. yds. of earth. About 175,000 cu. yds. of concrete will be required, with 1,000 tons of reinforcing steel and nearly 2,000 tons of structural steel.

The rock removed from Grand Mere Island is transported in large, flat buckets by Lidgerwood cableways 1,125 ft. in length, with a 2¾-in. cable suspended from towers 150 ft. in height, across the river and island. Cars, running on transverse tracks over the cut, convey the rock to the cableway, where it is hoisted, carried to the eastern bank and dumped into serving bins for the crushers. It is to be noted that all the crushed stone used in the concreting work is provided in this way.

The rock is crushed in a large gyratory crusher, assisted by a small reciprocating crusher into which feeds the extra large pieces from the main crusher. The broken stone is conveyed by belt (as are likewise the bags of cement from the cement storehouse) to the mixer. Another crusher operates in the sand and gravel pit to crush the larger stones rejected by the screens through which the gravel is passed.

Another cableway of 7 tons capacity and 1.650 ft. span conveys the concrete from the main mixing plant across to the power house and over a portion of the dam, while another of 600 ft. span conveys concrete from an auxiliary mixing plant on the west side of the river close to the power house site. On the 1,650-ft. span cableway a bottom-dumping bucket is used for carrying the concrete. The dumping is effected by releasing the tension on the ropes by which the bucket is traversed on the cableway, this tension ordinarily holding together the two overlapping hinged leaves which form the bottom of the bucket. Slacking the ropes allows the leaves to swing apart, thereby dumping the material. The bucket holds 2.4 cu. yds. of concrete and empties itself clean when dumped. During operations last summer it gave very rapid service and conveyed 450 cu. yds. of concrete over a distance of 1,100 ft. in the usual 10-hour shift. Hoisting towers with gates and chutes are used extensively in a distribution of concrete in the construction of the power house. Electric hopper cars convey the concrete from the cableway to the hoisting towers. In places not readily accessible to the cableways portable mixers are used.

The completion of the spillway over the eastern channel will be attended to by a fourth cableway of construction similar to those mentioned above.

While work was in full swing during the earlier part of the present season about 400 cu. yds. of concrete were mixed and placed daily, the excavation and crushing capacities being sufficient to provide rock aggregate at this rate. A certain amount of concrete work was effected last fall but the greater majority of it has been put in this

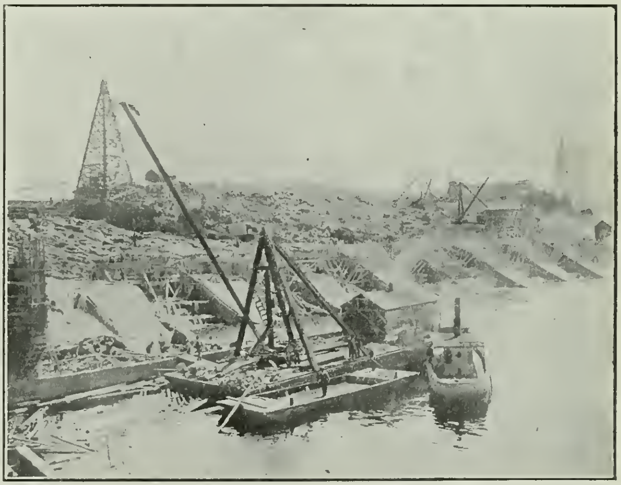

Fig. 5.—Recent View of Power House Construction.

season. It was delayed early in the summer owing to spring floods, which had not subsided from the power house site until early in June. Last Fall's operations on the power house structure consisted of the placing of the draft-tube forms and the pouring of concrete for the lower section. A portion of the adjoining dam was also constructed and the whole was brought above the normal

water level in the tailrace, to approximately the elevation of the scroll chambers. The lower cofferdam was then removed, it being no longer necessary. The draft-tubes were completed in February, 1914.

Since June of this year the power house and dam structures have been pushed with great rapidity, concrete being poured day and night. By August the steel work for the power house was practically complete, the wheel pits were finished, the partitions between gate openings were concreted, the turbine casings were ready for concrete, and the walls were carried up past the floor level of the generator room. About half of the dam was constructed in the east channel and the removal of the top of the island was nearing completion. The penstocks and practically all of the concreting of the scroll chambers and control devices were in place by the end of August. Late operations have included the construction of a cofferdam on the bed of the river at the wide channel on the east side. Here there is about 15 ft. depth of water and the current is exceedingly strong. A channel is being excavated through the centre of the island to provide a water course for the river and a passage for logs of the lumbering interests on the St. Maurice.

Electrical energy for the construction motors and for lighting is supplied from the Shawinigan Falls plant, four miles farther down on the St. Maurice. Current is transmitted at 50,000 volts and is stepped down by three 1,000-kw. transformers to 2,240 volts. A part of the current is further stepped down to 370 volts, by a bank of 100-kw. transformers, and then converted to 600 volts d.c. for operating the d.c. motors. Another portion of the 2,240-volt current is stepped down to 450 volts, by three 75-kw. transformers. Current for lighting purposes is delivered to the circuits at 230-115 volts.

The 9 turbine-generators, when installed and in operation, will provide the Laurentide Company with considerable surplus power, which will undoubtedly extend the fields of the industry in the St. Lawrence Valley. No arrangements have as yet been announced concerning the sale of the surplus. The company will perhaps require 25,000 h.p. for its own needs and it is stated that this alone will mean the saving of a bill for over 65,000 tons of coal, costing over $4 a ton, apart from a general increase of deficiency of operation throughout the mills. The estimated cost of the development is $4,200,000 exclusive of transmission lines or the cost of changes in the paper and pulp plant owing to the electrification of the entire manufacturing system.

WATER-PROOFING CONCRETE.

The following mixture has long been used by the United States Army engineers in water-proofing cement: One part cement, two parts sand three-quarts of one pound of dry powder alum to each cubic foot of sand. Mix dry and add water in which three-quarters of one pound of soap has been dissolved to each gallon. This is nearly as strong as ordinary cement, and is quite impervious to water, besides preventing efflorescence. For a wash, a mixture of one pound of lye and two pounds of alum in two gallons of water is often used.

American cast-iron pipe makers are turning their attention with greater interest to the Latin American market in view of the recent developments. This change, when it comes, will greatly strengthen the opportunity to obtain a large part of the business of the various Central and South American countries, which at present goes chiefly to England, Germany and other European nations.

HOW ENGINEERS MAY BEST USE TECHNICAL JOURNALS.

While much publicity has been given to the usefulness of the technical journal to the busy engineer, and to the proper methods for taking fullest advantage of the services which it renders, it still remains a problem that can best be met by the individual. Many men have many ideas as to the most efficient manner in which the engineering journal may be made of lasting service. All agree that it is indispensable—the differences of opinion centre around its application to each engineer's peculiar needs. There are engineers of all ages of manhood, and engaged, as we are told, in upwards of 110 accurately segregated branches of engineering. Requirements naturally afford leeway for wide variation. It is very gratifying, therefore, to have the instructive lesson which is contained in a paper read by John W. Alvord, consulting engineer, of Chicago, before the Convention of the Federation of Trade Press Associations, held in that city in September. Mr. Alvord views the problem from the standpoint of the young, the middle-aged, and the veteran engineer. His hints to each on how to read, and how to preserve, engineering data are of extreme value. We extract the following from his paper:

That we cannot keep abreast of the times without reading the engineering journals is obvious. That if we carefully read all the engineering journals in our chosen specialty we would have no time left to earn a living is easily capable of demonstration. What, then, is the proper attitude to adopt toward this ever-increasing flood of information that pours in upon us so relentlessly?

If we look about us to see how our fellow engineers solve this matter we shall find a great variety of attitude toward the problem. Some engineers simply do not take engineering journals; reading one occasionally here and there as opportunity offers. Others take all they can afford to take and let them pile up around the office, often unopened and unused. Others still limit themselves to a select few, which they carefully bind and shelve. Still others read journals when they can, and throw them away when they move on. As a rule, however, the engineer prizes his technical paper, and endeavors in some ill-defined and formless sort of fashion to preserve its information for future use. Generally he fails to find any practicable scheme which makes his rapidly accumulating material of much value to him after it has once passed under his eye, and for a large number of engineers, technical journals are only professional newspapers with which to idle away an hour or so and satisfy their curiosity. That their value is something much more than this, or should be more than this, is so apparent as to need no denial.

The problem of the engineer with his technical paper is much affected by his age, station and aim in life. To the man who is engineering only to get money and more money, the engineering journal is a newspaper, in which he may notice mainly where there are better jobs than his own that may be sought after and perhaps obtained. To the man who is anxious to fit himself every year of his life for something better it is an opportunity, quite unequalled many years ago, for a great variety of study. To the young engineer the engineering journal, properly read and noted, is a part of a post-graduate course in engineering. To the middle-aged man it is a mine of data, bearing in all sorts of ways on his work; and to the mature specialist only does it begin to become burdensome by its repetition of experience, and its volume of

matter on subject which has already, to him at least, been well digested. Let us see if we can outline how each of these classes can get more profit out of the matter contained in the engineering journals than do the careless or the indifferent, who, after their journal is once looked over, let it go to waste or idleness.

The young engineer and the college graduate need, most of all, practical experience. It is safe to say that engineering literature will never have any proper perspective for him until he has been connected in some capacity with engineering work himself, be it in ever so modest a capacity. With the actual doing of engineering work, however, should come contemporaneously the reading of technical journals, particularly along the lines in which he is working. Nothing can be more instructive, broadening, and enlightening to a man doing a particular kind of work than reading about similar work at the same time. It follows, therefore, that the young engineer should as early as possible, take at least one first-class engineering journal and own it himself; bind it if he can afford to, but lay it away in an orderly manner, in any event. If he can afford two journals so much the better, especially if they are selected so as to widen his outlook.

It is to be doubted if laborious reading of all kinds of engineering articles all the time is advisable for anyone. Mere quantity of reading is mentally detrimental. If one might advise, it would be to suggest enforced systematic reading of all articles particularly bearing on the line of work the reader is immediately engaged upon, and the optional reading only of such other articles as interest him. This ought not to be much of a task. In course of time as his experience broadens, engineering reading will become less burdensome and more interesting because its relation to practical matters will be more and more appreciated, and the discriminating use of engineering literature better understood. Of course, all this applies to engineering societies as well; but that is another story.

It is probably not wise for the young engineer to indulge extensively in card indexes, filing systems, and the like, for topically arranging his available engineering journal articles. Few men know very early in life where fate and interest will land their future attention, and filing systems and special indexes are expensive and time consuming, and when indulged in without definite aim nearly always quickly become too voluminous and thereby useless. If any suggestions are made along this line, it would be to start a loose leaf, letter-size (8½ x 11-in. page) notebook and note in it (separate pages for separate subjects) only what appears to be extremely useful, either in exceedingly brief abstracts from engineering articles, or diagrams, costs, etc.

The young engineer is tempted to read much about large enterprises—the Panama Canal, big bridges, astonishing tunnels, great dams. This does no harm, and probably holds his interest for the time being. Gradually he learns that, for him at least, the chief value of the technical journal does not lie in its dramatic side, necessary as that may be for our general information, interest and pleasure, but its chief value lies in a fund of small things, which make up routine work of the ordinary every-day job. These are to be watched for, and noted, as practically useful to the average man.

We next come to the man in early middle life, actively engaged in his profession, and note at once that his problem with the technical journal is the absence of "time." Absorbed in a multitude of responsibilities, harassed with unexpected difficulties, worn out at night with the long day of strain, how shall he derive any useful good from the multitude of journals which his more ample income can readily afford, but which pile high on his table after every brief absence from the office? Whether or not such an engineer shall make any effort to systematically assimilate, file, and study current technical journals depends in part upon the nature of his routine. If he is largely engaged in administrative work, or is a salaried officer in a large enterprise with a comparatively limited range of problem or a limited call for miscellaneous data, he may generally be content with a cursory examination of the engineering journal such as will keep him qualified on his undertaking, and the preservation of such journals in bound form, with the standard published indexes. If, however, he is entering upon novel work, or work presenting a great variety of problems, overlapping into a great variety of fields, ambition will compel him to do more than this, and some form of special indexing will appeal to him more or less strongly as he feels the need more often for research in up-to-date material.

The average editor can judge of a technical article with only a brief inspection—a sentence here and there, a headline, and a moment's reading of the summary and conclusion. Long familiarity with matter of a similar character gives him the assurance that he can detect in this rapid review anything novel, new, or original, and can fairly pass judgment upon it in a general way. The working engineer who has had some experience with technical literature can form the same habit, and save much time. It is really wonderful how much repetition there is in engineering writing and in the production of engineering papers. It thus happens that we are under the necessity of seeing much the same facts and principles repeatedly published in varying form, for some one is always attracted to really read them, with consequent benefit to himself, under the belief that they are new and novel.

The mature engineer notes that a large amount of engineering literature is of the purely descriptive order, merely giving outline of work that has been accomplished, without going into reasons or principles. All this kind of writing is valuable and useful, and has its proper place, but all of this class of literature has its limitations. One of the most severe of its limitations is that it rarely describes mistakes, errors of judgment, or failures, and in these lie the most valuable lessons to the seeker after truth. One is obliged to read between the lines or read with reservation, much as one does in reading accounts of battles in the daily press. It is always wise to look back and note the origin of the despatches in such cases.

A tremendous lot of engineering literature is written which is of little permanent value. Often it represents the writer's struggles to understand a subject. Often it is compiled largely from a desire for publicity. Fortunately the editors of the technical papers can limit this kind of reading by care in selection.

But amid all these drawbacks a discriminating mind will always find a great deal of wheat amid the chaff, and the wheat that will be gleaned will be of differing kind and amount, depending upon the type of mind of the reader, his present problem, and his desire to systematize his information. What, therefore, shall he do with his special selection when once he thinks he has separated it from the flood of raw material?

Several courses are open to him:

First, he may rely on his memory and the published index to his bound volumes. It is safe to say, however, that few engineers really make much practical use of this method. The intervening index and the bother of a search prove to be discouraging to that degree that a proposed reference search is abandoned in about one-half the sug-

gested attempts. The ideal filing system is one in which, with the least amount of effort, one can put his hand immediately and accurately on the thing itself, be it a book, a pamphlet, or a data sheet.

Second, he may keep a special card index of important data and reference to valuable articles. This at once involves labor and attention which few busy men can give and which, if done by assistants or librarians, largely loses its personal value to the one who needs it. The same objection as to the discouraging effect of intervening indexes holds good here, too, and it is further safe to say that of all the contrivances for indexing the most difficult to handle readily and examine rapidly is the card index system.

Third, he may abstract important data in a limited way on loose leaf transparent paper, standard letter-size, and he may remove or detach articles of special value from out his journals, to be filed in regular office file system, like correspondence.

The writer has tried all of the above methods at considerable cost in time and patience, and has, for many years, settled upon the third method. With all its admitted limitations it seems to be the best for an office which is expected to find out information on a great variety of subjects in a limited time, and with the least amount of effort.

Some description of its practical workings may be of interest:

All the technical papers of the office pass on to the desk of the head of the office and are at least looked over (not read) by him. Articles important to his particular specialty are checked with pencil, and articles of especial interest are looked over with care and double checked. Once in a long while data important enough to go to the data file are noted. This is either especially abstracted by the stenographer, or, if a diagram or cost data, perhaps traced in the drafting room, all on transparent paper for copying purposes. Special data of this kind, on $8\frac{1}{2}$ x 11-in. sheets, are filed in the office data file (a separate but common standard correspondence file). From the data file loose-leaf working note-books are made up from blueprints for office or travel purposes. They are altered, refilled, amended and sorted back from time to time as needed to keep them of usable volume and usefully up-to-date.

The technical journals, with checked articles, go to the office clerk or the stenographer at odd hours, or the librarian if one can be afforded, and the useful articles are removed by tearing them out with a ruler. They are folded, usually once, to standard size, with one edge lap left for binding, and are then filed in a subject index file, like current correspondence. The Dewey Decimal system, especially arranged for the office, is used, but only as a general subject plan. When the file is full, portions of its contents, especially that which is most useful, are simply bound in plain pasteboard covers and placed in the library shelves, with titles. Such a book (or many books) would contain all the recent articles thought to be of special value on a given single subject. The remaining portions of the technical paper are thrown away, but in a large office, warranting the expense, duplicate bound copies can be kept as well, with the general published index as their key.

The objections to this system are as follows:

First, it is too expensive for any but the most important offices doing specialized work. Second, data accumulate almost too fast unless rigidly kept down to a minimum. Third, it requires some personal attention of the head of the office, a competent assistant, or the employment of a regular librarian.

The advantages are:

First, it compels the office head to know all the time what is being published in current engineering literature, if only by inspection. Second, it removes all intervening indexes between the searcher and the final repository in bound volume. Third, it keeps one's library usefully up-to-date on all lines in which one should be especially interested. Fourth, it is economical of final shelf room and cost.

Obviously, one should not start so elaborate a system as this unless he is fairly sure of the special line of engineering to which his life will be devoted. Otherwise, waste effort and discouragement will be certain. It is not to be recommended to the young man, but only to the mature man of early middle life when his work clearly indicates the necessity for it. It is, however, the prime requisite of the engineering specialist. To him some such a system is invaluable. Not a few consulting engineers use this standardized system interchangeably, particularly the data file, thereby greatly increasing its usefulness to one another as a joint effort.

We come finally to the mature and experienced engineer of advancing years. How can he make engineering and technical literature of use? It is safe to say that when an engineer has much passed fifty or sixty years of age and has led an active life, his need for engineering literature lessens. Out of the mass of detail which seemed to him so overwhelming and endless in his youth and early manhood, fundamental principles emerge like peaks out of the clouds, and upon these as foundation all detail classifies itself simply and naturally, and therefore, he feels less need for accumulated data or particular description. Probably no one enjoys engineering reading as does the mature engineer, for he can read between the lines and find much to instruct as well as interest, and yet while he is probably the most interested and intelligent reader of engineering literature that the journals have, his ambition as a collector is gone and filing systems no longer appeal to him.

If his acquaintance is wide, he reads with interest the accomplishments of his friends, and the addresses of society presidents and articles on the ethics of the profession. Of failures he is the keen student. The personal column appeals to him, and if he is of right-mindedness he is conscious of more pleasure than formerly in the accomplishments of those who have succeeded and succeeded well in dire and burdensome responsibility. More often than the young man he will turn back for his satisfaction to papers that served him well in times past, and perhaps smile at the lack of improvement that later attempts to deal with their subject often show.

Technical papers, along with the technical societies and their proceedings, form the repository of the professions; they are the interchange of experience, the common store upon which we all draw. Without them we would be strangely helpless. We are indebted to every one more or less who records his experience for the common use, and that debt we should endeavor to helpfully repay in kind, but wisely, concisely and thoughtfully.

The Fort William plant of the Steel Company of Canada, on which construction was started last year and not completed owing to the dull manufacturing season, has resumed operations and a large gang of men is at work on the completion of the building. The plant will be ready for operation between November 15th and December 1st.

ANALYTICAL TESTS AT WATER PURIFICATION PLANTS.*

THE elimination of unnecessary analytical work is a matter that needs consideration at this time quite as much as the making of the necessary tests.

Laboratory practice at various purification plants has shown that many of the determinations which are ordinarily included in the standard water analysis schedule are here of little or no importance. For example, the determination of nitrogen in the usual forms of free and albuminoid ammonia, nitrites and nitrates serves no particular purpose in water purification except in special cases. They neither assist the superintendent in the operation of the filter, nor give any adequate idea of the safety of the filtered water. On the other hand, some of the simpler physical tests, such as numerical determinations of turbidity, color and odor, microscopical examinations and tests for alkalinity, iron and carbonic acid, have come to be regarded as most valuable; and in special cases various other tests, such as dissolved oxygen and manganese. Bacteriological tests are, of course, important.

One step in making an analysis of water has never received half the attention that it deserves, namely, sampling. Of what value is it to use analytical methods of great refinement if the samples themselves are not representative, if the mass of water from which the sample is taken is not homogeneous, or if the water changes in character from one day to another? Samples for chemical analyses are almost never larger than 4 liters (1 gallon); and samples for bacteriological analyses are seldom larger than 100 cubic centimeters (4 ounces), while the quantities actually used for the different tests are still smaller. In counting the number of bacteria, the quantity is less than a thimbleful.

On the other hand, we know that bodies of water are not homogeneous. In a lake or settling basin there are vertical and lateral variations; a river is constantly changing, not only in volume but in the character of the water; filter effluents vary, especially the effluents from mechanical filters where the runs are short and the rates are high. The causes of these variations which affect the results of water analyses through unfair sampling are so numerous that they cannot be studied by themselves, and the only course left is to apply to them the laws of probability, or, in other words, to arrange the data secured in some such way that the importance of the inevitable variations may be indicated and an index of the character of the water examined be obtained.

Thus we see that a question of fundamental importance is that of frequency of collecting samples. The question is, how often must samples be taken to obtain reliable results? As a general proposition it may be stated that the frequency of sampling should depend upon the frequency of change in the character of the water examined. For a water of constant quality, a few samples taken at infrequent intervals may serve to give a fair idea of the water, but if a water be subject to great fluctuations in character, a few samples taken at long intervals might or might not give a fair idea of the water. The reliability of the average result will be determined by the laws of probability. The average result does not tell the whole story, for it eliminates the individual results, and a water supply should be safe and wholesome all of the time.

*From the report of the Committee on Statistics of Water Purification Plants submitted at the annual convention of the New England Water Works Association, September, 1914.

The frequency of sampling has a limitation, which is controlled by practical and financial considerations. In a small plant the cost of daily analyses would usually be prohibitive, and even weekly analyses might be a burden. It would be recognized, however, that results based on infrequent samples are less valuable than those based on frequent samples; and that irregular sampling gives the most unreliable results. In order to emphasize this point it seems desirable to establish certain grades of control of operation, based upon the character of the records kept, as follows:

First Grade: Water purification plants under first-grade supervision are those where the analyses of the filtered water are made one or more times a day, and where engineering and such other data regarding the operation of the plans as are necessary are collected by one or more attendants constantly employed.

Second Grade: Water purification plants under second-grade supervision are those where analyses are made regularly, say once a week or once a month, by a trained analyst, and where an attendant constantly on duty makes simple daily tests.

Third Grade: Filter plants under third-grade supervision are those where analyses are made irregularly and infrequently, and where no daily tests are made by the attendant.

Sometimes it is difficult to grade the supervision given a plant. As an example, we have the Lawrence city filter, where daily tests are made during five winter and spring months of the year, and weekly tests during the remaining seven months. Here frequent analyses were made during those seasons which were most critical. This might be termed a mixed supervision of the first and second grades.

This grouping should not be considered as necessarily casting a stigma upon second- or third-grade supervision. Some water supplies may not demand first-grade records. In general it may be said that the safer the raw water, the lower may be the grade of analytical supervision. In other words, polluted waters require the purification plant to be operated with a higher factor of safety, and to this end a more careful analytical control is needed. Stored waters are safer than unstored waters, and with them a lower degree of analytical supervision may suffice. A corollary to this would be that small plants which cannot afford high-grade supervision of filters should endeavor to protect the quality of the supply by storage or by incorporating a large factor of safety in the design of the plant.

NOTE—The Committee on Statistics of Water Purification Plants, acting for the American Water Works Association, consists of Geo. C. Whipple, chairman; Robt. S. Weston, Frank D. West, Frank W. Green and E. E. Lockbridge. Blanks have been prepared illustrating the recommendations of the committee regarding the form of report, tests to be made and methods of recording results. These are arranged to show the analytical data by months and years, and are as follows:

Table 1.—Chemical and Microscopical Character of Raw Water.

Table 2.—Turbidity and Color of Raw Water.

Table 3.—Bacteria in Raw Water.

Table 4.—Chemical Character of Water Delivered to Mains.

Table 5.—Turbidity and Color of Water Delivered to Mains.

Table 6.—Numbers of Bacteria in Water Delivered to Mains.

Table 7.—Numbers of B. Coli in Water Delivered to Mains.

WIDTH OF ROADS FROM THE POINT OF VIEW OF ECONOMY.

An article appeared in the September issue of "Conservation" showing that in some instances wide streets may be actually cheaper than narrow ones. The author is Mr. R. Thomas Adams, senior town-planning adviser to the Local Government Board of Great Britain and recently appointed to act in the same capacity for the Commission of Conservation, Canada.

Some points in Mr. Adams' article are given below:

The advantage of wide roads is sometimes questioned. Where they are made in advance of requirements they may impose an extra burden on the existing ratepayers, for the benefit of posterity. This burden may be too great, even having regard to the ultimate benefit which may be derived, but of course this entirely depends on the degree of width and the extent of cost incurred. No definite standard of width can be satisfactory for adoption under all circumstances.

The ultimate economic gain to the community is one factor, but it is only one factor, in giving the matter consideration. The local circumstances may make it necessary for each road to be considered on its merits. The cost of expropriating land, the existence of buildings, the physical character of the site, the immediate gain as distinct from the prospective gain to the community must all be considered. There are, however, some general principles which afford us guidance in regard to these matters; for instance, where it is definitely known that a road will be required for use as a surface railway or tramway the width of the road should of course be greater than where such use is not contemplated.

There is no necessity for a road to be actually constructed in advance of traffic requirements. On that point there need be no difference of opinion. The sole question is whether the land should be acquired or earmarked for the road in advance of the full width being required. The investment made by the community to-day for the benefit of the future citizens may therefore be limited to the acquirement of the extra land. The construction can be spread over as long a period as may be desirable, but if the land is not purchased at the outset it may be assigned to private uses, such as the erection of expensive buildings, which would make it prohibitive to carry out the widening when actually needed. These possible losses and hindrances to the future development of a town must of course be considered, as well as the question of immediate gain, but the immediate gain, or rather absence of loss, probably makes the wider appeal to the ratepayers.

It is therefore of interest to have an example such as that afforded by the construction of a wide road at Liverpool, England. The city engineer of Liverpool has made extensive experiments in the making of wide roads round the suburbs of the city. Recently he demonstrated to his council that it was cheaper to make a road 120 feet wide than 80 feet wide.

The cost of the two roads, 80 feet and 120 feet wide respectively, is given by the city engineer as follows:

Comparative cost of widening a 40-foot road to 80 feet (tramways paved) with widening to 120 feet (tramways in grass).

Widening to 80 Feet.

Cost of land, 13⅓ yds. @ 5s.	£3: 6: 8
Street works per yard lineal	£7: 2: 6
Tramways (including paving) 1 yard @ £6: 15: 0	£6: 15: 0
	£17: 4: 2
	= £30, 286 per mile

The above estimate provides for the reconstruction of the old road to suit new levels.

Widening to 120 Feet.

Land for new road, 13⅓ yds. @ 5s.	£3: 6: 8
Street works per yard lineal	£4: 13: 7
Tramways (in grass) including land, 1 yd. @ £6: 16: 8	£6: 16: 8
	£14: 16: 11
	= £26, 128 per mile

This estimate does not provide for any alteration to the old 40-foot road.

It will be observed that in order to make the 80-foot road it is necessary to reconstruct the old road to suit the new levels, but that no such reconstruction is necessary in the case of the wider road. It is also important to note that the estimate for the 120-foot road includes the cost of the extra 40 feet of land for tramway purposes.

These circumstances are of course special to a certain extent. Instances might occur where the reconstruction of the old road would be necessary in either case. But even then the only extra cost per yard in making the wider road would be one-eighth the difference between £6: 15 and £6: 16: 8, the cost per yard of the tramway.

In this case the important point is that it is much cheaper for the Liverpool corporation to make a road 120 feet wide than 80 feet wide. All the ultimate advantages to the city are therefore additions to the immediate gain. The latter, however, is not limited to the saving of cost. In Liverpool they are finding out that these wide tree-planted roads are having the effect of keeping the homes of the well-to-do citizens within the city boundaries. Those who will not erect large houses in narrow uninteresting tramway routes are building them on the spacious highways which Mr. Brodie is constructing. Liverpool has for a long time suffered from the migration of its large ratepayers into outside districts. This not only increases the rates all round in consequence of lowered rateable value, but removes from the city those who, while in residence, subscribe to its charities and take an interest in its social life. That the policy of making wide avenues with grass margins is helping to retain these well-to-do inhabitants within the city limits is one of the indirect advantages which Liverpool claims.

A brisk demand for the product of the paper and pulp mills in the interior of Newfoundland has resulted from conditions growing out of the war in Europe. Steamers are rapidly arriving to take on board cargoes for England. It is expected that the mills will be obliged to supplement their present equipment, and it is anticipated that new pulp and paper concessions will shortly be in operation.

Milwaukee has a refuse incinerator with a total capacity of 300 tons a day. A 6,000 kw.-hr. turbo-generator is driven by the steam raised in a 200-h.p. boiler. The current from the generator is to be transmitted to a flushing-tunnel pumping station, some two miles distant, which will pump lake water into the north end of the Milwaukee River for flushing and cleaning purposes.

SOME CANADIAN DRYDOCK SCHEMES.

A drydock is to be constructed at Owen Sound by the Canadian Shipbuilding and Dry Dock Company, Limited. This corporation has capital of $2,000,000 and an Ontario charter. The head office is at Owen Sound. The company has authority to manufacture and deal in iron, steel and other metals; to construct and operate drydocks, harbors, elevators, warehouses, terminals, wharves, etc., and to carry on the business of a wrecking company.

The municipality of Owen Sound has decided to grant a subsidy to the company, which amounts to a cash bonus of $10,000 a year for a period of 20 years. This bonus is contingent upon the fulfilment of an agreement whereby the operating company must employ at least 200 men daily for an average of 300 days in each year. The company will be exempt from taxes, except school taxes, for a period of ten years. A site for the dock and plant has been selected on the bay shore of the city. The dock is to be 775 feet long from caisson groove to head peak, 104 feet wide at the top and 21 feet over the sills.

Those interested in the enterprise are Mr. F. F. Wood and Mr. E. D. Pitt Niagara Falls, Ontario; Mr. F. J. Nelson and Mr. John Roche, Buffalo. Mr. Pitt states that plans are being filed with the Dominion government and that the company's plant will be the largest and most complete for ship repair and shipbuilding and have the largest drydock on the great lakes.

The Dominion government has passed an order-in-council for a subsidy to the Amalgamated Engineering Works, Limited, of British Columbia, amounting to a maximum of $5,500,000, at 4 per cent. interest for a period of 35 years.

The subsidy is for the purpose of erecting at Vancouver modern drydocks to cost over $6,500,000. The plant of the company is to be located at North Vancouver, and will contain a drydock 1,150 feet long, capable of being divided into two sections of 650 and 500 feet in length, with a width of 100 feet.

Another large shipbuilding and drydock plant is proposed by the Dominion Shipbuilding, Engineering and Dry Dock Company, Limited, of Vancouver, B.C. Plans and specifications have been completed for the major part of the work. The plant will be located on the Burrard Inlet at Vancouver, B.C., and ultimately will represent an expenditure of about $2,800,000 for machinery, building and construction. It will have a graving dock, constructed of reinforced concrete, 1,000 ft. long and 100 ft. wide. Adjacent to the graving dock will be two marine railways and alongside of dock, wharves will be constructed to serve the traffic of the plant. One of these railways will handle vessels up to 1,000 tons, and the other vessels up from 1,000 to 4,000 tons. Seven shipbuilding berths will be constructed. Lynn Creek, a fresh water stream, located on an eastern edge of the rib will be dredged and retaining walls built on either side. The stream will then serve as a cleaning out basin and also as a fitting out basin.

The buildings for fabrication and general construction purposes will be located directly in the rear of the shipbuilding yards. The principal structures and their estimated costs are as follows:—

Machine shop, 250 ft. x 68½ ft.	$30,000
Pattern shop, 225 ft. x 137 ft.	30,000
Boiler shop, 250 ft. x 68½ ft.	20,000
Blacksmith and general forging shop, 250 ft. x 68½ ft.	30,000
Angle and plate shed, 600 ft. x 100 ft.	60,000
Woodworking shop, 100 ft. x 200 ft.	35,000
Copper shop, brass foundry, etc., 75 ft. x 125 ft.	45,000
General stores building, 75 ft. x 100 ft.	20,000
General office building, 60 ft. x 90 ft.	10,000

These buildings, with the exception of the last two, will be of steel frame construction with corrugated iron covers and concrete floors with asphaltum top. The general stores building will be similar except that the floor will be concrete without the asphalt surface. The general office building will be of brick and wood.

The principal item of expenditure will be for the graving dock; this with its puming plant is estimated to cost $1,500,000. The improvement of Lynn Creek will cost about $225,500. The stream will be dredged to a depth of 25 ft. and a width of 200 ft., for 1,800 ft., and retaining walls constructed on each side. The creek will be straightened out into a straight canal by diverting its channel. Wharves will be built on the top of the western retaining wall.

There will be two main wharves, one 900 ft. long, estimated to cost $12,000, the other 1,200 ft. long to cost $22,000. On the end of the longer wharf a hammerhead crane of 100 tons capacity will be erected. This will cost about $100,000. There also will be two marine railways, one of 1,000 tons capacity and one of 4,000 tons capacity, the cost, with power plant, being $15,000 and $130,000 respectively.

The Lake Superior Dry Dock and Construction Company, Limited, with an authorized capital of approximately $1,000,000, and a bond issue of £157,000, was recently organized to build a drydock at Sault Ste. Marie, Ont. In November. 1913, the city of Sault Ste. Marie voted a subsidy to the company of $20,000 per annum for a period of 20 years, subject to the payment by the company of taxes on a fixed assessment, which would return to the city about $10,000 annually. The Dominion government has granted a subsidy of 3 per cent. per annum on $1,386,528 for a period of 20 years. The bonds are said to have been underwritten in London and Messrs. Hoare and Company, of London, are trustees for the bondholders. Not long ago, the permanent board of directors was elected, the following being the list:—Mr. C. G. Bryan, director of the Canada Steamship Lines, Limited, director of the Richelieu and Ontario Navigation Company, director of Palmer's Shipping and Iron Company, Limited, London, England; Mr. Frederick R. De Bertadano, director of the General Accident Fire and Life Assurance Corporation, London, England; Mr. Rowland Hodge, director of the Northumberland Shipbuilding Company, Limited, of London, England; Mr. Francis Somerscales, late general manager of the Earles Shipbuilding and Construction Company, Limited, Hull, England; and Mr. Percival T. Rowland, barrister, Sault Ste. Marie, Ontario. The company's consulting engineers are Sir Douglas Fox and partners, of London, England.

In June, a payment of $25,000, the price agreed upon for their site, was made to the city of Sault Ste. Marie. Prior to the outbreak of the war, arrangements had been completed by this company, by which their bankers were prepared to advance them a sufficient amount against their underwriting agreements to enable them to commence construction at once. The agent of the contractors, the British Construction Company, and his staff, sailed from England for Canada on July 24th, with the intention of making arrangements to start immediately work on the drydock. The necessary machinery was shipped and is now on the ground. Owing to the conditions brought about by the war, the enterprise will be held in abeyance in the meantime.

The construction of the floating drydock and ship repairing plant of the Grand Trunk Pacific Railway Company at Prince Rupert, B.C., is making good progress. The first pontoon was launched August 24th. The second pontoon or section will be launched during September and within the next 60 days a section of the drydock will be available for repairs to craft in that locality.

The Drydock Subsidies Act of 1910 gives encouragement to enterprises of this nature. This act differentiates between first and second-class docks as follows:—

"A first-class dock shall be capable of receiving and repairing ships of at least 25,000 tons; shall cost not more than $4,000,000; and bonds to this amount or less shall be guaranteed for a term of 35 years.

"A second-class dock shall be capable of receiving and repairing ships of 15,000 tons; the cost shall not exceed $2,500,000; and the bonds shall be guaranteed for the term of 15 years."

Dawson, Yukon Territory, is planning to establish a municipal electric lighting and telephone plant at an estimated cost of $165,000. The Dawson civic league, which is planning various improvements, recently petitioned the Yukon council against the annexation of the territory to British Columbia, and the surrender of its independence.

About 65 per cent. of the permanent way of the Swiss Federal Railways is equipped with steel sleepers. The weight of the sleepers is 25.16 kilos. per running metre, and when the holes for the rail attachments are complete they weigh 72.5 kilos. (159.8 lb.) each. The tensile stress specified is from 35 kilos. to 45 kilos. per square millimetre, and the entire trough piece must be capable of being bent back double without showing any crack. At the switches double-trough sleepers are used, which weigh 125 kilos. (275.5 lb.) each.

SPEED VARIATION BY A GRAPHICAL METHOD

PERCENTAGE SPEED VARIATION FOR DIFFERENT GOVERNOR TIMES AND VARYING AMOUNTS OF LOAD CHANGES IN A HYDRO-ELECTRIC POWER PLANT, INDICATED GRAPHICALLY.

By T. H. HOGG, C.E., (Toronto).

THE problem of finding the percentage speed variation for different times of governor, and varying amounts of load change, is one with which the hydro-electric engineer has often to deal. The number of variables is such that it is difficult to grasp the range and variations unless resort is had to graphical means. The writer has recently had occasion to use such a method, which may be of interest to engineers dealing with like problems.

The methods used in modern hydro-electric plants to preserve uniform speed under various conditions of service are too well-known to warrant full discussion, but it will be necessary to give a brief résumé of the factors influencing speed-regulation in order that the chart illustrated may be understood.

With high head plants, speed regulation becomes increasingly difficult, on account of the increase in the length of the feeder pipe lines, and the necessity for the economical use of the small amounts of water often conserved in costly storage reservoirs.

The amount of energy stored in the moving water of these pipe lines precludes rapid speed regulation, unless other means are used to furnish deficient energy when load is thrown on, while the water is speeding up in the conduit to the new required velocity; and conversely, when load is thrown off, to take up the excess of energy which must be dissipated gradually.

While this adjustment of velocity of flow is being made, the increase or decrease of energy is usually taken up by one or more of the following remedies, *viz.*, synchronous by-pass, deflecting nozzle, flywheel, relief valve, breakplates, governor-actuated pressure regulator or surge tank.

Where the first methods are used, in case of load thrown off, the water is by-passed by means of a valve operating by pressure directly connected to the water-wheel gates and arranged to open as they close; when load is thrown on, dependence is placed on the extra flywheel attached to the wheel to give the additional amount of energy required. Modifications of this may be used, such as a by-pass indirectly controlled by the movement of the governor so that any movement of the governor actuates a relief valve. With load thrown on, however, a limit quickly comes to the available speed regulation on account of the flywheel required. It is to this aspect of the problem that the chart and discussion applies. The method used for the analysis of the problem is that given by Mr. W. Uhl in his paper published in the February, 1911, Journal of the American Society of Mechanical Engineers. The graphical treatment is based on methods illustrated in Peddle's treatise on "Construction of Graphical Charts."

In an open-flume turbine setting, the speed regulation is dependent upon the flywheel effect of the connected rotating masses; the variation being in accordance with the following formula: $s_1 = \dfrac{800{,}000 \times H.P. \times T}{n^2 \times (w\,e^2)}$, where s_1 equals the speed variation or ratio between total speed change and normal speed; $H.P.$ represents horse-power load variation; T the regulating time; $(w\,e^2)$ the moment of inertia of rotating masses, and n the normal revolutions per minute.

The value of s_1 must be modified, due to several causes; the friction load of the generator and turbine remains and will tend to reduce the speed variation. Also, providing the turbine is correctly designed so as to give its maximum efficiency at normal or synchronous speed, the efficiency will be reduced with either increasing or decreasing speed. The amount reduced varies with the type of runner, being greatest for a high-speed, high-power runner, and least for a low-speed, low-power runner, since if correctly designed, the change in efficiency will be greater for a high-speed than for a low-speed runner for the same per cent. of variation in speed. The new value of s_1 to be used we will call s_2, and $s_2 = c\,s_1$ where c is a constant, as follows:

Type of runner (Specific speed)	13.55	20.3	29.4	40.7	49 7 / 62.8	70 97 / 83.78
C	.714	.703	.69	.671	.645	.606

Regarding the value of T in the above. The governor manufacturer will state the time required for a complete stroke of the governor, and experience shows that the time required for a governor to alter the power of a water-wheel after a great or small sudden load change will be approximately constant and equal to the time required for a full stroke or T.

As noted previously, a large amount of energy is stored in the moving column of water when long penstocks are used. Changes in velocity, therefore, involve changes in the kinetic energy, and produce pressure variations or oscillatory waves in the conveying conduits. It is this pressure variation or water hammer which develops when the flow in a pipe line is disturbed by the movement of a gate located either at the upper or lower end or in an intermediate position. These waves or oscillations once set up, continue until they are smothered by the friction on the walls of the pipe and between the molecules of water.

The velocity at which these waves travel is of considerable interest as on this depends the time element of the disturbances. This velocity depends upon the compressibility of the water and upon the nature of the material of which the penstock consists. It is found to vary from 1,000 feet a second for large diameter pipes to 4,500 feet per second for small diameter, and may be figured for any given set of conditions. Knowing this velocity, a, the minimum regulating time of the governor must always be greater than $\dfrac{2\,L}{a}$ where L = length of the penstock, otherwise dangerous interference to regulation, due to speed oscillations, will be developed and extreme pressure heads will exist on the valves and penstocks.

Now, knowing or having fixed the regulating time of the governor for any particular plant having a long pipe line, it is possible immediately to obtain the pressure variation due to any given change of load (velocity). Let us call this pressure variation $\frac{dH}{H}$ with the sign + for governor closing and — for governor opening.

Therefore the speed variation of the unit due to any change of load may be immediately obtained from the following formula:

$$s_3 = s_2 \left(1 + \frac{dH}{H}\right)^{3/2} \text{ for load thrown off.}$$

$$s_3 = \frac{s_2}{\left(1 - \frac{dH}{H}\right)^{3/2}} \text{ for load thrown on.}$$

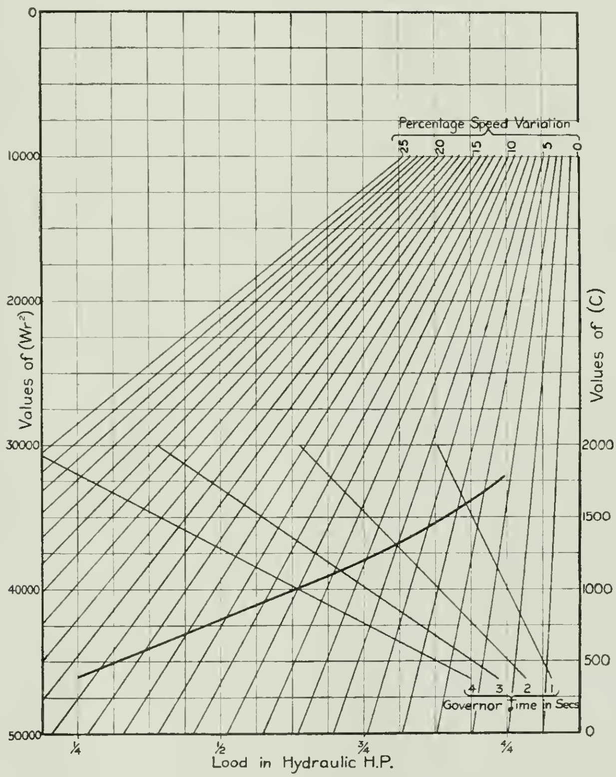
For a closing time of governor T greater than $\frac{2L}{a}$, the pressure increase or decrease $\frac{dH}{H}$ may be found from

$$\frac{dH}{H} = \frac{p}{2}\left(p \pm \sqrt{p^2 + 4}\right)$$

where $\frac{dH}{H}$ = pressure variation

$p = \frac{Lv}{gHT}$

L = length of penstock
v = velocity in penstock
g = acceleration of gravity.
H = gross head



Curve Showing Percentage Speed Variation for Different Governor Times and Varying Amounts of Load Change.

s_2 is the value previously obtained for open flume conditions and is here modified on account of the head variation.

It will be noted that the speed variation of a unit is inversely proportional to the (we^2) of the rotating parts, so that in order to secure any given percentage of speed variation we must install a certain value of (we^2) or flywheel.

T = time of governor
s_3 = speed variation in per cent.

We can now proceed to the construction of our chart.

Let us assume the following example: Two machines of 2,180 h.p. each on one penstock.

Length of penstock L = 1,655 ft.
Gross head H = 535 ft.

Velocity in penstock:

For $\frac{1}{4}$ load on one machine $v_1 = 1.17$ ft. per sec.
For $\frac{1}{2}$ load on one machine $v_2 = 1.91$ ft. per sec.
For $\frac{3}{4}$ load on one machine $v_3 = 2.49$ ft. per sec.
For full load on one machine $v_4 = 3.16$ ft. per sec.

and $n = 900$ revolutions per minute. The type of wheel used is one with a specific speed of about 13, and therefore $s_2 = .714\, s_1$.

$$\text{Therefore } s_3 = \frac{s_2}{(1 - \frac{dH}{H})3/2} = \frac{.714\, s_1}{(1 - \frac{dH}{H})3/2}$$

$$= \frac{.714}{(1 - \frac{dH}{H})3/2} \left\{ \frac{800{,}000 \times H.P. \times T}{n^2 \times w r^2} \right\}$$

$$\therefore s_3 = \frac{T \times C}{(w e^2)}$$ when c is a quantity varying with the percentage of load thrown on. Working out the values of c for $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$ and full load thrown on we get:

$c_1 = 292$
$c_2 = 790$
$c_3 = 1{,}195$
$c_4 = 1{,}790$

Therefore, we have the whole range of speed changes represented by the formula $(w e^2) = \frac{T \times C}{s}$ in which T represents time of governor for complete stroke, c is a quantity varying with percentage of load thrown on, and $(w e^2)$ represents moment of inertia of rotating parts of the unit.

First, let us plot the values of c for different amounts of horse-power thrown on from one-quarter to full load, using as ordinates the values of c and as abscisses, values of horse-power. This gives us the curve shown on chart.

The values of c must now be multiplied by the assumed values of T. For the conditions of the assumed example T will vary from 1 second to 4 seconds for good commercial operation, and may be any value between, subject to the choice of the designer and the manufacturer. To multiply values of c by T, plot a series of radiating lines making these lines stand for governor times and converging to a point on the zero line of the curve just drawn. These lines must be so drawn that the tangents of the angles they make with the vertical will be proportional to the times they represent. The results of this multiplication will be read on some horizontal axis, and they must next be divided by the assumed values of s_3. Choose a point of convergence for the speed variation lines and this must be located on the vertical line passing through the T centre. The allowable speed variation for commercial operation will not be over 25%. Therefore, from the point of convergence we must draw 25 lines, such that the tangents of the angles they make with the horizontal will be proportional to 1, 2, 3, etc., up to 25.

To determine the limits within which the desired results of $(w r^2)$ must fall, by working out a few cases we find that 0 to 50,000 will cover all the practical field of operation. Choose a scale such that these can easily be read; say, 5,000 equals 2 spaces. Therefore, we locate the centre for the speed variation lines on the vertical line which passes through the centre of the T lines, and 20 spaces above it. From this centre draw the radiating speed variation lines, according to the tangents of the angles.

To read the chart, enter at the bottom at the assumed load thrown on, and run up to the curve; from there go horizontally to the desired governor time, then vertically to the speed variation line, and then horizontally to the vertical scale representing value of $(w r^2)$. Or if value of $(w r^2)$, amount of load thrown on, and time of governor are known, enter as before at the load thrown on, run vertically to curve, thence to governor time and the intersection of the vertical through this point with the horizontal drawn from the desired value of $(w r^2)$ will be on or near one of the speed variation lines, thus giving the speed variation for the assumed condition.

AMERICAN GOOD ROADS CONGRESS.

Among the educational features to be presented at the American Good Roads Congress, at the International Amphitheatre, Chicago, December 14th to 18th, inclusive, will be a model boulevard, twenty feet wide and more than four hundred feet long extending around the arena. The boulevard will be divided into sections, each of which will be built of different materials or by different methods, so that practically every modern standard type of road and street construction will be shown.

In addition to the exhibits of several States and cities, a number of universities and colleges have signified their intention of presenting the exhibits which they have assembled in connection with their courses in Highway Engineering.

Work on the programme is progressing as rapidly as the circumstances will permit. The leading road-builders of the United States and Canada have consented to prepare papers or participate in the discussion on the phases of the subject on which they are best posted. This insures the presentation of all the latest developments in the lines of road organization, construction and maintenance. It also assures the wider and more comprehensive educational value of the proceedings.

INTERCOLONIAL RAILWAY BRIDGE OVER THE NASHWAAK RIVER, N.B.

The substructure work in connection with the bridge of the Intercolonial Railway over the Nashwaak River, and consisting of two abutments and four piers, has been completed by Baird and Howie, of Fredericton, N.B. The greater part of the concrete work on the piers and abutments was run last winter under severe weather conditions with no detrimental effect. Foundation work of a difficult character was encountered in some instances, one of the piers reaching 30 ft. below water level, below which again excavation to bed-rock was necessary.

The cost of the substructure will be approximately $45,000.

WORK FOR UNEMPLOYED AT BURNABY, B.C.

It is proposed in the municipality of Burnaby to set men to work under the supervision of Mr. Fred. L. Macpherson, municipal engineer, on the cutting of trees and the general cleaning up of road allowances throughout the municipality. A rock-crushing plant will also be installed. Crushed rock and cordwood are materials for which there has been a keen demand. The former has been subject to haulage from Pitt Lake.

The municipality is going ahead with all needed improvements and an extensive program has been arranged to provide employment throughout the winter.

STATISTICAL CONTROL OF RAILWAY OPERATION.*

By W. M. Baxter,
General Manager's Staff, Canadian Pacific Railway.

THE business of a railroad may be divided into two distinct departments, namely, acquiring traffic and moving traffic, which is similar in industrial enterprises to the selling end and the manufacturing end. A railroad manufactures and sells transportation.

The great difference between the producing of the railroad's commodity and that of a flour mill, or coal mine, from the viewpoint of management, is in the fact that the plant and equipment of the railroad is dissipated or spread over a large stretch of territory or country, while that of the flour mill or coal mine is concentrated, so that all supervision must be delegated, most of the work being done by transportation units, which are continually changing their location, so that they cannot be supervised except in a scattered manner.

An unusually large number of employees must work without supervision, and the margin of operating profit is exceedingly small, when compared to the average returns on the investments in manufacturing and farming.

As the general manager usually spends the larger portion of his time in inspection, and under normal conditions seldom directs the movements of trains, he sees but an infinitesimal volume of the company's business moved. As the scope of his vision is thus limited, other methods must be resorted to in order to check the operation. The means of accomplishing this is to separate the operation of the road into rigid and definite units and then to compare these units with similar ones on other roads, or with the same road at various periods, or with arbitrary standards chosen as guides, or bench-marks.

Controlling a railroad by means of statistics might be defined as the process of determining the unit in each operation and then maintaining these units as nearly rigid as possible, seeing that they are collected, reported accurately and promptly.

The basic operating unit in freight traffic is the ton-mile, which is the product of the ton and the distance. The basic unit in passenger traffic is the passenger mile.

There are 6 important statistical units deducible from these two fundamentals, which are defined as follows:—

1. The average train load, either freight or passengers, is obtained by dividing ton mileage and passenger mileage by train mileage.

2. The average car load, freight and passenger, obtained by dividing ton mileage and passenger mileage by the respective car mileage.

3. The average length of haul for passengers and freight, respectively, obtained by dividing passenger mileage and ton mileage by the total number of passengers carried and the total tons moved.

4. Ton miles per engine hour obtained by dividing the engine ton miles by the number of hours the engines are in service.

5. The average revenue per passenger mile and per ton mile, obtained by dividing the freight receipts by ton miles and passenger receipts by passenger miles.

6. The average density of traffic per mile of road, obtained by dividing ton miles and passenger miles by the length of road.

It is unfortunate that this data cannot be given to the executives earlier than 5 or 6 weeks after the operations have occurred, owing to the enormous concentration and calculations which must be resorted to in arriving at them on a large system economically. While they are of final value in determining the general efficiency of the system, it is necessary to have a more immediate check in the form of current records.

Perhaps the most tangible source of daily information is the train sheet, which is received by the train masters and superintendents, from the despatchers. This sheet records the movements of all trains on the division, showing their consist as to loads and empties and number of cars in the train, and sometimes shows the number of passengers carried on each of the passenger trains, as well as the general movements of traffic, the observance of schedule time, the cause of delays and weather conditions.

By this means of concentrating upon a number of primary officers as much first-hand detail information as they can absorb, the foundation of statistical control has been laid.

The results of these primary officers' observations are collected and passed on to their next superior, who receives similar reports from many such primary officers, and in this way the operations of the road and work performed is reported with diminishing detail, until the chief executive is reached.

The division superintendent is undoubtedly the most important primary officer. The operation of his territory is reported to him daily, and frequently on congested terminals he receives certain information hourly. In addition to this daily data, he has a number of statistical sheets prepared monthly, which show in condensed form, sometimes grapically, the comparative results of a large number of operations on a division, one month as against another, one day as against another, and one year as against another.

When these records are graphically presented the sheets are ruled with a number of vertical lines, representing the number of days in a month, or the months in a year, or, in other words, progress of time, while a horizontal ruling to scale represents volume or quantity.

In this way the directing officer can readily see, for example, what has been the average tons per train mile, and the average pounds of coal consumed per 1,000 ton miles for a certain district or territory for a number of months, compared with the same months of the previous year, or if the records have been kept for a number of years, fair indication will be had of the season's effect on the traffic.

The important daily returns which a superintendent receives are those showing the number of trains of loaded cars, empty cars, and total cars received and forwarded in each direction at all of the terminals, also this same information for train movements at important intermediate points. He must know the entire train movement and the tonnage movement, and the failure to perform a given service of these movements as expressed in delays and other causes, must be thoroughly investigated and remedies applied. He is informed about the conditions of each of the yards and terminals on his division, and also about outside important terminals, which may affect movements in his territory. He knows the demand for freight and passenger equipment and the class of each required at the various points, as well as the available supply, and the condition and amount of power to move it. All of this information is of a statistical nature.

---

* From a paper read before the Canadian Railway Club, Montreal, Sept. 8th, 1914.

The officer next superior in rank is the general superintendent. He has received through the superintendents statements showing by divisions the number of engines assigned, total number of through engines shown on the train sheets, the number of through freight engines out of a shop and available for service before a specified time, usually at midnight, the number of through freight engines in shop for repairs and reported as coming out within 24 hours, and those which will not be completed in 24 hours, and also the average mileage made by these engines in service, special engine assignments, such as way freights, passenger engines, switch engines, work trains pick-ups, etc., together with general remarks on the entire power situation.

He also receives reports on the cars handled at stations, showing the number of cars of merchandise on hand and when unloaded, together with information relating to special car movements. He is also notified concerning traffic exchange at all foreign line connections, and if there is a special traffic, originating in his territory, such as coal mining, or some big manufacturing industry, he is advised of the number of cars moved and supplied, and a statement of detentions and their causes, as well as a report on the weather. While these are the principal reports he receives there are numerous special and minor statements furnished or compiled in his office daily, weekly, and monthly, which are beyond the scope of this article.

It is evident that no general superintendent could exercise close watchfulness over the thousands of separate items which these reports cover, and in reality he does not. A man in this position not trained on the property could not make efficient use of them, as the information gained is not so much absolute as relative. As the great majority of the data he thus receives must be judged comparatively to be of use, the graphic method of recording statistics is perhaps most practical and is instantly read.

The general superintendent, being familiar with all the conditions of his territory and knowing how it ought to operate, can look for the deviations from the results he is expecting. It may be fairly said that his system of control is by deviations from known standards.

The general manager, however, receives a smaller number of reports dealing only with the principal topics. All of these general considerations, and many other local ones, the managing executives have clearly in their minds, but accurate statistical information must be the basis of their judgment in any specific case. They must receive constant advices relative to the current productive power of various localities on the system, the state of the wheat crop, the cotton crop, the lumber market, or seaport traffic, so as to be able to foresee the possible future requirements necessary to handle the business expeditiously. This is again a matter of statistical organization, but it can be made to yield large results in actual operating efficiency.

The traffic department and the operating department must work hand-in-hand in their investigation of anticipated business, although from different motives.

The traffic manager is interested primarily in car supply and train service. It is his duty to secure the largest possible number of routings of business actually in sight, and also devise means for creating business that is not in sight. His business is divided into two main classifications, local traffic and competitive traffic, and he requires daily statistics to show how his local traffic compares with his expectations or with other seasons, and it is of great importance to him to know how his local agents are handling the competitive situation.

Even the local traffic is probably competitive with the traffic of other roads serving other markets, and the traffic manager must gauge the prosperity of his local industries largely in terms of their output, and this can be done only by comparative statistical data.

The intricacies of the mechanical department are, perhaps, most susceptible to statistical control. It deals with plain units in great variety, as, for example, pounds of coal consumed per specified service as per train mile or ton mile, or engine miles between stoppings or axle miles per hot box. There are really myriads of details in the mechanical performance of cars and locomotives, which can be standardized by means of statistical records. And deviations from these selected or normal standards will show up in great contrast, thus plainly denoting where investigation and remedy is needed.

The superintendent of motive power and his primary officers are continually engaged in these investigations.

Statistics of earnings and expenses are the ultimate check on all of the road's records, and when taken in conjunction with the statement of work performed and shown graphically, present the final picture of the system.

Without knowledge of the work done, however, earnings and expenses are not an adequate means of control. Many roads west of the Mississippi River in the United States operate for 60 per cent. of gross earnings, or slightly less, while in the East the average is nearer 70 per cent. Thus the operating ratio is an uncertain test of efficiency. The high rates in the newly-settled parts of the country make relatively easy a showing which the best operation in the world could not accomplish in a territory of intense competition of long duration, where the struggle for business has reduced the margin of profit of the railroad to a minimum.

These comments apply primarily, of course, to the statistical use of the operating ratio by the banker or broker, or student of railway affairs who is trying to judge one property in terms of another. The manager of the road confronted habitually by the same set of conditions can form a great many accurate opinions from the reported earnings, and they are of the highest statistical importance to him. Where detail knowledge of the property is absent, however, there could scarcely be a more perilous standard of railway efficiency than the relation which operating expenses bear to earnings. A road in mountainous country must pay relatively high sums for every ton moved, because of the necessity of double heading or of breaking up trains into short sections. On the other hand, a road operating in a swampy, water-level territory, as some of the roads in the Mississippi Valley do, are likely to have an abnormal maintenance cost. A road hauling large proportions of merchandise will have a high ton mile rate, but also a high ton mile cost, because of the necessity of rapid service and small tonnage in car loading. A railroad operating in the cotton belt, or wheat belt, will fluctuate greatly from one season to another, while a road in Canada will report a marked increase in operating cost during winter months.

Similar difficulties confront the banker and broker in making comparisons of efficiency based on the ton-mile. When 1,000 tons are moved 100 miles, a service of 100,000 ton-miles has been performed, regardless of the nature of the commodity. Some of the railroads in Indiana and Illinois, built to haul coal, frequently produce 100,000 ton-miles by moving a 4,000-ton train 25 miles, with a single engine and train crew. On the other hand, a road loading light manufactured articles might be doing

well to load three tons per car, and in this instance it would take a single train moving approximately 1,000 miles, or 40 trains moving each 25 miles, to produce 100,000 ton-miles.

The worst of it from a statistical point of view is that most railways are moving a thousand different kinds of traffic all at the same time, and cannot always manage even to haul their coal and light manufactured articles in separate trains. The ton-mile in consequence is an average figure composed of a multitude of dissimilar parts.

This, however, does not confuse the general manager or his assistant. They have been watching the operations of each of the districts for years, and if a new superintendent on a division increases the average loading from 690 to 720 tons, they regard it as a measure of increased efficiency, because they are comparing the results of a known territory at a particular season, under known circumstances with the same territory, and circumstances in another season.

Even this discriminating use of the ton-mile, when expressed in terms of average train load, often leads to its own peculiar form of error. When traffic is handled smoothly at efficient speeds, big train loads almost always mean economical operations, because they indicate that the business is being done with the fewest locomotives and train crews. But, if freight is held at terminal points longer than competitors are holding it, in order to collect maximum loading, or if the tonnage ratings are pushed to the limit, with resulting engine failures, blockaded traffic, overtime for crews and abnormal coal consumption, the big train load results in expensive economy.

This example of an over-done economy is likely charged to statistical government, but it illustrates a point. Statistics are only of use comparatively when measured against similar performances elsewhere, or against a standard arbitrarily chosen and designed in advance. But the analogy must be a real one. It is useless to compare results obtained with dissimilar commodities, or with the same commodities handled under different conditions of grade, curvature, and motive power.

UTILIZING ONTARIO'S WATER POWERS.

The mines and metallurgical plants of northern Ontario are now for the most part operated by electricity generated by water powers. At Cobalt, the falls and rapids on the Montreal and Matabitchewan Rivers are utilized; at Sudbury, mines and smelters are supplied with power by the Spanish, Wahnapitae and Vermilion Rivers; power is conducted to Porcupine from the Mattagami; at Michipicoten the Michipicoten and Magpie hoist the ore and operate the machinery at the Helen and Magpie mines; the Canadian Exploration Company's gold mine at Long Lake, also utilizes water power. A new water power installation is being put in at Gowganda Lake to operate the Miller Lake-O'Brien silver mine and a transmission line is under construction from the Blanche river at Charlton to work the gold properties in the new field at Kirkland Lake. Water powers are numerous in northern Ontario, and, as at Iroquois Falls on the Abitibi River, are employed also to operate pulp and paper mills. They have been of great service to the mining industry in providing cheap power.

The Argentine Minister of the Interior has under consideration a project to establish a motor omnibus service in the national territories of Argentina. It is proposed to initiate a service in the tobacco-growing districts of San Javier and Tacaruare in the territory of Misiones, where tobacco cultivators frequently suffer losses because of lack of transportation facilities.

ROAD WORK IN SASKATCHEWAN.

Good progress is being made on road construction in Saskatchewan, according to an announcement made by F. J. Robinson, chairman of the Highway Commission in Regina. He stated that more than 1,500 men and 1,000 teams were now at work on road construction. It is expected that the number of men employed on this class of work will be greatly increased within the course of another week.

Of a total sum of $1,200,000, voted by the Saskatchewan Government for highways improvements, $1,002,-685.84 was spent on the roads during the year ending April 30, 1914, according to the annual report of the Saskatchewan Highways Commission, tabled in the House a few days ago. Of this sum $507,517.02 was spent on road improvement direct and $417,065.69 was spent by municipalities under commission regulations. For steel bridges and concrete abutments there was a vote of $300,000, the total sum spent on this class of construction being $337,483.18.

At the recent session of the Saskatchewan Legislature it was announced by Premier Scott that the provincial government has decided to spend $750,000 instead of $500,000 as originally intended, on roads in the southwestern part of the province. Here the farmers are dually handicapped by long hauls to market and over extremely poor roads.

THE EMPRESS-BASSANO BRANCH OF THE C.P.R.

A very important line now under construction by the Canadian Pacific Railway Co. lies between Empress and Bassano, Alta., and has just been opened to service. It forms a part of the double-tracking scheme, and is considered by the company an important link in the Transcontinental route, as it reduces the distance between Swift Current and Bassano by 25 miles, and avoids some very heavy grades which exist on the line through Medicine Hat. The new line has been provided with 85-lb. Algoma steel rails. At an early date all the transcontinental trains of the C.P.R. will be routed over it.

It is proposed to make a further reduction in the mileage from coast to coast by a new line between Cabri and Moose Jaw, as well as to avoid some heavy grades thereby.

ELECTRIFICATION OF THE LONDON AND PORT STANLEY RAILWAY.

The work of renovating this line, preparatory to its electrification by the London Railway Commission, is progressing rapidly, a good portion being completed. The whole line is being reballasted by the Pere Marquette Road, which is still operating it. The steel on the main line, with the exception of around the switches at the terminals, has been renewed with 80 lb. rails, Canadian Northern Section; and the ties are being replaced with new untreated cedar ties. The following contracts were made: Algoma Steel Co., 3,000 tons of rails and angle bars, 30,000 tie plates; J. J. Gartshore, 380,000 spikes; Canadian Ramapo Iron Works, 52 sets of switches and frogs; Steel Co. of Canada, 34,000 track bolts and 65,000 tie plates; and Canadian Concrete Products Co., 1,100 ft. of concrete piping of various sizes. The inspection of most of the material was made by R. W. Hunt and Co.

Specifications are nearing completion for the electrification of the line, including sub-stations, overhead construction, bonding, cars and locomotives. Terminal plans are also being considered. The engineering work is all being handled by the engineering staff of the Hydro-Electric Power Commission of Ontario, for which F. A. Gaby is chief engineer.

AT WHAT PRICE IS POWER CHEAP?

By H. E. M. Kensit, M.I.E.E.

CHEAP power is one of the principal topics of conversation from coast to coast in Canada; cities that have it, or think they have it, spend thousands in advertising it, and those that have it not are eager to spend a million or two on any scheme that appears to offer it.

Yet, it is safe to say that the great majority of people who talk glibly on the subject have no clear idea as to what constitutes cheap power nor of whether power at a given price would be cheap for a given purpose; in fact, the general idea appears to be that if power at a certain price is "cheap" for any purpose it is therefore cheap for all purposes.

If the following questions were put to any but experts on the subject the replies would, in about nine cases out of ten, be as shown:

(1) Is power cheap at $25 per h.p. year? Yes.

(2) Is power cheap at 6 cents per kw.h.? No.

(3) Is power at $25 per h.p. year cheaper than at 6 cents per kw.h.? Yes.

But, as a matter of fact, the answer given is just as likely to be wrong as right, depending entirely on the circumstances of the individual case for which the power is to be used.

To demonstrate this, it is only necessary to analyse the accounts of a few miscellaneous users of power. The following is condensed from the actual accounts by meter of consumers supplied under a sliding tariff ranging from 6 cents per kw.h. for consumers taking less than 100 kw. per month to 2 cents per kw.h. for users taking over 8,000 kw.h. per month, with a fixed charge of $1 per month per rated h.p. of motors installed. The equivalent cost per h.p. year is the total annual account divided by the rated h.p. of motors installed and connected (column 3). Column 5 is the rated h.p. at $25 per h.p. divided by the kw.h. actually used.

The fact that the actual cost exceeds 6 cents in some cases is due to the fixed charge of $1 per month per rated h.p. having a large influence where the consumption is small.

Going back, now, to the questions given above and taking them in the same order:

(1) Is power cheap at $25 per h.p. year? It will be seen from column 3 that in 8 out of the above 13 cases it would not be cheap and in some of them it would be very expensive. In case 7 it would be equivalent to 44 cents per kw.h.

(2) Is power cheap at 6 cents per kw.h.? It will be seen from columns 2 and 4 that in 5 cases it would have been decidedly cheap, equivalent to from $3.40 to $15.40 per h.p. year.

(3) Is power at $25 per h.p. year cheaper than at 6 cents per kw.h.? It will be seen from column 5 that in 9 cases it would have been cheaper and in 4 cases (45%) it would have been dearer.

Most people, including engineers, will declare unhesitatingly that 6 cents per kw.h. is too dear for power, but that $25 per h.p. year is cheap power. Yet, here are 45% of actual cases in a list of 13 miscellaneous industries in which 6 cents per kw.h. works out cheaper than $25 per h.p. year, and in one case works out to $3.40 per h.p. year. In fact, the table shows that for small industries with poor load factors 6 cents is quite a cheap rate.

On the other hand, even a two-cent rate on an 80% load factor, such as might be obtained in pulp mills, cement works, electro-chemical works, etc., works out at 88% motor efficiency to about $120 per h.p. year.

Referring again to the table, it will be seen that a sliding tariff of 2 to 6 cents, such as could be given by any ordinary steam power station, works out in practice to a very reasonable cost for power supply to a miscellaneous list of industries, the only exception in the list being an hotel and not a factory.

Comparative Cost of Power for Small Industries, Per K.W.H. Actual and Per H.P. Year Calculated.

		1	2	3	4	5
	Class of work.	Rated h.p. of motors.	Actual cost per kw.h.	Equivalent cost per h.p. year.	Rate per h.p. year equivalent to 6 cents.	$25 per h.p. year would have been equivalent to:
1.	Foundry	13½	5.79 cents	$14.70	$15.30	9.85 cents
2.	Brewery	33¼	3.63 "	19.60	32.40	4.62 "
3.	Printing	11½	7.63 "	41.20	32.40	4.63 "
4.	Printing	11	5.27 "	26.70	30.40	4.94 "
5.	Printing	5	7.15 "	12.00	10.00	14.80 "
6.	Brickyard ...	35	3.34 "	6.33	11.40	13.20 "
7.	Planing mill..	77½	5.44 "	3.08	3.40	44.20 "

NEW FRASER RIVER CHANNEL.

Fraser River shipping will receive an enormous impetus upon the opening of the new channel, which has been in the process of construction during the past summer. This channel provides from 18 ft. to 20 ft. of water at low tide. It lies about half a mile north of the main waterway, which has been a menace to the shipping interests of the Fraser River towns owing to the continual formation of sandbars in the channel. The new waterway will be ready for use as soon as the necessary aids to navigation have been placed.

Editorial

A SLACK TIME FOR ENGINEERS.

An example more illustrative than that which has brought about present conditions, of the setbacks that the practice of engineering may experience would be hard to find. Engineering, as the term is used in its most familiar sense in Canada, cannot be said to include in its various branches many of the same that have been spurred on to working double shifts as a direct result of the European crisis. As a general thing the opposite exists, and half time, or less, prevails. Sherman may not have had engineering prominently in mind at the time, but what he said applies, nevertheless.

The Canadian Engineer has received assurances from the Federal Government, from various departments of the Provincial Governments, from numerous industrial, and from a few municipal bodies, that the war is not causing a material cessation of present undertakings, small or large, and that all engineering work that can possibly be continued will not be interrupted. It is very obvious, nevertheless, from the numbers of engineers with little or nothing to do, that the former assertion does not universally apply, while the latter gives little assurance for the future even to many who are still the proud possessors of work in hand. It all emphasizes the dependency of the present-day engineer upon financial interests over which he has little or no control. It is a fact that no other learned profession is suffering so acutely from the present condition of affairs and the lesson is profoundly brought home that, while it is no disgrace at all for a good and capable engineer to be at present out of a job, there is at all times room for a broader aspect on his part, when judged in conjunction with the execution of the material duties upon which mankind depends. For the past 10,000 years or more the engineer has been doing the important things in the improvement of civilization, and the time is about ripe for him to have a little more to say in connection with their administration. This has been the feeling oft repeated by *The Canadian Engineer*. Adherence to the old definition of the engineer might well be more concrete. Or, the following definition advanced by Parsons in his "The Philosophy of Engineering" might be applied with better advantage to the new engineer as he should be found in the 20th century: "The man of commerce, industry, business, who makes engineering a means rather than an end—the man of affairs." Although the above is faintly apropos of the present circumstances in engineering work, it is well for each engineer to weigh carefully the soundness of his method of conducting his business. Many have now time to do it. Engineering is business and there should be better business methods in engineering.

As for a pronounced revival, in the near future, of engineering activity, it is useless to predict. There are, however, frequent instances where engineering services are to be required and it is wise for the engineer to devise and employ suitable means of keeping in continuous touch with these new developments, though they may seem few when compared with the constructional activities of the past few years. The Construction News section of this journal, for instance, is a medium which reports weekly what undertakings of note are about to be entered upon or proposed throughout the Dominion. It would be surprising to many of our readers, perhaps, to learn what advantages are derived therefrom by the many who have learned its value and follow it closely. The impression entertained by some is incorrect as to its items being of use only to engineering and industrial corporations. The engineer out of employment might well apply what it offers to his own needs, and with material benefit; it displays to him an additional service of which he may not have availed himself heretofore, to wit, a list of opportunities—and opportunities appear to be what many are most interested in just now. We are not unintentionally encroaching upon the field of this journal's circulation department in expressing our belief that *The Canadian Engineer* can be of distinct service to the unemployed. Apart from its other services, it is able to afford a channel of access to employment, at this stage when employment bureaus, our own included, are choked at one end with applications for work, and are food for the ivy green at the other.

This is a time when the engineer must be more systematic and persevering than ever in keeping in touch with what is going on. Emerson's man in the depth of the forest, whose ability in some line of work would compel the world to wear a road through the wilderness to find him, has no place among conditions as they are.

THE ENGINEERING STUDENT AND THE CRISIS.

In our universities and colleges an atmosphere pervades, the like of which has never been known to Canadians of the present day. It is the atmosphere of war, and it has associated with it evidences of loyalty of which we might well be proud, even if the Canadian coasts formed a prominent part of the setting of the great European struggle. The circumstances clustered around the cause for which Britain is so staunchly contending may or may not be clearly understood by all our young men, but the justness of her stand is not for a moment being made a topic for deliberation. Every step toward military training adopted by our engineering schools, relieves but momentarily the pressure from behind, owing to the students' eagerness to uphold her principles.

Through it all, however, the importance of the investment which he is making in an engineering training must not be lost sight of by the student. The dividends therefrom should be regarded by him as the future source of his daily bread, or, if he does not deign to consider them as such, engineering is to be, at least, the prominent part of his life's work. The state of war, though it may be more immediate at present, is momentary compared with his engineering career. The former may demand his services in the field for a short period of time or not at all. The latter will surely demand his services throughout the remainder of his efficient lifetime.

With this in view, then, the engineering course must not be forced into the background. After graduation he will deal in a professional way with the public and with public officials. In this capacity he may become an exemplar in the application of his training to public service; or, he may drift along "without giving offence to anybody and without accomplishing anything progressive." It depends upon him and the benefit he derives from his

technical course. He must strive toward usefulness to his country in peace as well as in war.

This will entail greater effort on his part at the present time. His military study will encroach upon the time intended by him for sport and pastime and to a degree perhaps, upon his time for academic work. But it remains for him to make his training his business, and to adhere to the Empire's slogan, "Business as usual."

ENLARGEMENT OF THE LACHINE CANAL.

The Department of Railways and Canals has completed the widening of the Lachine Canal above Cote St. Paul, thereby removing a difficult curve and effecting a decided aid to navigation. The work has been under way since last March and only a few scattered jobs remain unfinished. Before the opening of navigation last spring the necessary length of the canal was dewatered and concrete construction brought up above water-level at the Cote St. Paul lock. This was completed without interfering in any way with navigation. Excavation work was then commenced and during the summer the narrow curve approaching the lock has been converted into a wide basin.

COST OF OILING STREETS AT FORT WILLIAM.

A report presented last week at a meeting of the Board of Works, Fort William, presents some interesting figures on the cost of oiling streets, compared with the cost of watering. The streets were oiled three times during the past season, these three oilings having been found sufficient to keep the dust nuisance in check throughout the whole summer, and it is thought that next year the same streets will only need one or two applications, thereby furthering the reduction in cost.

The cost per foot frontage for oiling amounted to 5.7 cents, or 1.9 cents per foot frontage per operation. The corresponding cost per foot frontage for watering these streets regularly day after day was 5.6 cents. Moreover, as stated in the report, the latter method of settling the dust during hot weather was efficient only for an hour or so. In view of the above results the Board of Works has recommended the installation of a storage tank to provide a larger capacity for oiling streets in future.

The hydro radial project is meeting with favorable reception. Eleven out of thirteen municipalities in the counties of York and Ontario carried municipal by-laws on Monday, authorizing the signing of contracts.

DON SECTION, BLOOR STREET VIADUCT.

THE accompanying illustration is a view of one of the alternative designs submitted in connection with tenders for the Don section of the Bloor Street viaduct. It will be remembered that tenders for this section were advertised for late in July, to close October 5th. This date was later extended to October 13th. At that time eleven tenders were in the hands of the Board of Control. One, however, was irregular, while another one referred only to the superstructure. The nine valid tenders, five of which were for concrete and four for steel structures, were referred to Mr. R. C. Harris, Commissioner of Works, for a report.

The following is a list of the tenders and prices:

For Steel—

(1) Quinlan & ~~Robinson~~, Montreal ....$ 996,564.81
(2) Wells & Gray, Toronto 1,009,760.75
(3) Navin Bros., Moose Jaw 1,316,954.12
(4) Sherwood & Sherwood, Toronto ... 1,353,074.91

For Concrete—

(1) Jones & Girouard, Ottawa ....$ 849,055.35
(2) Barzaghi-Vought Co., New York .. 875,000.00
(3) Daniel B. Luten, Indianapolis, Ind. 1,098,781.82
(4) C. E. Deakin & Co., Toronto 1,125,000.00
(5) Jas. Cowlin & Sons, Montreal 1,249,701.00

Of the steel tenders, the first two are stated to be based on designs prepared by the Canadian Bridge Co., Walkerville, Ont., and the remaining two on designs of the Dominion Bridge Co., Montreal.

Of the alternative designs in concrete tenders No. 1, 2 and 4 are understood to be based on a design prepared by ~~James~~ Jones, Loudon & Hertzberg, consulting engineers, Toronto, (illustrated herewith). The third tender is based on Mr. Luten's own design, while we are informed that the fifth is an English design.

At the time of writing no award has been made. It is expected that the Commissioner's report will be in the hands of the City Council next week.

Alternative Design in Concrete for Bloor Street Viaduct (Don Section).

THE RELATIVE VALUE OF DIFFERENT PAVING MATERIALS.

In considering the different kinds of material it is necessary first to establish a standard for a perfect pavement and study its different properties. A perfect pavement should be cheap, durable, easily cleaned, present light resistance to traffic, be not slippery, be easily maintained, favorable to travel, and sanitary. Admitting that a perfect pavement should have these properties, it must be understood that they are not all of the same importance and, therefore, a discussion of these properties is enlightening.

In a paper read by Geo. W. Tillson, consulting engineer, New York City, before the Cleveland Engineering Society the author assigns a percentage value to each type, assuming that a perfect pavement has a value of 100. Following are portions of his paper.

Cheapness.—It may be said that cheapness is not a physical characteristic of any material. While this is undoubtedly true, at the same time it must be admitted that it is an important factor in the selection of a material. It matters not how good or how adaptable any material may be, unless the authorities have money enough to use it, it is not available. So that cost must be considered as much in the examination as it would be by a private individual if he were about to purchase any article for himself. The question then resolves itself into what is the best that can be obtained for the money at hand. Cheapness, therefore, is given a value of 15.

Durability.—This is an economic and an important factor. It depends, however, upon a great many conditions. There are some materials which have a certain life only, no matter what the traffic, because they will be destroyed by the action of the atmosphere. This is true of asphalt and untreated wood, and treated wood to a certain extent. With stone, brick and such materials the durability depends almost entirely upon the amount and character of the traffic. The influence of traffic, however, is governed by several conditions, *viz.*, the width of roadway, character of the pavement, presence or absence of street car tracks, state of repair, and how well the pavement is cleaned.

It can be easily understood that the width of the roadway is an important factor, although of course traffic should be measured by the tonnage per foot or yard of width. This, however, must be somewhat modified, as in a narrow roadway the traffic both ways is confined almost to the same lines, so that the wear will be greater for the same amount of traffic than if the roadway were wider, permitting vehicles to move freely in the portion of the roadway assigned to their use.

By character of pavement is meant the detailed method used in laying the different materials; for instance, if a block pavement is used, the character of the foundation, joint filling and method of laying; asphalt pavement, according to the mixtures; and wood pavement, whether the same is treated or not and the method of laying.

The presence of car tracks on a street makes a material difference in its life, for the reason that the traffic is confined almost to one line on each side of the track. In a report to the City of Buffalo, where careful records have been kept of the life of asphalt pavements, it is stated that the presence of street car tracks will diminish the life of the pavement two years.

Whether or not a street is kept in good condition makes a great difference in the life of the pavement. The old proverb, "A stitch in time saves nine," applies undoubtedly to street pavements as forcibly as to any other class of construction. If a pavement be kept smooth so that traffic can be brought upon it perpendicularly, the wear will be reduced to a minimum. If, however, the pavement is allowed to be rough so that the wheels of vehicles strike it irregularly and with abnormal force, the wear is much greater than it should be. While this is particularly true of a block pavement it applies to a certain extent to sheet pavements.

The effect of street refuse on a pavement depends entirely upon the character of the pavement itself. If it be of asphalt, and the refuse is damp or moist to a considerable extent, it will have an injurious effect upon the surface. If, on the other hand, the pavement be of stone or brick, the refuse on the pavement will reduce the wear from traffic and not injuriously affect the material itself. This question, however, is not as important as it was some years ago, as all cities recognize the necessity of keeping pavements clean. Taking all things into consideration, durability is given a value of 21.

Easiness of Cleaning.—This is an economic factor, although the state of cleanliness of a pavement has a bearing upon its sanitary influence, so that the degree to which a pavement can be cleared by ordinary appliances and without undue expense is important. For that reason a value of 15 is given easiness of cleaning.

Resistance to Traffic.—This is an exceedingly important consideration. Street pavements are constructed primarily for the transportation of vehicles throughout the city, and anything that will reduce the traction required to move the loads is highly important. This property, therefore, has been given a value of 15.

Non-Slipperiness.—The slipperiness of a pavement depends upon its material and detailed construction, also its condition. The efficiency of a horse varies with its foothold. It does not matter so much what his strength is, if he cannot apply it to the best advantage. Any material that will allow him to do this has a particular value. It is varied to a great extent by the condition of the pavement; for instance, the presence of sleet or snow. Taking all matters into consideration, non-slipperiness is assigned a value of 7.

Maintenance.—The maintenance of a pavement is closely allied to first cost, and in considering the entire cost of a pavement the expense of maintenance is an important factor. This of course depends not only upon the character of the material itself, but also upon the traffic the street receives. It is unquestionably a fact that a certain amount of traffic is beneficial to wood or asphalt pavements, as it keeps the upper surface of the pavement dense and to a certain extent impervious to water, while as has been said before the imperishable materials wear in accordance with the amount of traffic. This property has been assigned a value of 10.

Favorableness to Travel.—By favorableness to travel is meant the ease and comfort which are enjoyed by driving over a smooth pavement and also the decrease in wear and tear on vehicles on a smooth pavement as compared with one that is rough and uneven. The first of these characteristics can be appreciated by anyone driving in the streets. While the wear and tear on vehicles cannot be exactly computed, information obtained from large department stores in Brooklyn shows that the changing of the old cobblestones of the borough into asphalt has very materially reduced their cost of repairs. In a paper read before the Institution of Civil Engineers in England in 1871 it was stated that the new pavements which had recently been constructed in Liverpool had made a saving of $50,000 per year for every mile of pavement on the dock lying streets, without counting the reduction to the

wear and tear on horses and vehicles. This property will be of more value and is receiving more attention on account of the introduction of automobiles and motor trucks. At the present time it is assigned a value of 5.

Sanitariness.—The sanitariness of pavements is increasing in importance from year to year as more attention is given to health conditions in our large cities, and the fact that certain pavements can be more thoroughly cleaned and that the material itself does not absorb moisture are not the only considerations. Schools and hospitals are increasing in number in all of our cities, and it is a recognized fact that as noiseless a pavement as possible is necessary in front of both. Not only that, but in the large office buildings where a great many clerks are employed from day to day the noise caused by heavy vehicles driven over a rough stone pavement has a disturbing effect upon their nerves. While this may seem a little extreme, it is an important consideration. This property, therefore, is rated at 13.

Having thus obtained a tentative standard for a perfect pavement, the different paving materials can be compared and in this way a value obtained for each material. Taking up, therefore, the materials that have been referred to as standard, the stone will be first considered.

Stone Pavements.—Granite and the harder sandstones are those that are principally used in the stone block pavements of this country. The particular kind to be used will depend upon the availability and cost. It would be foolish to consider granite as a material where it must be obtained at great expense and where a good sandstone is available. In this study, however, granite is considered, as it is a material that is used in New York City and one with which the author is most acquainted.

In this connection it should be stated that the figures arrived at in this study by the author must be varied in every locality and must vary to a great extent according to the judgment of each individual engineer. He wishes it understood, however, that he does not consider the exact figures as of so much importance as the method of obtaining the results. So that too much importance should not be given to the results shown.

The granite pavements of to-day are very much better than those that were laid even four or five years ago. It has been found that on account of their being laid on a concrete foundation it has been possible to reduce the depth of the blocks and make them of somewhat smaller size otherwise, thus rendering it possible to get a better cut block at the same expense as before and allowing the blocks to be laid with a closer joint, thus reducing abnormal wear.

The locks are laid on a sand cushion on a concrete base, the joints being filled with cement grout, tar and gravel, tar pitch alone, and sometimes a combination of pitch and sand. The author believes that with a small joint and a combination of good pitch and sand the best results will be produced. While a cement grout joint makes a smooth pavement, it is often difficult to close the street long enough to allow the cement to set, and it also makes a pavement that is exceedingly difficult to repair after it has been torn up for any substructure purpose.

In considering the value of different materials as applied to different streets it is assumed that an intelligent selection of the different materials has been made, as upon that will depend the results entirely. For instance, a granite pavement could be laid on a residence street with light traffic, where its durability would be long and the cost of maintenance practically nothing. On the other hand, an asphalt pavement could be laid upon a heavy business traffic street, where its life would be short and the cost of maintenance enormous. If, however, an intelligent selection of material is made for all streets of the city, what will be the natural life and cost of maintenance will be found.

In 1913 in the Borough of Brooklyn the granite pavements cost 3.9 cents and the Medina sandstones 6 mills per square yard, all on concrete.

Considering all the properties of a perfect pavement, and taking them up in detail, for granite pavements values have been given as shown in the accompanying table.

Wood Pavements.—Wood pavements have been laid at intervals in this country for some seventy years. The first pavements were not only of untreated wood, but of wood selected without much regard for its natural durability. The result was failure, as could have been expected. The repeated failures of the different kinds of wood, however, although they delayed, did not prevent entirely the establishment of wood in this country as a standard material. The success of the wood pavements in Europe made it positive that they could be laid successfully in this country under proper conditions.

The first treated wood pavement in this country was laid on Tremont Street, Boston, in 1900. This pavement has been in use during this entire period with very small repairs, and is in good condition at the present time. It is composed of blocks treated with a composition made up of one-half creosote oil and the other half resin. Pavements of this character were laid in New York and other cities, but on account of the increased price of resin it was dropped out of the mixture and creosote oil only used.

There has been a great deal of controversy as to the character of the creosote oil to be used for this purpose, the principal point being the specific gravity. The theory of mixing the resin with creosote was that, it being a more stable material, it would prevent the volatilization of the creosote and so preserve the blocks from decay for a greater length of time. The object of treating the wood is to prevent decay and also to make the blocks stable by preventing the absorption of water so that they will not shrink in dry weather or swell in wet and thus cause bulging. It was thought that by using a heavier oil this result could be obtained as well as by the use of a light oil with resin. The relative values of the heavy and light oils have never been determined, but the author has always been in favor of the heavier oil.

The present method of laying wood pavements in this country has not been in use long enough to determine what the cost of maintenance is, but figures obtained from St. Louis, Minneapolis and other cities indicate that it is exceedingly small. The first pavement of this character to be laid in Brooklyn was in 1902, and it has had practically no repairs for wear and tear since laid. It is, however, on a light traffic street. The total cost of maintenance of the wood pavements in Brooklyn in 1913 was 1.4 cents per square yard on pavements that had been in use from eight to eleven years. This cost, however, included, besides actual wear and tear, damage caused by openings in the pavement, although not the cost of repaving the openings themselves. In Paris in 1911 the cost of repairs was 26 cents per square yard. In London the average cost is 20 cents per square yard.

The fillings for joints in wood pavements are sand, asphalt or coal tar pitch, and cement grout. The practice in Brooklyn has been to fill the joints with sand, and first-class results have been obtained. Some people, however, prefer the bituminous and others the cement filler;

either will give good results when properly used, although the author does not look with much favor on the cement grout filler.

There is no question that wood block is an important paving material, and on streets where the traffic is heavy and noise is a great detriment it is most advisable. Its strongest point is its noiselessness and its weakest its slipperiness. It has been given a value as shown in the table.

Brick Pavements.—The first brick pavements in this country were laid in Wheeling, W. Va., in 1870, but the material did not come into general use for some time. Many failures have occurred in brick pavements because people did not understand the difference between bricks, and it was not easy in the early days of the industry to determine previous to its use whether a certain brick would or would not make a good pavement, and then it was not known what was the best method of laying. Both of these matters, however, have been fully threshed out, and, in the judgment of the author, this is mainly due to the work of the National Paving Brick Manufacturers' Association, which has maintained a paid secretary to look after the interests of the brick manufacturers, not simply to enable the manufacturers to sell their product, but that every city should get the best possible brick pavement obtainable.

With the present knowledge of the art of making brick and the methods of testing and laying, it is as possible to determine in advance what the results will be with brick as with any natural material.

It is conceded, of course, that brick pavements, like all others, must have a good foundation so that the question at issue, after the bricks themselves have been determined upon, is principally the cushion on the concrete and the character of the joint filling. The National Paving Brick Manufacturers' Association has always been very strong in advocating a 2-inch sand cushion laid upon the concrete. Most engineers in the east, however, believe that only 1 inch is necessary and that no more should be used, the idea being that all that is required is to have a sufficient quantity to allow the brick to be well bedded and have an even bearing over its whole surface. If, however, experience demonstrates that a 2-inch cushion is better than a 1-inch, the extra expense is negligible and it should be adopted.

Three kinds of joint filling have been used: sand, coal tar pitch, and cement grout. At the present time sand is not used to any great extent, as it is conceded that a material should be used that will protect as much as possible the corners of the bricks so that the wear may be in accordance with the principle previously laid down in this paper—as nearly vertical as possible.

The question of coal tar pitch and cement cannot be so easily dismissed, however. The advocates of both materials are very many and present strong arguments, and it must be admitted that good results have been obtained with both kinds of filling. The author believes, however, that if proper care be taken in the laying and in the application of the filler, cement grout will give the best results, as it will come more nearly to making the pavement a monolith. Some trouble has occurred in the past with this filler on account of the rumbling of the pavement under traffic. This trouble, however, has been nearly if not entirely obviated. There is the objection to a cement filler, however, that it is more difficult to open a pavement and replace it in case it becomes necessary on account of the subsurface work.

It is almost impossible to set any figure for the life of a brick pavement or the cost of repairs, as these depend almost entirely upon traffic. The figures given in the table have been made out principally from data received from large cities, and undoubtedly they would be modified if obtained from the State of Ohio, for instance. But as has previously been said, all figures of the table must be adapted to local conditions. The results determined upon are shown in the table.

Asphalt Pavements.—Under the head of asphalt will be considered sheet asphalt, asphalt blocks and bitulithic, although the latter is perhaps more often used with coal tar pitch than with asphalt.

Sheet Asphalt.—The first pavement of any note of this character was laid on Pennsylvania Avenue, Washington, D.C., in 1876. So great was its success that it soon came into general use all over the country. While called asphalt pavement, it is almost entirely composed of sand, as the standard pavements have but 10 to 12 per cent. of bitumen, which is the valuable property of the asphalt, the rest being made up of sand and a small portion of stone dust. The pavement is pleasing in appearance, smooth, not noisy, and on light traffic streets seems to be almost ideal. It is more slippery than the hard block pavements, and in the coast cities it is not generally laid on grades over 3 or 4 per cent. In the interior, however, where the atmosphere contains less moisture, it is often used on grades as high as 7 per cent. without trouble.

Data collected from the cities of Brooklyn, Boston, Buffalo, Chicago, New York, Philadelphia, St. Louis and Washington show that these cities in 1890 had a total of 246 miles of asphalt pavement, and in 1911 2,348 miles. This gives an idea of the popularity of the pavement, although it must be taken into consideration that this was during a period when there was great activity in laying new and smooth pavements. In Brooklyn, for instance, in 1895, there were 18 miles of asphalt pavement, while at the present time there are 540 miles. Brooklyn is a residential city, without many steep grades, and one to which this material is particularly adapted.

The cost of repairs to the asphalt pavements in the Borough of Brooklyn in 1913 was 3½ cents per square yard, and in the Borough of Manhattan for 1912 it was 14.1 cents per square yard, this being due to a great extent to the difference in traffic in the two cities. In the City of Paris in 1911 the cost was 19½ cents per square yard.

In Berlin asphalt repairs are made by contract. The price paid is for streets from 5 to 20 years old, 10 cents per square yard; from 20 to 30 years old, 12½ cents per square yard; from 30 to 40 years old, 15 cents per square yard.

In London the contract price on Cheapside per yard per year was 56 cents for 15 years beginning after the pavement had been down 2 years. The average cost of repairs in London is 30 cents per yard.

Asphalt Block.—This is another form of asphalt pavement and consists of blocks, made under heavy pressure at a central plant, composed of asphalt and broken stone aggregate rather than sand, as is used in the sheet pavement. The mixture of the material can be absolutely regulated and the pressure made uniform, so that the blocks produced should be uniform in density and quality. On account of the stone aggregate being coarser (say from ¼ inch downward) than the sand, the surface of the pavement affords a better foothold than the sheet asphalt, and also on account of the joints between the blocks. So that where a smooth pavement on grades is desired asphalt blocks are particularly desirable. They are used, of course, to a great extent on streets of light grades.

An objection to them is that as they have to be manufactured at one location the entire surface of the pavement must be transported from the plant to the street, while with sheet asphalt the plant can be located at a convenient point so that the haul is not so large. This makes a difference in the expense against the asphalt blocks. On the other hand, however, an asphalt block pavement can be repaired without the use of a mixing plant, as the blocks can be purchased and brought upon the street and used when desired.

Asphalt block pavements in the Borough of Manhattan in 1912 cost 9.8 cents per square yard for repairs, and in the Borough of Brooklyn for 1913 1.2 cents per square yard.

Bitulithic Pavements.—This pavement was first laid about ten years ago. A gentleman who had formerly been interested is asphalt pavements conceived the idea of improving the then existing methods of laying a macadam pavement by filling a portion of the voids with a bituminous product or bitumen mixed with some other material. By the gradual elaboration of his original idea there was evolved a pavement which is now known as "bitulithic." It is essentially a macadam pavement of selected and graded stone, so that the voids in the stone shall be as small as possible, the binder being a bitumen, either coal tar or asphalt, both having been used. The pavement, being formed of coarse materials, can be laid on quite steep grades with satisfactory results. It has been laid very extensively in this country and would undoubtedly have been used to a greater extent if it were not patented. It is considered as standard and ranks with asphalt pavements.

Sheet asphalt, asphalt block and bitulithic pavements are given the same values, as shown.

The table then is as follows:

	Per cent.	Granite.	Wood.	Asphalt.	Brick.
Cheapness	14	8	8	14	11
Durability	21	21	16	15	16
Easiness of cleaning...	15	10	14	14	15
Light resistance to traffic	15	13	14	12	15
Non-slipperiness	7	7	4	5	6
Ease of maintenance ..	10	10	8	6	6
Favorableness to travel	5	2	5	4	3
Sanitariness	13	9	13	12	10
Totals	100	80	82	82	82
Cheapness eliminated ..		72	74	68	71

Heavy traffic.				High-class residential.				Ordinary residential.			
Gran.	Wood.	Asph.	Brick.	Gran.	Wood.	Asph.	Brick.	Gran.	Wood.	Asph.	Brick.
21	16	15	16	10	14	14	15	Omitting light resistance to traffic.			
13	14	12	15	7	4	5	6				
7	4	5	6	2	5	4	3				
10	8	6	6	9	13	12	10				
51	42	38	43	28	36	35	34	67	68	70	87

Knowing, however, the kind of material and the properties thereof are not sufficient for the official whose duty it is to determine the particular one to be used. He should also know the requirements of the streets to be paved. In order to do this he should have records of the kind and character of the traffic upon each street, or upon typical streets. Of course it is not necessary to get a total census of traffic on all residential streets, but of those where by an inspection it can be told to what class they belong.

And in speaking of traffic it should be understood that as at present considered the words "heavy," "medium," and "light" traffic mean very little, except with reference to any one particular city. There should be a standard unit of traffic, so that when the traffic on a certain street is given it could be distinctly comparable with traffic in another city. To do this it is necessary that the effect upon the different materials be known. Little attempt has been made to determine this, but within the last two or three years the English Road Board has constructed a machine for making this determination, and a somewhat similar machine was exhibited at the American Highways Association meeting in Detroit last fall.

It can be easily understood that a vehicle weighing with its load 15 tons will have an entirely different effect upon a pavement than fifteen vehicles each weighing 1 ton. It makes a difference, too, whether the tires are steel or rubber, whether they are 1 inch or 3 inches in width, and whether the vehicle is moving at a rate of 6 or 30 miles an hour. Experiments can be made so that the wear of the different vehicles under different loads can be ascertained and referred to one unit, and until this is done the adjectives "heavy," "medium," and "light" must be considered very indefinite.

The borough engineer of Fulham, London, has established what he thinks is the wear that will take place on wood pavements under a certain traffic, and, having observed the traffic on any particular street, he figures out how long a wood pavement should last. This, however, is indefinite for the reasons before given.

And even after the value of the traffic unit has been established it will be difficult to apply it positively, as in every case the weight of the vehicles upon it must be estimated.

Then, after all that has been determined, there are certain local conditions which must also be taken into consideration. For instance, if the traffic requirements are such that a brick or stone pavement should be used for economic reasons, it is possible that hospitals, school houses or churches may be situated on certain portions of the streets, so that it would be necessary to lay wood on account of its noiseless property. Then, too, the official will learn that the wishes of the users of the street and those doing business on it must also be taken into consideration, and he often finds that the two will conflict, as the truckman cares nothing about the noise and the businessman cares little for tractive or non-slippery properties. So that, despite all information that can be obtained, in order to arrive at a satisfactory result the different conclusions must be treated together and intelligently. If, however, all these matters are taken into consideration, it is seldom that an improper determination will be made.

It might be in order to discuss to a certain extent the economics of the different kinds of pavement. When an original pavement is paid for by assessment upon the abutting property, with repairs and repaving done by the city at large, it often becomes necessary to establish legally just when a street should be repaved. This is more easily determined by inspection in a block pavement than in a sheet pavement, as it can easily be seen when the blocks are worn out, but with a sheet pavement patching can be carried on for a long time and to a great extent without there being any formal repaving. Take for instance the case of an asphalt pavement, and assume for the sake of the illustration that the original pavement is paid for by a bond issue continued during the life of the pavement, which in this case is assumed at 18 years. The

The items of cost in the maintenance of this pavement on a street are:

First cost;

Interest on the bonds;

Annual repairs;

A sinking fund to be collected each year to pay for the bonds when they mature.

Assume that an asphalt pavement will cost $2 per square yard, that the interest on the bonds is 4 per cent., and that it will cost on an average 4 cents per square yard per year for repairs. This can be shown in a formula, such as:

$$A + CI + \frac{R}{N} = \text{annual expense},$$

—when A equals sinking fund charges, C equals first cost, I equals rate of interest, R the estimated cost of total repairs during the life of the pavement, and N the life of the proposed pavement.

Substituting these values in equation we have:

$$.078 + .08 + \frac{72}{18} = .198 \text{ for the first period};$$

—that is, the cost to be raised by the city every year to maintain this pavement would be 19.8 cents per square yard. When, therefore, the annual repairs on a street approximate this amount the question of repaving should be carefully considered. If, however, the same pavement is continued upon the street, succeeding pavements would cost less, as the foundation must have a material value.

RUSTING OF IRON IN WATER.

Many years ago Crace Calvert concluded that the rusting of iron in water was occasioned by dissolved carbonic acid and oxygen, the former being the predisposing cause, since no action occurred in its absence. These conclusions have since been widely supported. Experiments conducted by W. A. Bradbury, according to Chemical News, show that rusting takes place very rapidly in tap-water, while in well-boiled tap-water no rusting should occur. During rusting atmospheric oxygen is absorbed. The solution of iron by carbonic acid should result in the production of hydrogen, thus $Fe + 2H_2CO_3 = FeH_2(CO_3)_2 + H_2$, but in experiments with tap-water no gas could be collected after over a week. Water saturated with CO_2 did evolve considerable quantities of gas. These experiments confirm the view that rusting is due to the combined action of oxygen and carbonic acid, and show that the oxygen is utilized in two ways: (a) in the oxidation of the nascent hydrogen liberated, and (b) in the oxidation of the iron bicarbonate to rust. Further tests showed that magnesium chloride solution does not act on iron in the absence of carbonic acid, although it has been stated that such solutions do react with iron, even in the cold, according to the equation—$Fe + MgCl_2 + 2H_2O = Mg(OH)_2 + FeCl_2 + H_2$.

NATURAL GAS PRODUCTION IN UNITED STATES.

The production of natural gas in the United States last year was the greatest in the history of the industry. The total gas production in 1913 is estimated by the United States Geological Survey at 581,898,239,000 cubic feet, valued at $87,846,677, an average price of 15.10 cents per 1,000 cubic feet, as compared with a production of 562,203,452,000 cubic feet, valued at $84,563,957, an average price of 15.04 cents in 1912. Of this total product, about 32 per cent. was utilized for domestic purposes, at an average price of 27.33 cents per 1,000 cubic feet, and 68 per cent. utilized for industrial purposes, at an average price of 9.4 cents. The industrial consumption includes gas used for both manufacturing and producing power.

Coast to Coast

Saskatoon, Sask.—Twelve carloads of cement are weekly being mixed and placed on the new bridge over the South Saskatchewan, at 25th Street, Saskatoon. A pneumatic concrete mixer is being used, and it is expected that the arch rings of the bridge will be completed before the frost sets in. Each arch ring contains about 500 yards of concrete, and the mixer and placer fills one of these in 17½ hours. When completed, it is said, the bridge will be one of the largest and most beautiful arch bridges in Canada.

Edmonton, Alta.—The offer recently made by the Wabamun Power and Coal Company to the city of Edmonton is to supply the city with electrical energy delivered to any point within the limits, the first 25,000,000 k.w.h. at 1 cent, the next 10,000,000 at .95, the next 15,000,000 at .90, then 20,000,000 at .70, and the following 20,000,000 at .65 per k.w.h. In addition, the foregoing prices would be considered as taking care of the load of the city at time of delivery, which would not be later than the fall of 1915. The property of the Wabamun Power and Coal Company is located 28 miles west of the city on the main line of the G.T.P., and includes a mile on the shore of Lake Wabamun, which makes readily available an unlimited supply of water for boiler purposes. Though the company will agree not to sell power to any outside concern at a lower rate than that offered to the city, yet the company is negotiating for the establishment of a plant of sufficient capacity to supply power also to the towns of Wabamun, St. Albert, Calder and other communities along its route to Edmonton. The term of the contract offered for consideration is for 25 years; though the company would agree to supply Edmonton's electrical energy for a period of 150 years. Also, the contract contains the proviso that the company will sell to the city at any period agreed upon the entire plant, transmission line, mine and all assets of the company at a price equal to the cost and 10 per cent. profit.

Cedars Rapids, Que.—A report recently issued by the Cedars Rapids Manufacturing and Power Company covering the progress made upon the company's plant during the four months ending August 31, showed 93 per cent. of the rock and 97 per cent. of the earth excavation completed; while four months ago, 58 per cent. and 73 per cent. respectively were the amounts reported. Of the rock excavated, 94 per cent. had been transported and placed; and of the earth excavated 97 per cent. had been replaced. The concrete in the power house structure was completed, all that remained to be done being the placing of the stone protection, 50 per cent. of which was completed. Half the work on the transformer house was done during the past period, the other half still remaining to be completed. The power house building was substantially completed, and work had been started on the wing dam at the north end. The north end of the building had also been closed in. According to the report, the removal of the balance of the material in the tailrace would be substantially completed by October 1: and the tailrace coffer-dam would then be removed. Three generators had been completely erected in the power house, and were ready for operation, and work was well advanced on all the remaining units. The transformer house, 60 per cent. of which was already completed, was constructed by the unit method, with the exception of the columns, which were cast in place. Practically all of the slabs which go to make up this building had been cast; and the work of assembling them was progressing rapidly.

PERSONAL.

H. A. McLEAN is leaving Sarnia, Ont., where he has for some years held the position of city engineer.

R. J. McLELLAN, city engineer of Kingston, attended the convention of the Electric Railway Engineering Association in Atlantic City.

J. HENRI DUBUC, previously engineer of highway bridges in the city engineer's office, Montreal, has been appointed chief clerk in addition to his former duties.

R. A. CAMPBELL has resigned his position as superintendent of the Tagona Water and Light Company, Sault Ste. Marie, and has been succeeded by R. D. S. BECKSTEDT, B.A.Sc.

J. E. ALDRED, of New York, president of the Cedars Rapids Manufacturing and Power Company, paid a visit last week to the company's power development now under construction near Montreal.

E. J. REED, formerly sales manager of Miles, Sykes and Son, Limited, and for several years chief publicity writer for the British Westinghouse Company, has been appointed advertising manager of Ed. Bennis and Company, Limited, of Bolton, England, manufacturers of mechanical stoking apparatus.

M. C. HENDRIE, hydraulic engineer, Water Power Branch, Department of the Interior, Ottawa, addressed the recent Irrigation Congress in Calgary on the power and storage investigations of the Department on the Bow River, west of Calgary. These investigations, as has been already stated in these columns, show that there is available for development over 50,000 dependable 24-hour h.p.

OBITUARY.

An accident occurred on August 12th in the vicinity of La Tuque, on the construction of the National Transcontinental Railway in which Mr. A. H. Johns, resident engineer, lost his life.

CANADIAN SOCIETY OF CIVIL ENGINEERS, OTTAWA BRANCH.

The annual meeting of the Ottawa Branch of the Canadian Society of Civil Engineers was held on Oct. 7th in the rooms of the Commission of Conservation, through the courtesy of Mr. James White, assistant to the chairman of the Commission.

The retiring chairman, Mr. Geo. A. Mountain, gave a very suitable address, reviewing the work of the past year and commenting favorably upon the large attendance at meetings. On several occasions over 300 were present. The Committees on Library, Rooms, Entertainment and Papers presented reports. The Secretary-Treasurer's report indicated that the affairs of the Branch are in very satisfactory condition. It was announced, however, that new headquarters will shortly be required.

The membership of the Branch has increased since the last annual meeting. Three deaths, however, have occurred in the persons of Ambrose Duffy, R. W. Farley and T. H. Schwitzer. A number of members have gone to the front.

The election of officers resulted in the following executive:—

Chairman—A. St. Laurent, Assistant Deputy Minister of Public Works, Canada.

Secretary-Treasurer—A. B. Lambe (re-elected).

Managing Committee—W. J. Dick, R. de B. Corriveau, W. F. Cochrane, Alex. Gray and W. S. Lawson.

MANUFACTURE OF ASBESTOS PRODUCTS IN CANADA.

A list of engineering supplies used, but not manufactured, in the Dominion was published in *The Canadian Engineer* for Oct. 8th, page 520. It was compiled from a more exhaustive list issued by the Department of Trade and Commerce, Ottawa, serving as suggestions for manufacturers.

The list included asbestos pipe covering as an article not manufactured in this country. On the contrary, however, the Asbestos Manufacturing Company, Limited, Montreal, with a large plant in operation at Lachine, Que., turns out all kinds of asbestos products, including pipe covering.

It is 85 per cent. magnesia pipe covering that is not manufactured here.

MR. JANIN'S ENGINEERING CORPS.

A formation of an engineering corps for active service with the English and French forces in the field has been effected by Mr. Geo. Janin, chief engineer of Montreal. Membership in the corps has been over-applied for. Subscriptions aggregating about $6,000 have been raised for the purposes of organization. The men are training at the Engineers' Armory in Point St. Charles.

MANITOBA BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

On Oct. 8th the Manitoba Branch held its first meeting of the season, Professor E. Brydone-Jack presiding. The speaker was W. G. Chace, B.A.Sc., chief engineer of the Greater Winnipeg Water District, who explained many of the features of the Shoal Lake water project now under way. He traced the efforts made by the city to obtain an adequate water supply, and leading up to the adoption of the present undertaking.

CALGARY BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

On Oct. 6th the Calgary Branch entertained the engineers in attendance at the International Irrigation Congress. The banquet was presided over by Mr. H. B. Muckleston, assistant engineer, Department of Natural Resources, Canadian Pacific Railway, and chairman of the Branch. Mr. F. H. Newell, Director of the United States Reclamation Service, was a speaker. The keynote of his remarks was the necessity of an engineer getting into close touch with the men who would prove out his work. Mr. S. M. Savage, supervising engineer of the St. Mary's Milk River project; Mr. D. W. Ross, consulting engineer, California, and Mr. Wm. Young, comptroller of Water Rights, British Columbia, were prominent among the speakers of the evening.

The Manchester Municipal School of Technology, England, has recently issued a notice to all graduates in the hope of securing a complete return with a view to ascertaining how many of its students, past and present, have enrolled for service, whether in the Navy, in the Regular Army, in the Territorial Force or on Medical or other service. We trust that those of our readers who are members of the college, and who have been out of touch with the registrar, will comply with the request which this notice implies.

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

DON SECTION, BLOOR STREET VIADUCT, TORONTO

SOME NOTES ON THE PRELIMINARY WORK ATTENDING THE WHOLE PROJECT—FOUNDATION TESTS—FEATURES OF DESIGN OF DON RIVER SECTION.

THE rapid development during recent years of the northeastern section of the city of Toronto has produced an acute need for better transportation facilities across the Don river. While the business and residential sections of the city lie almost entirely west of this river and the ravines adjacent to it, annexation and development has resulted in a large and increasing population which is served by two thoroughfares; *viz.*, the Queen St. bridge, accommodating practically all downtown traffic over the Don, and the Gerrard St. bridge. These thoroughfares are both relatively near the waterfront, and necessitate considerable deviation of traffic that rightly belongs to the northern portion of the city, together with an excessive congestion at busy periods of the day, along the present avenues of communication.

With the development of the Danforth Avenue section of the city and the establishment of a civic car line to convey traffic between the extreme eastern section of the city and the bank of the river (where communication with the business section of the city is effected by transfer to a south-bound car service) it became more and more obvious that a viaduct to span the Don river and Rosedale ravine, thereby affording direct transport to and from Bloor Street and the central portion of the city, was required, to dispense with the handicap which had so long prevailed both to freight and passenger traffic.

During the summer of 1912 the Department of Works of the city, under the direction of Commissioner of Works R. C. Harris, made a thorough survey of the best available route, taking all necessary levels, cross-sections, etc., to enable the Department to prepare plans and specifications for the proposed viaduct. In addition to information regarding the physical condition of the site, it was necessary to collect and arrange a great deal of information relative to the growing demand of city traffic, both surface and underground. In January, 1913, a by-law was passed by the ratepayers authorizing the sum of $2,500,000 to be expended on the enterprise. Since that time the investigations have been carried on to the most minute detail and have just recently been completed. At the present time tenders for the Don section of the viaduct are under consideration, and it is probable that tenders will be solicited for the Rosedale section in a short time.

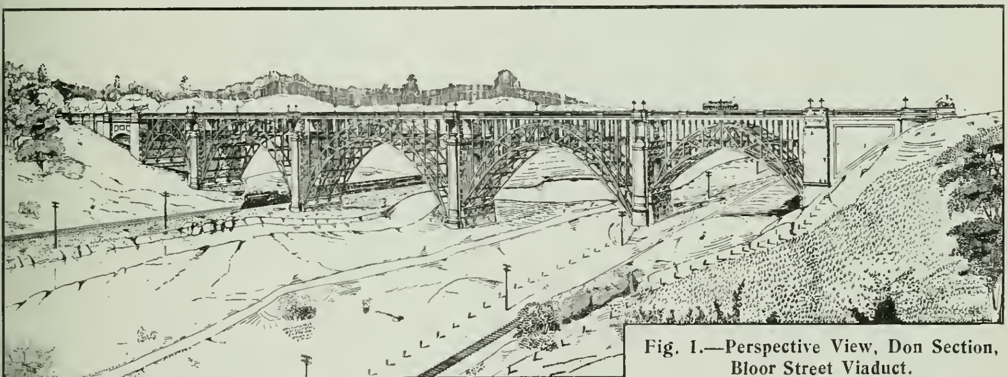

Fig. 1.—Perspective View, Don Section, Bloor Street Viaduct.

The surveys for the whole of the viaduct consist in general of its alignment, together with that of the adjacent streets and properties likely to be affected; the taking of levels for a distance of 100 ft. from the centre line on either side, at 10-ft. intervals, the results therefrom giving cross-sections for every 10 ft. between Sherbourne Street on the west and Broadview Avenue on the east side of the site. These cross-sections were necessarily very extensive at certain places, particularly between Sherbourne Street and Edgedale Road, in the Rosedale Valley between Parliament Street and Castle Frank Road, and also on the east side of the Don Valley. To facilitate measurements during the process of construction, permanent monuments were set and their location and elevation carefully determined.

In addition to the topographical work, extensive subsurface exploration was necessary. This included about 3,400 ft. of wash-boring and core-boring. Samples were carefully taken, labeled and preserved for reference. The rock found at varying depths consists of a shale.

Owing to the high unit stresses which the main piers of the proposed structure will impose on the shale, tests were made to determine as accurately as possible its safe carrying capacity. As the cores obtained by the use of the diamond drill were too small for compression tests, samples were selected from the quarry of the Don Valley Brick Works, in comparatively close proximity to the site. Care was taken to select the softest pieces obtainable and of the same character as the softest shale encountered in the boring operations. On account of the nature of this shale it was impossible to obtain good specimens.

Six test blocks, however, were obtained, of approximately cubical form, 2 inches to the side. These were tested to destruction, failure occurring under loads of 1,381, 831, 535, 1,500, 862 and 362 pounds per square inch respectively.

To acquire a fairer estimate of the carrying capacity of this material in place, the waterworks sections and the railway and bridge section of the city's Department of Works co-operated in making two loading tests on similar shale exposed in an excavation at the main pumping station. These tests were of the following nature: A steel platform was constructed with a bearing 8⅛ inches square. Weighed pig iron was placed upon it until the desired loading was obtained. On account of the settlements being small, special measuring devices were used and the total settlement checked by means of the level and target rod. In the first test a settlement of .45 inches was recorded under a unit pressure of 986 lbs. per square inch. Careful examination of the rock after the removal of the platform was made and the shale was found to be crushed only to such a degree as to have lost its characteristic structure for a depth of about 3 inches, while the shale immediately surrounding the loaded area showed no sign of injury.

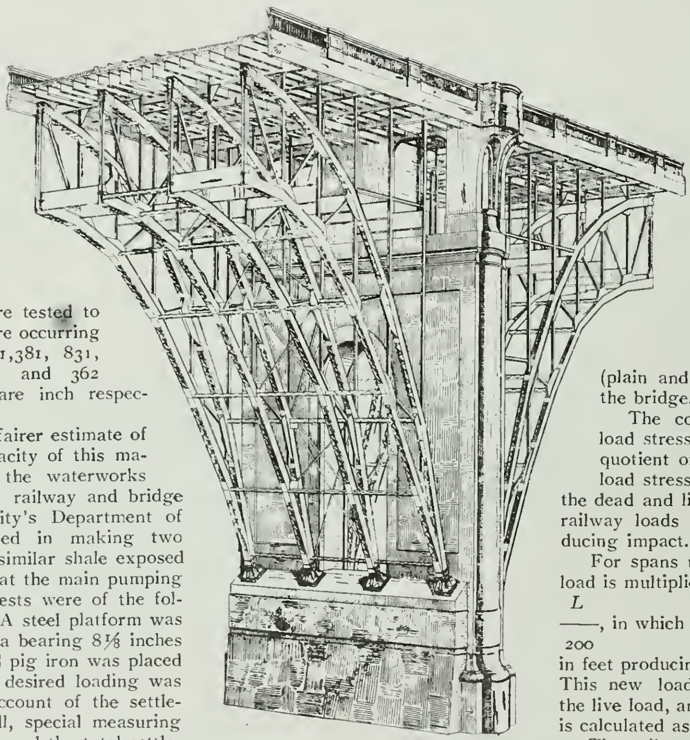

Fig. 2.—Perspective View of Pier "D."

In the second loading test a unit pressure of 402 lbs. per square inch was imposed, resulting in a settlement of .08 inches. Examination after the test showed that its effect on the texture of the shale could scarcely be observed.

The design of the Don section of the viaduct shown in Fig. 1 is based upon a steel structure with approaches and piers of reinforced concrete. It is a three-hinged, four-ribbed arch construction of five spans with footings carried down to rock foundation. The floor system is of concrete slabs supported on steel. The whole structure is 1,618 feet in length with a height of 130 feet above water level. The river span is 281½ feet, with a span of 240 feet, on either side, and on the outer side of these again, spans of 158 feet. The western approach will include a span of 80 feet. The specifications call for 26,175 cu. yds. and 3,050 cu. yds. of excavation for the east and west approaches respectively, and 20,000 cu. yds. for the piers. About 5,500 tons of structural steel and 43,000 cu. yds. of concrete will be required. As will be noted in the cross-section (Fig. 3) the design provides for a 20-ft. roadway on either side of car tracks, placed 11 ft. 11 in. c. to c. On either side, also, is a cantilevered sidewalk 10 ft. 9 in. in width, making a total width of 86 ft. Provision is made for the installation of a lower deck to connect with a future system of underground railways. A 42-in. water main will also be carried on either side under the main floor structure.

The following are among the assumptions governing the design of the concrete (plain and reinforced) portions of the bridge.

The combined dead and live load stresses are increased by the quotient of the square of the live load stress, divided by the sum of the dead and live load stresses. Only railway loads are considered as producing impact.

For spans under 80 feet, the live load is multiplied by the factor $1.40 - \frac{L}{200}$, in which L is the loaded distance in feet producing the maximum stress. This new loading is then considered the live load, and the impact allowance is calculated as above.

The rails and ballast are assumed to distribute each wheel load uniformly over a length of 5 feet. The load on each track is assumed to be distributed over a width equal to the length of ties plus one foot.

In calculating bending stresses produced in the slab by the 20-ton truck, each wheel load is assumed to be distributed over a square, each side of which is equal to 9 inches, plus the effective depth of the slab. In calculating punching shear produced in the slab by the 20-ton truck, the area of contact is considered as a square 9 inches to the side.

The length of span for reinforced concrete subjected to bending shall, in general, be considered to be the distance centre to centre of supports.

All slabs are considered, unless otherwise shown on the drawings, to be partially continuous and shall have reinforcing in the upper portions at the supports. In all

such cases the maximum positive bending moment in each individual span is taken as eight-tenths of that which would be produced in the same span resting freely on two supports, and the negative bending moment over intermediate supports is taken as ten-twelfths of the maximum positive bending moment in an adjacent span.

For beams and slabs the straight-line formula has been used, based on the following assumptions:

(*a*) All tensile stresses are considered to be resisted entirely by the steel reinforcing.

(*b*) There are no initial stresses in the beams.

(*c*) All shearing strain is cared for and there is no slipping between concrete and steel.

(*d*) The modulus of elasticity of concrete in compression is constant up to the limit of the allowable working stress.

(*e*) A section, plane before bending, remains plane after bending; that is, the stress on any fibre is directly proportional to its distance from the neutral axis.

Diagonal tension existing simultaneously with the maximum bending moment is considered as provided for by the concrete without web reinforcement, when the quotient of the vertical shear and the area between the centre of steel and centre of compression in the concrete does not exceed 50 lbs. per square inch.

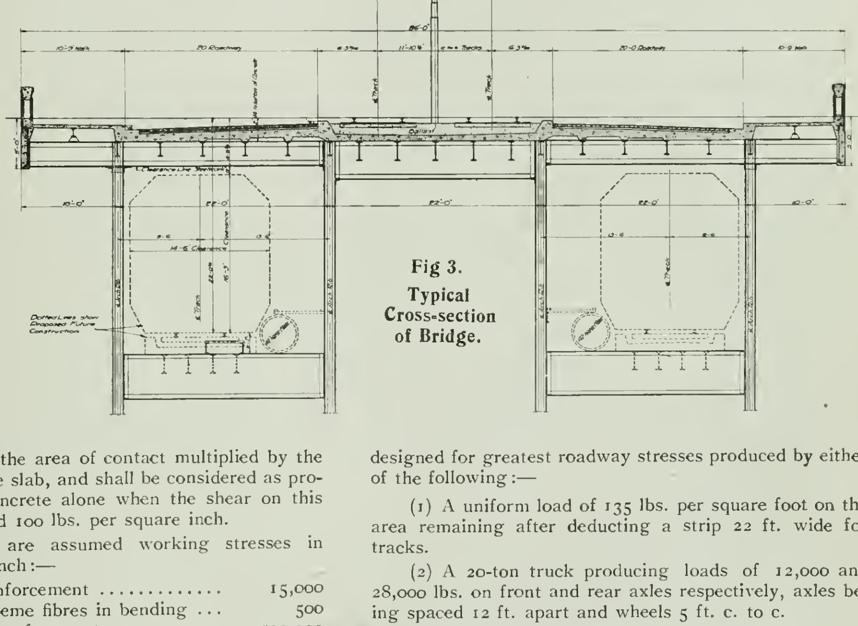

Fig 3. Typical Cross-section of Bridge.

Punching is assumed to be resisted by an area of concrete equal to the perimeter of the area of contact multiplied by the effective depth of the slab, and shall be considered as provided for by the concrete alone when the shear on this area does not exceed 100 lbs. per square inch.

The following are assumed working stresses in pounds per square inch:—

Tension in steel reinforcement	15,000
Compression in extreme fibres in bending	500
Modulus of elasticity of concrete	1,500,000
Modulus of elasticity of steel	30,000,000
Compression on 1:2:4 concrete under bearing plates and pad stones	400
Compression on 1:2½:5 concrete in body of pier	350
Compression on 1:3:5 concrete in caissons	300
Bond between deformed bars and concrete	100

The following assumptions are among those governing the structural steel designing:—

The steelwork is arranged to provide for the future traffic on the lower level, the clearance being 17 ft. 3 in. in height and 14 ft. 6 in. in width for each of two tracks. The top corners are bevelled 3 ft. 9 in. to a side, and the base has a width of 11 ft. 6 in. at rail level. Clearance is also provided for installation of two 42-in. water mains.

For purposes of dead load stress computation the weights of the different substances are assumed as follows:—

Concrete (plain or reinforced)	150 lbs. per cu ft.
Steel, as ordinarily listed per lin. ft.	
Broken stone ballast	100 lbs. per cu. ft.
Timber ties	54 lbs. per cu. ft.
4-inch wood block paving and ½-inch sand cushion	25 lbs. per sq. ft.
Rammed sand or gravel	125 lbs. per cu. ft.
Loose sand and earth	100 lbs. per cu. ft.

The floor system and posts are designed to carry on each upper deck track two 50-ton electric cars, producing live loads of 25,000 lbs. per axle (4 per car), the spacing in feet being 5 ft. 6 in. : 20 ft. : 5 ft. 6 in. : : 13 ft. : : 5 ft. 6 in. : 20 ft. : 5 ft. 6 in.

The arches and foundations are designed for a uniform load of 1,600 pounds per lineal foot of electric railway track.

The floor system and posts are designed for greatest roadway stresses produced by either of the following:—

(1) A uniform load of 135 lbs. per square foot on the area remaining after deducting a strip 22 ft. wide for tracks.

(2) A 20-ton truck producing loads of 12,000 and 28,000 lbs. on front and rear axles respectively, axles being spaced 12 ft. apart and wheels 5 ft. c. to c.

The arches and foundations are designed for a uniform load of 80 pounds per square foot for spans of 200 feet or over, and $80 + \frac{200-S}{5}$ pounds per square foot for spans under 200 feet. (S = span in feet.)

The slab, stringers, and posts for the sidewalk are designed for a uniform load of 100 pounds per square foot and the arches and foundations for a uniform load of 80 pounds per square foot.

The bridge is designed for a wind pressure of 50 pounds per square foot on the unloaded structure. For the upper deck the wind pressure is assumed to act on a vertical surface, ten feet in height from bottom of stringers upward. For the lower deck it is assumed to act on a vertical surface four feet in height taken twice.

For the truss members and posts it is assumed to act on twice the exposed area of one rib.

Each part of the structure shall be so proportioned that the maximum condition of stress in pounds per square inch shall not exceed the following:

Axial tension on net section of rolled plates and shapes 16,000

Axial compression on gross section of rolled plates and shapes:—

For flat or fixed ends, $16{,}000 \div \left(1 + \dfrac{L^2}{18{,}000\, r^2}\right)$

For one flat and one pin end, $16{,}000 \div \left(1 + \dfrac{L^2}{12{,}000\, r^2}\right)$

For pins at both ends, $16{,}000 \div \left(1 + \dfrac{L^2}{9{,}000\, r^2}\right)$

where L is the length of the member in inches and r is the least radius of gyration in inches.

Bending, on extreme fibres of rolled shapes, built sections, and girders, net section 16,000

Shearing, shop-driven rivets in reamed or drilled holes 10,000

Power-driven field rivets in reamed or drilled holes 9,000

All other field rivets 8,000

Lathe-turned bolts in reamed or drilled holes ... 8,000

Webs of girders, gross area 10,000

Bearing on diameter of rivets, twice the shearing value given above.

Bearing on pins 22,000

No compression member is to have a length exceeding 45 times its least width, nor an unsupported length in any direction exceeding 100 times its least radius of gyration about an axis perpendicular to that direction, excepting wind bracing and lateral struts, which may have an unsupported length of 120 times the least radius of gyration.

The preliminary work has been done, and the bridge designed, by the staff of the Department of Works, City of Toronto, assisted as regards architectural features of piers, approaches, and handrail, by Mr. Edmund Burke, Toronto, in the capacity of consulting architect. Considerable controversy has been created in connection with the proposed development as to the material, steel or concrete, that should be used, the nature of the soil structure having a very important bearing upon the question. The City Council has permitted the submission of tenders for both steel and concrete, and, as already announced in this journal, four of the former and five of the latter are under consideration.

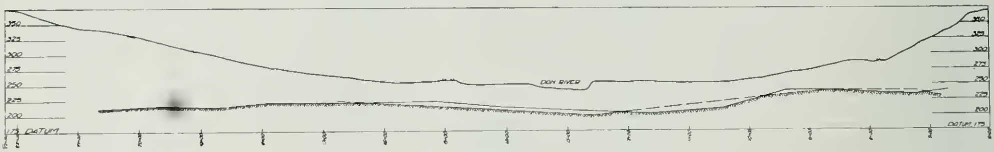

Fig. 4.—Profile of Don Section.

THE PITOT TUBE THEORY.

In *The Canadian Engineer* for May 28th, 1914, Page 784, a paper appeared entitled "Remarks on the Theory of the Pitot Tube," by N. W. Akimoff. The following discussion of the paper has recently appeared in the Journal of the American Water Works Association. The writer is Mr. J. W. Le Doux:

There has been recently a large amount of discussion of the apparatus known as "Pitot tube," the points of greatest interest being the shape and arrangement of the openings; the methods of calibration; the influence of disturbing factors; the formula of flow, particularly as to the term "g" representing the acceleration of gravity, and the constancy of the coefficient throughout the range of the velocity.

In regard to the first it would seem to the writer that as any particular form requires calibration, that which is the simplest and easiest to handle, offers no material obstruction to the flowing water and produces the highest deflection of head for a given velocity should be the most satisfactory.

It has been held that the results are different if a tube is moved in still water from what they are if the tube is stationary and the water moves. It is hard to see how this can be so, providing the conditions are alike in each case; for instance: if a long column of water of the same uniform cross-section be used for each determination. If a Pitot tube be made to advance at uniform speed through the centre of a canal of uniform cross-section, the coefficient thus determined should be the same as if the Pitot tube were stationary in the same relative position and the column of water advanced at the same velocity. If, however, the coefficient were determined under the first of these conditions and afterwards placed in a circular pipe under pressure, it is conceivable that the coefficient would be different, although if moving and still water determinations could be made for the pipe itself, the results might be the same.

The influence of disturbing factors, such as the proximity of fittings or variation in the shape of the conduit or pipe, can never be allowed for in advance, and the proper thing to do is to avoid them as far as possible.

The formula of a Pitot tube, as well as that of the flow through all orifices or contractions in a pipe, is almost universally recognized to be that of a parabola, which is the simplest formula of a conic section, there being but two terms and two variables, one of these being in the first power and the other in the second. The first variable is the head or pressure, and the second the velocity, or quantity flowing. The parabola formula can be placed in the form of $v^2 = c\,h$, in which h is the head, v the velocity, c a constant.

If this formula is true and c is a true constant, it is only necessary to obtain the value of h and v experimentally which will determine c by calculation, and when this is once found it is good for all other values.

As the formula is one of bodies moving under the action of gravity, it is evident that the constant is influenced by the term "g"; that, however, need not concern us as long as we have to determine the constant anyway by experimental methods, and it is very important that this determination be made under such conditions as will obtain in subsequent practical use.

RAILWAY CONSTRUCTION IN SASKATCHEWAN.

In the annual report of the Saskatchewan Department of Railways the whole railway situation in the province is thoroughly canvassed, and the report contains much information, interesting as well as instructive.

The growth of operating railway mileage annually in Saskatchewan compared with the other provinces of the Dominion is shown in the following table in the report:—

Province.	1909. Increase.	1910. Increase.	1911. Increase.	1912. Increase.	1913. Increase.
Saskatchewan	550	301	189	633	897
Ontario	296	1	92	224	454
Quebec	89	132	87	1	103
Manitoba	94	16	245	54	473
Alberta	...	167	6	403	315
British Columbia	63	36	10	13	96

The following further statement of mileage of steel laid in Saskatchewan is furnished to indicate the history of railway construction in the province:—

	1905.	1906.	1907.	1908.	1909.	1910.	1911.	1912.	1913.
C.P.R.	1,090.1	1,181.4	1,235.85	1,528.84	1,650.39	1,819.14	2,080.18	2,271.38	2,479.34
C.N.R.	461.87	604.28	854.51	1,004.78	1,143.91	1,383.60	1,683.27	1,750.19	2,060.16
G.T.P.R.	....	....	154.08	260.67	465.15	531.75	635.75	873.09	1,087.36
Total	1,551.97	1,785.68	2,244.44	2,794.29	3,259.45	3,734.49	4,399.20	4,894.66	5,626.86

The following reference is made in the report to the effect of railway development in the province in the past and to the desire of the Government to see progress in the construction of branch lines maintained in the future:—

"The question of railway development in the province, despite the progress already made, remains one of paramount importance. The rapid development of the country impresses a realization of the need of railways. There are many rich and fruitful districts being retarded and vast regions remaining unopened and unproductive awaiting railway facilities. This lack of adequate means of transportation is the problem which has to be faced and which presses for solution. The population agriculturally employed is concerned in securing two things more than anything else, viz.: markets and transportation facilities to bring together the producers and consumers. That this is a matter of vital concern is plainly seen, for without markets and railways the industry of the farmer and the yield of the soil does not render him the best returns, the prices being generally determined by the facility and cost with which the produce can be placed on the market. For want of communication a great portion of the products of interior points possess little commercial value, but to which transportation facilities would give high commercial value. Increased rail transportation is necessary also to unite the different settlements which are now scattered and should be consolidated by providing means for social as well as commercial intercourse. The effect of railway development in the past touching the prosperity and well-being of the people has been perfectly obvious and appreciable, although not capable of being expressed in language or figures, and from this viewpoint it is earnestly to be desired that it will be possible for the era of railway expansion to continue, especially in view of the swelling immigration and development of the province."

A SIMPLE TYPE OF SECTION FOR MOVING A SHOVEL OVERLAND.

A. L. Van Dyke, of Woodstock, N.B., has given a description of a method, which he has used with much success, for moving a 70-ton shovel across country. Mr. Van Dyke states in the "Excavating Engineer" that when a shovel is to be moved for any distance it is most important to build sections instead of using rails, ties, and bridles.

Three 33-ft. sections are sufficient. Sixty-pound rails have been found suitable. These have not been found too light for the service. The rails are spiked to ties, of 3 by 6-in. hard pine, spaced about 8 in. apart. Beneath the rails, 3 by 12 or 16-in. hard pine planks are spiked to the bottom of the ties. To serve as runners, 1 by 3 or 4-in. strips are nailed beneath the planks.

In order to make the sections stiff, blocks should be put under the rails between the ties and spiked fast on top of the planks. The rails should be allowed to stick out from 4 to 6 in. over each end of the section, in order to provide clearance for easy connections. In making connections with the sections, use straps similar to those used with the ordinary 6-ft. sections, but instead of using a bolt and nut, use a spike with a key slot ¾ by ⅛ in. and a wedge-shaped key. This will prove simpler and more effective than bolts and nuts, as the threads are constantly being knocked off. To both ends of the fourth or fifth ties on each end of the section, fasten a ½ by 3-in. strap bent in a V shape.

Use two teams, one to pull the sections back from the rear of the shovel 6 or 8 ft., and the other to haul them around and in front of the shovel. Eight men with bars are sufficient to throw the section over in line, so connections can be made. Two others should be used to pull out and put in the bolts. In this manner, a mile to a mile and a half may be made in 10 hours without unduly driving the men. With 80-lb. rails, bridles, and ties, the work is very strenuous, and as a rule the men are exhausted by noon, consequently cutting down the progress in the afternoon. A turn can be made easily by using a 6-ft. section between the two long sections. Another advantage of the long section is that a shovel is not as liable to get off the track as is the case with ties and bridles. And even if this does happen it may be pulled on again easily by fastening a chain around one or two of the ties and the other end to the propelling chain. Jacks have rarely to be used.

COMPARATOR BUILDING OF THE DOMINION LAND SURVEY.

FOR some years the need has been keenly felt of proper facilities to test subsidiary standard tapes for the Dominion Land Surveyors. By the Dominion Land Surveys Act, the Surveyor-General is required to provide the surveyors with subsidiary standards tested and certified by him as correct. In order that these tapes might be properly tested and re-tested from time to time it was necessary to erect a building equipped with the most up-to-date apparatus for this purpose.

Building.—The building was of necessity of special design as it was of extreme importance that the temperature inside the building should vary as little as possible with any variation of outside temperature. It consists of two rooms, one a small room used as office and vestibule, and the other used for the testing. The inside dimensions of the main room are 150 feet long by 10 feet 6 inches wide with 12-foot ceiling. The walls are approximately 4 feet thick and consist of five thicknesses of brick, a 1-inch air space, sheeting, tar paper, 18 inches of shavings, 1 inch sheeting, 4 inch air space, tar paper and finally double sheeting. Between the ceiling and roof is a layer of shavings 4 ft. thick and beneath the floor a layer 2 ft. in thickness, under this cinders to a depth of 5 ft. to the solid rock. The only openings besides the door are two air intakes, one at each end of the room, and four ventilators in the ceiling. The air intakes (which are at the base of the wall) are arranged so that the quantity of air admitted can be regulated and during the tests can be completely shut off. Supported from the ceiling at each end of the room is an electric blower fan (shown in Figs. 2 and 3), used to circulate the air and so insure a uniform temperature throughout. The ceiling ventilators can be closed completely or opened any desired amount for ventilation. The exit into the outer room is of special construction, consisting of two doors with a 4-ft. air space between. The outer door is of the ordinary type, whilst the inner one is an insulating air-tight door of the refrigerator design.

In order to protect the apparatus from frost and moisture and also to raise the temperature to near standard temperature (62° F.) during the colder periods of the year an electric heating system was installed. Of necessity any system adopted must heat the testing room as uniformly as possible. A large number of small special heaters were used, placed around the walls near the floor. A double heater was also placed in each air intake in order to head the fresh air admitted. The heaters are of the three-heat type, giving low, medium and high heat. They may be controlled closely from a Vermont marble switchboard, the arrangement being designed so that different circuits may be regulated as to heat generated. The heaters with the conduit wiring may be noticed just above the floor in Figs. 2 and 3.

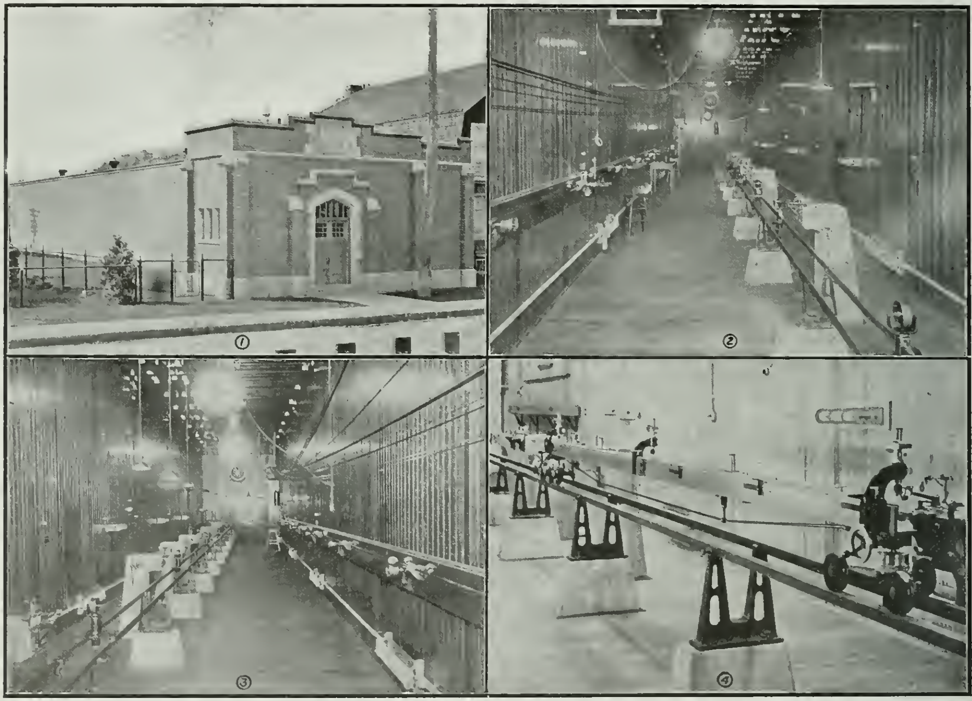

Fig. 1.—Exterior, Comparator Building; Figs. 2 (and 3).—Interior of Tape-testing Room, Looking North (and South); Fig. 4.—Meter Invar Bar in Position for Reading.

Apparatus.—Generally speaking, the existing bases for standardization of wires and tapes are of two types:

1st, The permanent bench marks of microscopic construction (*e.g.*, Russian bases at St. Petersburg); 2nd, the permanent bench marks consisting of lines traced on the edge of a series of polished surfaces (*e.g.*, bases of International Bureau and of the National Physical Laboratory). After careful consideration of the two systems it was decided to adopt the second one.

The apparatus installed was made by the Societe Genevoise pour la Construction d'instruments de physique Geneva. The general arrangement may be seen from Figs 2 and 3, the views being taken from the centre of the room looking towards the ends. The bench marks are permanently fixed to cement pillars. These pillars are isolated from the floor and extend down to solid rock. The bench marks are placed at 0^m, 4^m, 8^m, 10^m, 12^m, 50 ft., 16^m, 20^m, 66 ft., 24^m, 28^m, 30^m, 100 ft., and 32^m.

The distance between bench marks is determined by means of a standard invar bar 4 metres in length, standardized at the International Bureau of Weights and Measures at Paris. The bar is supported on a carriage which rolls over rails laid throughout the length of the base. This carriage, shown in Fig. 4, consists of two three-wheeled trucks supporting attachments for regulating vertical and horizontal movements. By this means the graduations on the bar and the bench marks may be brought very close together and the lines on the bar and bench marks sighted simultaneously by means of microscopes mounted on the carriage. Small two-candle power electric lamps are mounted on the piers to illuminate the graduations. The bar is protected by cases which rest on the support of the bar, the cases are notched at proper intervals to allow bringing the bar close to the bench mark and to uncover that portion of the bar in use.

The temperature of the bar is taken by means of two thermometers inside the case and read through openings in the latter. Suspended at equal intervals along the walls of the room and lying horizontally in cage guards are twelve delicate thermometers graduated to 0.1° C., it being possible to estimate to 0.01° C. By means of these thermometers an accurate determination of the room temperature may be obtained.

The rails which provide the runway for the carriage are supported every two metres by cast iron supports, these in turn being supported by cement piers isolated from the floor and carried down to solid rock. The iron supports are of U form to allow the tapes and wires to sag freely and to be freely manipulated. The supports used for suspending the tapes may be placed at any point along the runway and may be firmly clamped to the rails by means of two thumb-screws. The cord or wire which is fastened to the tape passes over a grooved pulley on the support and is attached to a weight to give the desired tension. The pulley is mounted on ball bearings and may be adjusted vertically or horizontally in order to bring the tape to the correct position. Intermediate supports which can be placed at any desired interval consist of pulleys mounted on ball bearings and are also adjustable.

As far as is known, only one set of apparatus exactly similar to that of the Dominion Government exists, this being one belonging to the Servian Government.

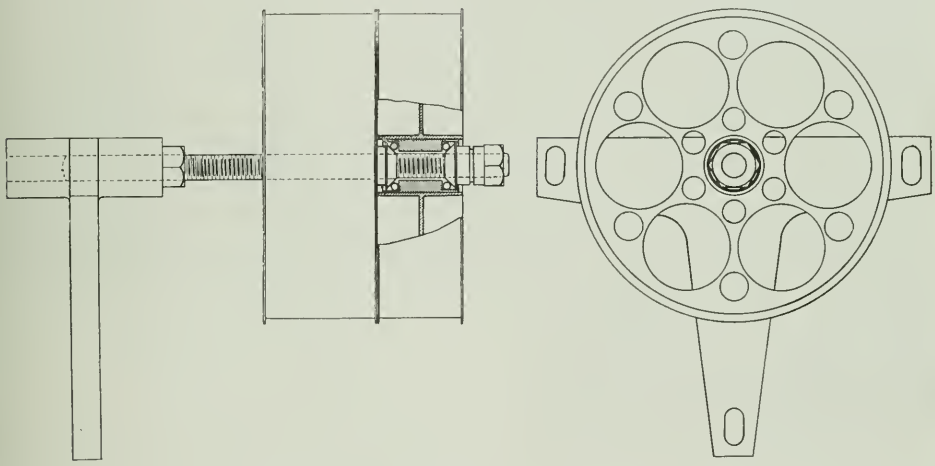

Fig. 5.—Intermediate Pulley Support for Tape-testing Apparatus.

The foregoing apparatus is used only to test the laboratory standards or when this method is specially requested by an engineer desiring to have tapes standardized. As previously mentioned, it is of extreme importance that the temperature of the room be as close to standard temperature as possible and also that the exact temperature be determined, as shown in the following example. If, during the comparison of a 100-ft. tape with the bench marks (the spacing of which does not appreciably alter with small variation of temperature), an error of 1/5° F. was made in determining the true temperature of the tape it would cause an error of .000124 ft. in the results due to dilation of the tape. The coefficient of dilation used is C = .0000062, which is an average value, but as this value has been found to vary with different tapes it is important that the temperatures during the test be kept as near as possible to the standard temperature (62° F.) at which the certificate is issued. If the tape is tested at 72° F., a variation of 10° F. from standard temperature, an error of .0000005 in the coefficient of dilation would cause an error of .0005 ft. in reducing the results to standard temperature.

In order that small changes of temperature might be neglected and that subsidiary standards be tested quickly and accurately, Dr. Deville, the Surveyor-General of Dominion Lands, decided to design a secondary apparatus, shown attached to wall on left and right of Figs. 2 and 3 respectively. This apparatus is so constructed that the tape to be tested is suspended on a series of delicate pulleys, side by side with one of the laboratory standards. The pulleys (Fig. 5) are in pairs mounted on the same shaft and the set supporting one tape may turn independently of the set under the other. Microscopes are provided to make the comparison and as the length of the laboratory standard is known to a high degree of accuracy, very accurate determinations may be made.

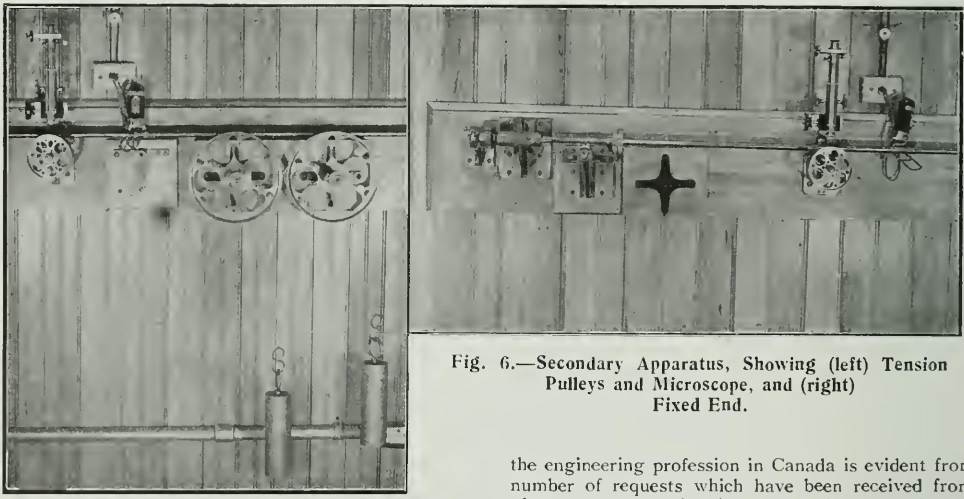

Fig. 6.—Secondary Apparatus, Showing (left) Tension Pulleys and Microscope, and (right) Fixed End.

The construction and method of using this apparatus enables determinations to be made directly for standard temperature. The only possible sources of error in comparisons of this kind would be due to: (1) Variation of temperature; (2) differential sag of tape and standard; (3) friction in the pulleys altering the applied tension. Due consideration was given to these points in the design of the apparatus. Any slight change in temperature affects both tapes to the same degree and may, therefore, be neglected. As the different tapes undergoing test are not all of the same weight per unit length as the standards there is a considerable variation in the sag of the two tapes, very often as much as ¼ in. with 66-ft. tapes supported only at the ends. This difference would cause an error of 0.00082 ft. in the final results unless a correction be applied. To overcome the necessity of using such a correction for varying weights of tapes the intermediate pulleys are used and spaced at such intervals that the alteration in length due to the difference in sag of the two tapes is so small that it may be neglected. After a series of careful determinations, the total friction of one set of pulleys for testing a 66-ft. tape, including end supports, proved to be but .014 lbs. This variation, when testing a 66-ft. tape under 10 lbs. tension, would affect the comparison of the length by less than 2 in 10,000,000.

The method of suspension is so delicate that it was necessary in order to keep the tapes steady during a reading, that the weights be attached to but one end, shown in Fig. 4. The wires imparting the tensions to the tape and standard by means of the attached weights are supported on separate pulleys mounted on ball bearings. The other end of the laboratory standard is fastened to a fixed point and the corresponding end of the tape is attached to a screw in such a way that the tape can be moved lengthwise to enable the various readings to be taken at different parts of the scale (Fig. 7). Horizontal adjustment is also provided to accommodate tapes of varying widths. A steel rod supported by ball bearings extends from one end of the apparatus to the other and when turned it imparts a motion to the adjusting screw by means of small gears. By this means the tapes may be set at any desired reading at any position along the tape-testing apparatus.

During the period in which the apparatus has been in use the results and accuracy obtained are all that could be desired. That a building of this nature is needed for the engineering profession in Canada is evident from the number of requests which have been received from engineers and surveying instrument dealers to have commercial measures verified. Although the building has been in operation but a short time, one hundred and fifty-three tapes have been tested for outside parties at their request.

HUDSON BAY RAILWAY.

The plant engaged on grading and bridge work, track laying and ballasting, for the Dominion Government Railway to Hudson Bay, consists of 3 steam shovels at Pas, and 2 at mileage 110; 13 locomotives; 100 Hart convertible cars and numerous box and flat cars, in addition to 2 passenger cars being operated as far as mileage 110. It is expected to have complete by the end of the year, track laying to the Manitou rapids of Nelson River, and grading from the Manitou Falls to within 110 miles of Port Nelson. Also the foundation work for a large bridge to be built at Manitou rapids, is to be finished this year. In connection with the terminals work in progress at Pas and at Port Nelson, two tracks have been laid at Pas, one from the roundhouse at Eighth Street, and another from the C.N.R., connecting with the bridge across the Saskatchewan River. Eight tracks are to be laid in the yards at once in such a manner that six additional tracks may be added as required. Though the complete details of track laying in the yards has not yet been worked out, it is expected to lay between six and eight miles of track in the yards during the summer. The work in progress at Port Nelson is of a more preliminary character.

SAFETY IN USE OF GRINDING WHEELS.*

Flanges should be of same size, and recessed out from centre, about 1/16 inch deep, for a distance leaving a flat bearing surface near rim of about 1/16 diameter of flange. A compressible washer of blotting paper or rubber, slightly larger than flanges, should be used between flanges and wheel.

Inner flange should be keyed or shrunk on spindle. Accidents have been caused by heavy pieces of work rubbing against a loose inside flange and the brake action caused nut to crawl, and enough pressure was set up by flanges to crush wheel. There should be no dirt between flanges and wheels. Sometimes a wheel breaks because wheel and spindle fit too tight.

It is not necessary to draw the nut up very tight; only enough to firmly grip the wheel between flanges. It has been calculated that on a 1½-inch machine with 8-inch flanges, a man with a 2-foot wrench can easily exert a crushing pressure between wheel and flanges of 3,600 pounds, or over 1½ tons.

If bearings become badly worn, there will be excessive vibration, causing wheel to run out of balance. If bearings are not properly oiled, the spindles run hot and heat is conducted to lead bushing in grinding wheel, and breakage may occur due to expansion of bushing.

Speed recommended by wheel manufacturer should not be exceeded. Under ordinary conditions, wheels will safely stand an overspeed represented by the testing speed. However, wheels may get damaged after being tested, and it is not possible to tell whether a wheel is damaged or not by looking at it. Tapping a wheel a light blow with a small hammer will usually tell if it is damaged, for if the wheel is perfect it will give out a clear ring, but if it is cracked it will have a dead sound.

When there are cone pulleys on a machine, sometimes a loose belt will automatically shift to the small cone pulley, and cause the wheel to run faster than it should. A belt-locking device is a good thing to use on a machine which has cone pulleys.

Most revolving cutters are made of chilled iron and break very easily. A hood on a dresser will catch most of the broken pieces.

Protection hoods provide greater safety than do safety flanges. Protection offered by any given taper decreases with decreased diameter of wheel. To provide equal safety on all sizes of wheels would require, therefore, a graduated difference in taper. A hood with adjustable tongue furnishes equal protection for a wide range in diameter of wheels. A hood adjustable to base of grinding machine also serves same purpose.

Cost of operating a given grinding machine is of importance. Adjustable hoods have the better of the argument, for as the wheel wears, protection flanges must be changed frequently. Such change involves the removal and remounting of the two flanges and wheel; whereas with hood, the change would involve merely setscrew adjustment.

To provide adequate protection for large wheels, the thickness of flanges should be increased beyond those of any flange now on market. This adds momentum to the revolving spindle, which, in turn, would require greater rigidity and strength than is found in the majority of present day grinding machines.

Laws in almost every country and state require removal of dust from dry grinding. This requires a hood, and if a hood is used, it might just as well be strong enough to offer protection in case of accident. A proper hood offers complete protection. Where a hood would interfere with proper use of wheel, a tapered wheel mounted between flanges of a corresponding taper affords the next best method of protection.

*From paper by R. G. Williams, of Worcester, Mass., presented at Chicago convention of American Foundrymen's Association.

PATENTS OF GERMAN AND AUSTRIAN INVENTION.

As provision has been made for the voidance or suspension of patents owned by German or Austrian patentees, a list has been prepared of such patents issued during the month of June, 1914. Those pertaining to engineering and allied industries appear below. A later issue will contain a compilation of such patents issued during the month of July to patentees in these countries.

1. 155947, June 2, 1914, projectile.
2. 155958, June 2, 1914, ball bearing.
3. 155959, June 2, 1914, ball bearing.
6. 156006, June 2, 1914, electric soldering.
7. 156015, June 2, 1914, process of butt-welding rails.
9. 156030, June 2, 1914, firearm.
10. 156066, June 9, 1914, igniter for shells, mines, etc.
11. 156116, June 9, 1914, surface for controlling electrically operated mechanism.
13. 156152, June 9, 1914, piston.
14. 156168, June 9, 1914, pump.
17. 156192, June 9, 1914, glazed mortar coating.
18. 156211, June 16, 1914, steel production.
19. 156212, June 16, 1914, telephone station.
22. 156220, June 16, 1914, apparatus for cooling superheater pipes.
23. 156245, June 16, 1914, cartridge magazine for firearms. Hungary.
26. 156376, June 23, 1914, filter.
27. 156378, June 23, 1914, nitrogen production.
30. 156440, June 23, 1914, electric switch for lamps.
32. 156452, June 23, 1914, wireless telegraphy system.
34. 156498, June 23, 1914, mitering machine.
35. 156506, June 30, 1914, crimping machine.
38. 156537, June 30, 1914, electrolysis of alkali of Halogenes.
39. 156543, June 30, 1914, motor plough mechanism.
40. 156621, June 30, 1914, sound transmitting machine.

Anyone interested may, on payment of a fee of $10 to the Commissioner of Patents, make application to have any one of these patents set aside or suspended. It will be necessary for the applicant to show that he intends to manufacture the invention, and that it is in the interests of Canada, or part of Canada, or of a particular trade, that he should be permitted to manufacture the patented invention. It is within the discretion of the Commissioner, then, to void or suspend the patent.

We are indebted to Messrs. Ridout and Maybee, Toronto, solicitors of home and foreign patents, for the above list.

EFFECT OF ELECTROLYSIS ON THE COMPRESSIVE STRENGTH OF CEMENT AND CONCRETE.

THIS is the subject of a paper read recently at a meeting of the American Institute of Electrical Engineers by C. E. Magnussen and B. Izhuroff, enlarging upon a previous paper entitled "The Electrolytic Corrosion of Reinforced Concrete," presented in 1911. In the earlier paper it was stated that the results obtained were not entirely conclusive, as the experiments were of only 30 days' duration. The series dealt with in the present paper continued for several months and the conclusions corroborate the results reported in the former paper. For the current density covered by the experiments, the current was found to produce no change in the compressive strength of concrete tubes, from which it is deducted that the failures of reinforced concrete due to electrolysis are due entirely to the forces produced by the increase of volume when iron is changed to iron oxide, and not by any direct action of the current upon the concrete.

This series of experiment was begun in September, 1912. Exceeding care was taken to keep the cubes moist. By tightly wrapping them with rubber and friction tape practically all electrical leakage was eliminated, so that all of the current in each circuit was made to pass through the cubes in series.

The tensile strength of the cement used complied with the specifications for standard Portland cement, as given by the American Society for Testing Materials. Chemical analysis and physical test data for this cement are given in Table I.

TABLE I.

Chemical analysis and physical test of the cement.

SiO_2	21 %
AlO_3	7 %
Fe_2O_3	2 %
CaO	66.5%
MgO	1 %
SO_4	0.5%
Na_2O and K_2O	2 %
Specific gravity	3.12%
Fineness:—	
Weight of sample	50.0 gr.
Aver. of 3 sample: retained on 200 mesh..7.9 gr.,	14 %
" " 100 " ..0.29 "	0.58%
" " 50 " ..0.02 "	0.04%
Normal consistency 400 gr. cement 88 gr. water	21.6%
Penetration	10.5%
Tensile Strength:—	
Aver. of 3 sample: 24 hours	108 lb.
7 days	499 "
28 days	717 "

The data from a chemical analysis and specific resistance are given in Table II. for the "fresh water" used.

TABLE II.

	Mg. per l.
Nitrics	0.0
Nitrates	0.0
Free ammonia—a trace	
Albumenoid ammonia	0.0
Free oxygen	0.8
Chlorine	3.5
Total solid	41.0
Fixed solid	21.0

Electrical conductivity per cm^3	at 20° C.	at 30° C.
Cedar River water	20,100 ohms	15,600 ohms.
Fifth normal NaCl solution	54.4 "	45.4 "

The "salt water" used was a 3 per cent. NaCl solution in the above water.

Natural sand, screened to pass a sieve having 20 meshes per linear inch and retained on a sieve having 30 meshes, was used.

The gravel was screened to pass a sieve having 4 meshes per linear inch, and retained on a sieve having 8 meshes.

Two hundred and forty 2-inch (5-cm.) cubes were made as follows:

(a) Sixty cubes of cement with "fresh water."
(b) Thirty-six cubes of mortar with "fresh water." Ratio of cement to sand, 1:3.
(c) Twenty-four cubes of concrete with "fresh water." Ratio of cement : sand : gravel = 1 : 1 : 1.
(d) Sixty cubes of cement in "salt water."
(e) Sixty cubes of concrete in "salt water." Ratio of cement : sand : gravel = 1 : 1 : 1.

The cubes were made in accord with the specifications of the Committee on Uniform Testing of Cement, American Society of Civil Engineers.

Six bronze molds were used and six cubes were made at a time, and in the tables this is termed a "set." In making the cubes due care was taken to secure uniform conditions. The consistency was adjusted to give a reading of ten on the scale of a Vicat needle. The cubes were kept in the molds under cover of a damp cloth, to keep the air moist for 24 to 28 hours. At removal from the molds each was numbered, and then immersed in water "fresh" for groups (a), and (b), and (c), and "salt" for (d) and (e), where they were kept for forty to sixty days.

Four cubes from each set were then placed in the electric circuit; No. 1 nearest the anode, next No. 2 and No. 3 with No. 4 nearest the cathode. The remaining two cubes, No. 5 and No. 6, were kept in the water as control. As the four cubes in the electric circuit were kept moist throughout the experiment the only factor affecting cubes No. 1-4 more than No. 5-6 would be the electric current passing through the former.

The arrangement of the cubes and the wiring are shown in Fig. 2. At each end an iron plate was placed, extending a little beyond the surface of the cubes, and having a copper wire soldered to one edge for electrical connection. A glass plate and a rubber strip were placed outside the iron for insulation and the whole secured by a wooden clamp. By means of this clamp pressure could be applied so as to give a fairly good contact between the iron plates and the cubes, and also to bring the four cubes into close contact. The sets were wrapped tightly with rubber tape, and this secured by friction tape. In order to keep the cubes moist small openings were made through the tape on top of the cubes. These openings were covered by inverted test tubes, full of water, salt or fresh according to which had been used in making the cubes. See Fig. 1. Absorbent cotton was placed under the test tubes and in this way the water could slowly seep through the cotton and keep the cubes moist. A storage battery of 60 cells in series with a lamp bank was connected to the iron plates. The voltage was applied continuously.

The currents in the circuits were characteristically irregular. The iron plates corroded at the anode ends of all the sets. In the salt water sets the corrosion was much more rapid than with the fresh water cubes. The cotton under the test tubes near the anode became saturated with the iron oxide. In the salt water sets the dis-

coloring appeared in a few hours, while with the fresh water three or four days were required. In set No. 7 the cotton was colored a greenish blue or Fe_3O_4, while all of the rest showed the red color of Fe_2O_3.

No odor was noticeable from the fresh water cubes. The chemical reactions probably consist simply of a decomposition of water and the formation of iron oxide.

$$3\ H_2O \longrightarrow 6\ H + 3\ O$$
$$3\ O + 2\ Fe \longrightarrow Fe_2O_3$$

No tests were made to determine a possible migration of sulphates and other salts.

An odor of chlorine accompanied the reactions in the salt water sets. The following equations give the main reactions:

$$4\ NaCl \longrightarrow 4\ Na + 4\ Cl$$
$$4\ Cl + 2\ H_2O \longrightarrow 3\ H\ Cl + H\ ClO + O$$
$$H\ Cl\ O \longrightarrow H\ Cl + O$$
$$2\ Fe + 3O \longrightarrow Fe_2\ O_3$$
$$Fe_2O_3 + 6\ H\ Cl \longrightarrow 2\ Fe\ Cl_3 + 3\ H_2O$$

The chlorine odor indicates the presence of hydrochloric acid and this may cause a secondary reaction that might affect the crushing strength of the cubes.

Testing Cubes.—Finally, the cubes in the electric circuit and the controlling cubes were tested for their compressive strength, using a Riehle 60,000-lb. testing machine. All cubes were tested under as nearly identical conditions as possible, using the same machine and at the same speed. One half of the tested cubes was crushed in the direction of the flow of the current, and the other

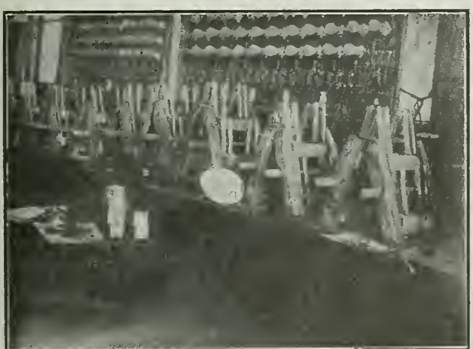

Fig. 1.—Arrangement of Test Apparatus.

half was tested in direction perpendicular to the flow of the current. (Fig. 3). One half of the control cubes was crushed in the direction of the open ends of the bronze mold and the other half in the direction of the sides of the mold.

Summary.—(*a*) The compressive strength of fresh water cement cubes was not affective by an average current density of 1.2 milliamperes per square inch (0.17 milliampere per cm^2) applied for 310 days.

(*b*) The compressive strength of fresh water concrete cubes was not affected by an average current density of 1.8 milliamperes per square inch (0.26 milliampere per cm^2) applied for 225 days.

(*c*) The compressive strength of salt water cement cubes was probably not affected by an average current density of 10.2 milliamperes per square inch (1.4 milliampere per cm^2) applied for 113 days.

(*d*) The compressive strength of salt water concrete cubes was not affected by an average current density of 13.8 milliamperes per square inch (1.9 milliampere per cm^2) applied for 110 days.

For (*a*), (*b*), (*d*) the average values for the cubes treated with the electric current were 1, 2, 3.0 and 2.5 per cent. respectively stronger than the corresponding control cubes. For group (*c*) the cubes in the electric circuit were 14 per cent. weaker than the control. An examination of the crushing strengths shows that the ap-

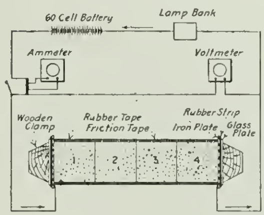

Fig. 2.

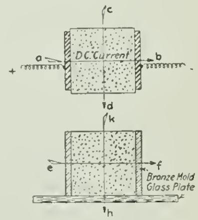

Fig. 3.

parent decrease is most likely due to a chance selection of too many of the stronger cubes for the control. If any action were due to the current the liberated chlorine would be the most likely agent. Since the chlorine is liberated at the positive pole it would appear at cube No. 1. In sets No. 22 and No. 23, the cube No. 1 was weakest, but in sets No. 27 and No. 29, cube No. 1 was strongest. Moreover, cube No. 1 in set No. 29 was the strongest in the whole series and hence not likely to have been weakened by the current. The series shows less uniformity in strength than the cubes in either (*a*), (*b*) or (*c*).

Averaging the averages for the four groups, the strength of the cubes Nos. 1, 2, 3 and 4 was only 1.8 per cent. less than the control cubes Nos. 5 and 6; and this difference is well within the errors of the experiment.

Summarizing the results, we find that for the current density covered by the experiments the current produces no change in the compressive strength of the cubes. This is in accord with the preliminary observations in the earlier paper (A.I.E.E. Trans. XXX., p. 2067).

Within the limits of current density for which these conclusions apply, it follows that failures in reinforced concrete due to electrolysis are due entirely to the forces produced by increase in volume when the iron is changed into iron oxide and not by any direct action of the electric current upon the strength of the concrete.

Messrs. Hering and Fuller, consulting engineers, of New York, made a periodical inspection of the filtration plant under construction at Montreal last week. It is reported that the proposed extension, which the Board of Control intends to carry out next year, was also under consideration.

A new process of manufacturing white lead is being tried out in the United States, and is being watched with interest by Canadian paint manufacturers and engineers who have occasion to specify lead paints. It is called the Euston Process, and is followed by the Euston Process Co., Scranton, Pa. Mr. Euston claims his lead has great uniformity, smoothness, tenacity and opacity; that it is non-checking, adhesive and durable. The particular advantage of this process seems to be the rapidity with which the lead can be manufactured compared with older methods.

PHOTOGRAPHIC SURVEYING.

THE photographic method of surveying is sometimes known by the names phototography and topophotography. The principle is to measure by means of perspectives, usually photography. The conception of this method is due to Laussedat (Austria). His first experiments, according to Dr. Deville's book on the subject, were made in 1849, the perspectives being drawn with a camera lucida. Shortly after, he substituted photography for the camera lucida. Wherever photographic surveys are now made, they are executed by the application of the principles laid down by Laussedat.

It is in Canada that the method has received its most extensive application; it was first employed when the surveys of Dominion lands were extended to the Rocky Mountains. In the prairies, operations are limited to defining the boundaries of townships and sections; these lines form a network over the land by means of which the topographical features, always scarce in the prairies, are sufficiently well located for general purposes.

In passing to the mountains, the conditions are entirely different. The topographical features are well marked and numerous; the survey of the section lines is always difficult, often impossible, and in most cases useless. The proper administration of the country required a tolerably accurate map, and means had to be found to execute it rapidly and at a moderate cost. The ordinary methods of topographical surveying were too slow and expensive for the purpose; rapid surveys, based on triangulations and sketches, were tried and proved ineffectual; then photography was resorted to.

Up to 1892, the photographic surveys were confined to the Rocky Mountains, in the vicinity of the Canadian Railway; at the end of that year, they covered about 2,000 square miles. In the same year, an International Boundary Commission was appointed to examine the country along the boundary between Canada and the United States territory of Alaska. The Canadian Commissioner, Mr. W. F. King, decided to carry out his share of the work by photography. In 1893 and 1894, his parties surveyed about 14,000 square miles.

Irrigation surveys were commenced in the south-westerly part of the North-west Territories, where the rainfall is not quite sufficient for agricultural purposes. In addition to the gauging of streams, the establishment of bench marks, etc., it is necessary to ascertain the catchment areas and to define the sites best adapted for reservoirs. For this purpose photography has again been resorted to in the foot hills and on the eastern slope of the mountains. It has, in this case, a peculiar advantage. Whether or not a site is a favorable one for a reservoir cannot be known until the plan has been partly plotted. It must be possible to bring water to the proposed place and to run it off; the capacity must also be adequate. If favorable, a detailed survey of the site is required. With the ordinary surveying instruments, a preliminary survey has to be made; if, after plotting it, the site is found favorable, the topographer has to go over the ground a second time to make a detailed survey. Or, the whole of the work may be executed at once, with the contingency that the detailed survey may turn out useless. With the camera, the plan may be plotted so far, and so far only, as required; the photographs which furnish a general plan can be made to give all the detail wanted without going again into the field. Whether the site is a good one or not, there is no labor wasted.

Notwithstanding the many publications on photographic surveying, the great advantages assigned to it and the numerous experimental surveys executed, it has not yet come into general use; in many quarters there is still an adverse feeling against it. There is such a fascinating simplicity about the method that it is at first difficult to understand the reasons which prevent its adoption. Can anything more convenient be conceived than a method which enables a topographer to gather rapidly on the ground the material for his maps and to construct them afterwards at leisure in his office?

Dr. Deville in his book says: "Assuming that the plane table can be used in the field whenever the weather is fair enough for the camera, which is not always the case, also that the topographer can plot and draw in the field as quickly as in the office, where he has every convenience at hand, the same survey by the plane table would require the same length of time at actual work or four days. To this we must add four days lost on account of the weather, or eight days altogether.

"The cost of our parties in the field is $20.50 per diem; at office work the only expense is the salary of the topographer, $5.00 per diem. Summing up, we find the comparative cost as follows:

Plane Table—	
8 days in the field, at $20.50 per diem	$164.00
Camera—	
2 days in the field, at $20.50 per diem	$ 41.00
3 days in the office, at $5.00 per diem	15.00
	$56.00

"This shows that the plane table survey would cost at least three times as much as the camera survey. In reality, the difference is greater, because part of the work, as well on the ground as in the office, is executed by the assistant, an arrangement which cannot very well be made with the plane table. The figures above are derived from our practice; with more views or more detailed plotting, the difference in cost would be still more in favor of the camera.

"If we analyse the causes of the superiority of the camera, we find that a very small portion of the topographer's time is spent in surveying operations. Nearly the whole of it is devoted to travelling for the purpose of seeing the country and he can map all that he, or rather his camera, can see. His work consists of two distinct parts; on the ground he simply collects data, and, with the exception of a few angles, does not waste any of his time in plotting or making measurements. This is left for the office, where the only expenses are the salaries of the surveyor and assistant. In the next place, the party consisting of an assistant and two men is, if not smaller, at least as small and inexpensive as for any other kind of survey. One man is sufficient to carry our camera and tripod almost anywhere, while an ordinary plane table, if it could be taken where our camera has been, could not be carried there by any single man.

"It is objected that plotting from photographs is more laborious than plotting on the plane table. There is, indeed, a slight additional labor; against this may be set off the fact that no useless line is ever drawn, as when, on the plane table, a point is sighted upon which cannot be recognized from the next station. The greater convenience of working in an office, instead of in the open air, turns the scale in favor of the camera. But photography has an overwhelming advantage in the numerous processes which the laws of perspective place at the disposal of the topographer. The plane table cannot compete with the perspectometer or the perspectograph.

"Another objection is, that points cannot be so easily identified on photographs, nor the forms of the surface

so truly represented, as when the topographer has the ground under his eyes. This is a mistaken idea; there is no difficulty whatever in identifying any number of points on moderately good photographs, and, moreover, the topographer does not need, as with the plane table, to trust to his memory in order to recognize them. The undulations of the ground are, it is true, less distinct on the photographs, but this is more than compensated by the advantage of having, side by side, views of the same place from several stations."

Surveying Cameras.—The number of instruments devised or proposed for photographic surveying is considerable. They are divided into three classes:—

(1) Ordinary cameras.
(2) Surveying cameras or "photogrammeters."
(3) Photo-theodolites.

Ordinary cameras must be provided with a level; the relative positions of the plate and lens must be invariable, and when adjusted, the plate must be exactly vertical.

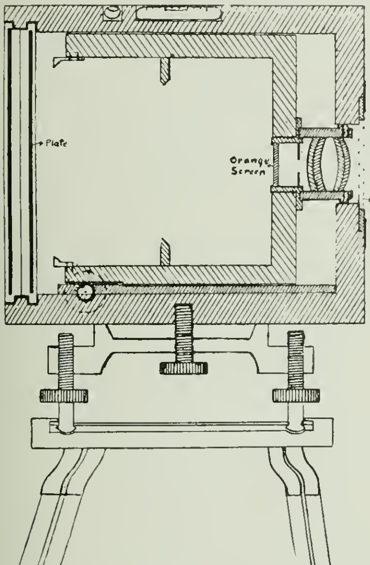

Fig. 1.—Sectional View of the Deville Surveying Camera.

The horizon is determined by two zenith distances of well-defined objects as far apart as possible. The principal points are ascertained from the azimuths of at least three points. It is expedient to make these determinations for every photograph. See specimens of plotting Figs. 2 and 3 (Wheeler).

The employment of ordinary cameras for surveying is not recommended. The present Surveyor-General, Dr. Deville, has invented a camera suitable for this work. A section of this camera is shown in Fig. 1. There are, however, many patterns of surveying cameras, one of the earliest is Meydenbauer's. It is a camera with tapering bellows set on a horizontal circle: it moves on a vertical axis.

Canadian Equipment.—The equipment of a party on the Canadian Surveys consists of a transit theodolite and two cameras. The transit theodolite and its tripod are carried by the surveyor, and a camera without the tripod by one of the men who always accompanies the surveyor. The assistant has his own camera with a tripod.

The transit is one of the ordinary patterns used by surveyors. It has three inch circles and reads to minutes. The tripod is a short one, specially designed for mountain work. It is three feet four inches long and has sliding legs, the joint being perfectly stiff. The surveyor observes

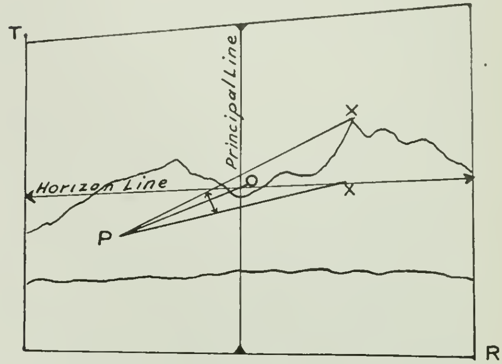

Fig. 2.

either in a sitting or kneeling position. For the purpose of packing, the head of the tripod is taken off and put in the transit box; when folded, the legs are twenty inches long and are placed under the box of the transit, as shown in frontispiece. The heavy parts of the instrument are made of aluminum; the whole, including tripod

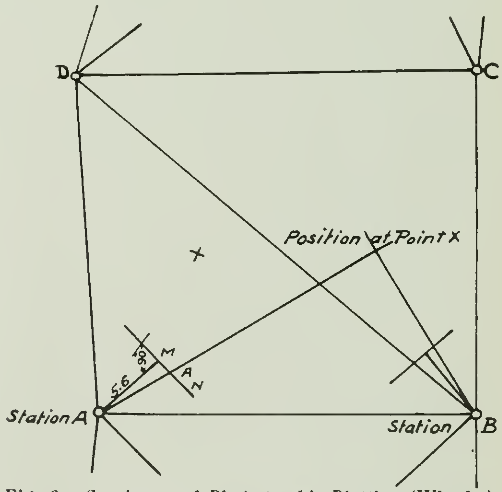

Fig. 3.—Specimens of Photographic Plotting (Wheeler).

and case, and also the camera base, weighs fourteen pounds and eight ounces.

Plotting the Survey.—The minutes of Canadian surveys are plotted on a scale of 1/20,000. They are afterwards reduced for publication to 1/10,000. The equidistance is 100 feet.

The angles measured are equal to those on the ground, for any triangle ABC of the ground is represented on the model by a similar triangle *a b c*. The altazimuth set in *a* gives between *b* and *c* the same angle as it would between B and C, if set at A.

Thus, if the plan be required on a scale of 1/20,000, the model is assumed to have been reduced to that scale, and the problem consists in making a plan full size by means of angles and photographs obtained on the model.

No change being made to the camera, the focal length preserves the same value; if one foot, it covers on the model a distance corresponding to 20,000 ft. on the ground. A distance of a mile contains 5,280 ft. on the ground, and is represented on the model by 5,280 "scale feet."

The focal length of one foot mentioned above would be a focal length of 20,000 "scale feet." It follows that, although the problem consists in representing a model full size, the scale may be employed to measure the actual dimensions, the value of one division being considered as an arbitrary unit.

In plotting, the primary triangulation is assumed to have been previously calculated; the primary stations can therefore be plotted at once by their co-ordinates. For example, the camera station has been observed from one or more triangulation points. A camera station, M, having been observed from a triangulation point A, triangles may be formed with M, A, and other triangulation points observed both from A and M, such as B. In the triangle MAB, the angles at M and A have been observed, and $B = 180^\circ - (A + M)$. Similar calculations made for other triangulation points give the directions of the station as seen from these points; the plotting is done as if the station had been observed from every such point.

From the foregoing it is evident that the surveyor should endeavor to obtain at least one direction from a triangulation point on every camera station; the plotting is less laborious and the result more accurate.

Contour Lines.—A sufficient number of heights having been determined, the contour lines are drawn by estimation between the points established. In a rolling country a limited number of points is sufficient to draw the contour lines with precision, but in a rocky country the reflections on the surface are so abrupt and frequent that it is utterly impossible to plot enough points to represent the surface accurately. Every point, however, plotted has been marked on the photograph, and the altitudes may be taken from the plan.

Precision of the Method of Photographic Surveying.—The precision of a survey executed by the methods exposed, when all the points are established by intersections, is the same as that of a plan plotted with a very good protractor or made with the plane table. There is, however, this difference: the number of points plotted by photography is greater than by the other methods.

Points plotted by means of their altitude below the station are far less accurate, their positions being given by the intersection of the visual ray with the ground plane, the angle of intersection being equal to the angle with the horizon plane or to the angle of depression of the point. With the camera employed, embracing 60°, this angle is always less than 30°; even that is seldom obtained in practice, a declivity of 30° being almost a precipice. Therefore, the intersection is always a poor one and the uncertainty becomes considerable with points near the horizon.

With perspective instruments, doing mechanically the same construction, the results are still less precise, being affected by the instrumental errors.

On the other hand, it must not be forgotten that when these methods are employed, the ordinary topographer would fall back on sketching; the results furnished by topography are therefore indefinitely more precise.

UNITED STATES PRODUCTION OF EXPLOSIVES.

As explosives are essential to mining, and the use of improved types of explosives lessens the dangers of mining, the U.S. Bureau of Mines undertook the compilation of information showing the total amount of explosives manufactured and used in that country, its first report dealing with the year 1912. It now issues the second technical paper relating solely to the production of explosives. It is expected that similar publications will be compiled annually, and that with the co-operation of the manufacturers these statements will be published within a few weeks after the end of each year.

The figures show that in 1902 only 11,300 pounds of permissible explosives was used in coal mining, whereas in 1913 the quantity so used was 21,804,285 pounds. The quantity of permissible explosives used in the United States is larger than in a number of other countries. In 1912 it represented about five per cent. of the total quantity of explosives produced, and in 1913 six per cent. The total amount of explosives used for the production of coal in 1913 was 209,352,938 pounds, of which about ten per cent. was of the permissible class as compared with eight per cent. in 1912. The use of permissible explosives in coal mining has had gratifying results, and few, if any, serious accidents can be attributed directly to their use.

The total production of explosives, according to the figures received from manufacturers, was 463,514,881 pounds in 1913, as compared with 489,393,131 pounds for 1912. This production is segregated as follows: Black powder, 194,146,747 pounds; "high" explosives other than permissible explosives, 241,682,364 pounds; and permissible explosives, 27,685,770 pounds. These figures represent a decrease of 36,146,622 pounds of black powder and an increase of 7,212,872 pounds of high explosives and 3,055,500 pounds of permissible explosives.

NOVEL POWER DEVELOPMENT SCHEME.

A method of producing power from sea water by the rise and fall of the tides is proposed. Portions of the coast where high tides are the rule are chosen and a number of clefts in the cliffs are constructed or those of nature especially adapted. The water runs far into the openings at high tide and by means of pipes is trapped into a huge reservoir. Where the tide falls hundreds of gallons of water are thus left behind. Being on a high level it is then a comparatively simple matter to drop this water by means of pipes to a level many feet below and utilize the power thus obtained by the usual water jets acting on specially constructed wheels.

The latest statistics regarding the development of wireless telegraphy in the German Empire are up to the beginning of 1913. At the beginning of that year there were 23 coast stations and 376 ship stations. Of the coast stations, 12 were open to general traffic, 10 with limitations, and 1 for official use. Of the ship stations, 237 were for public, 134 for official, and 5 for private traffic. The number of wireless telegrams sent from the shore to the ships in 1912 was only 5,312; in the contrary direction, 14,893. Between ships 7,242 telegrams were exchanged. This makes a total traffic in telegrams of 27,447. Receipts for the year totalled 250,000 marks. In these figures the German Protectorates are included.

THE MAKING OF SOUND STEEL INGOTS.*

By Bradley Stoughton, Ph.B.,
Consulting Metallurgical Engineer, New York, N.Y.

THE metallurgist of to-day bears almost the same relation to steel as a doctor does to his patient. Where formerly a simple examination and a small number of tests completed a diagnosis, to-day the physician investigates the physical life history of the patient, together with some matters in the physical life of his parents and grandparents. The metallurgist also is not now content with the condition of the steel as revealed by mechanical and physical test, but wants to be informed as to its life history during manufacture, and as to the quality of pig iron from which it was made and the conditions prevailing during the conversion and during the the manufacture of the pig iron itself.

It is comparatively easy to tell by the usual tests whether the structure and composition of steel attain a given standard or quality, but certain dangerous defects, which may be inherent in the metal, will often escape the customary inspection, and may be difficult to discover even by such extraordinary investigations as sulphur-prints, microscopic examination, hardness tests, shock tests, etc., unless these are carried on at such an extensive scale as to destroy the steel for service. Defects of this character are generally classified under the head of unsoundness, and the chief ones may be described as follows:—

1. Presence of blow-holes;
2. Presence of combined and occluded oxides;
3. Presence of an unwelded shrinkage cavity; and
4. Excessive segregation.

The most effective means of preventing these elements of unsoundness is the exercise of great care and watchfulness during the manufacture of the steel, and also during the manufacture of the iron from which the steel was made, because it now seems to be removed practically beyond controversy that certain unfavorable conditions during the smelting of iron ores in blast furnaces will produce a grade of pig iron which, during the ordinary process of manufacture, will be converted into an unsatisfactory grade of steel. It is not our purpose to discuss this matter at length in this paper, but the literature on cast iron during the years 1913 and 1914 will afford ample proof of the accuracy of this statement. Fortunately, careful and expert inspection of the manufacturing process, and suitable testing of the product, are sufficient to prevent steel of this undesirable quality going into service.

Expert care and inspection during the manufacture and rolling of steel is also the best safeguard for preventing unsound metal from any of the other causes mentioned above going into the service of the consumer. Steel that is dangerously filled with blow-holes, or which is badly segregated, will give some indications of this condition during the ingot-forming or rolling stages. The presence of a residual unwelded shrinkage cavity can usually be prevented by proper inspection during cropping, although this is not an infallible safeguard. Oxide inclosures result from improper conditions of manufacture during the conversion of ingot-forming stages, such as: too late addition of ore to the open-hearth furnace; improper composition of the final open-hearth slag; insufficient fluidity of metal; wildness; excessive or improper addition of deoxidizers in the melt, etc.

The subject of prevention of oxide inclusion has received a good deal of attention from several eminent investigators during the past two years, and a number of remedies have been suggested. The most effective means which has been extensively applied during manufacture is the addition to the liquid bath of steel of properly proportioned quantities of titanium alloy.

Segregation does not occur to a dangerous extent when the phosphorus and sulphur are reduced to reasonable limits, provided the steel is properly deoxidized before teeming; is not wild in the moulds, and is poured in ingots not exceeding 5 to 10 tons each in weight. The larger the ingot, the smaller should be the proportion of sulphur and phosphorus in the steel, and ingots of very massive sections should not be used, unless the central core is to be drilled out and discarded, as is the case in the manufacture of large guns, for example.

The presence of blow-holes is not dangerous in low-carbon steels, except in certain situations, the causes for which are now well understood and can be eliminated. In medium and high carbon steel, the presence of blow-holes will always be indicated by the action of the liquid metal in the moulds, and suitable care in manufacture forbids such material going further in the manufacturing process. The careful steel-maker sends it at once to the scrap pile.

The prevention or elimination of the shrinkage cavity in steel ingots and castings without prohibitive expense, or equally prohibitive complication in manufacture, has taxed to the utmost the ingenuity of metallurgists, and many hundreds of thousands of dollars have been spent in experiments and investigations of numerous schemes and inventions. For many years the compression of the ingot during the process of solidification, in order to reduce the size of its outer envelope and thus compensate for the shrinkage taking place during solidification, has been practised at steel works where steel of the highest quality is made. The expense of this compression process, consisting of interest on investment, complication in the process of manufacture, and cost of operation, is not wholly compensated for by the lesser proportions of the ingot which has to be converted into scrap. The compression during solidification is also claimed to improve the strength of the metal, and this claim, although not granted by all metallurgists, has some practical evidence in its favor.

An English and an American investigator have used the compression process for elimination of the pipe in a way which aims to eliminate interference with the manufacturing process and interest on the investment, by taking the steel ingot before it has completely solidified and reducing its section in an ordinary pair of blooming rolls; then returning it to the heating furnace until entirely solidified, and subsequently completing the rolling operation in the usual way. Other recent investigators have aimed to accomplish a reduction in the cost of treating the steel by substituting some other method for the compression process, but none of these newer inventions secures the elimination of the shrinkage cavity, but only its reduction to a smaller size or a greater concentration at the top of the ingot, with consequent smaller proportion of cropped-off metal being necessitated.

Sir Robert Hadfield burns charcoal on top of the steel ingots in a special mould with a sand top, so as to delay the cooling of this portion of the metal and consequently draw the shrinkage cavity to that point.

*From a paper read before the Mining and Metallurgical Section of the Franklin Institute.

Emil Gathmann, by a very ingenious method of casting ingots with the smaller end down and then stripping them without excessive inconvenience, as well as by distributing the metal in his ingot moulds, also produces a more rapid cooling of the lower parts of the ingot than of the top, and thereby concentrates the cavity in the upper portion.

The Goldschmidt process involves heating the metal in the top of the ingot by the well-known thermit reaction, or else by creating a stirring reaction in the ingot by means of a can of thermit through which, it is claimed, blow-holes, pipes, and segregation are all reduced.

Each of these cavity-reducing processes has been tried on a commercial scale long enough to prove its advantage under a given set of conditions. It is probable, however, that, in the production of very large quantities of steel, cropping off as much of the ingot as is necessary to remove the shrinkage cavity is cheaper than introducing a complication into the process of manufacture, and that careful inspection is an adequate safeguard for avoiding the dangerous defect in finished steel known as an unwelded pipe in the great majority of cases.

FOURTH AMERICAN ROAD CONGRESS.

Final arrangements for the Fourth American Road Congress, to meet in Atlanta, Georgia, during the week of November 9-14, are nearing completion. All indications point to a record-breaking attendance and exceptionally strong program, while the demand for exhibit space on the part of manufacturers will far exceed the supply of space available.

The Construction and Maintenance Section program as now made up is as follows:

Drainage Structures.—By W. F. Atkinson, state highway engineer of Louisiana. Discussion opened by S. D. Foster, chief engineer, State Highway Department of Pennsylvania.

System in Road Management.—By C. J. Bennett, Highway Commissioner of Connecticut. Discussion opened by Paul D. Sargent, state highway engineer of Maine.

Maintenance Methods and Relation to Traffic.—By George W. Cooley, state engineer of Minnesota. Discussion opened by H. R. Carter, state highway engineer of Arkansas.

Convict Labor.—By George P. Coleman, state highway commissioner of Virginia. Discussion opened by J. E. Maloney, state engineer of Colorado.

Rights of Way.—By Austin B. Fletcher, highway engineer of California. Discussion opened by W. S. Gearhart, state engineer of Kansas.

Surfaces for Light Volume Mixed Traffic.—By S. Percy Hooker, state superintendent of highways of New Hampshire. Discussion opened by Frank F. Rogers, state highway commissioner of Michigan.

Efficiency in Highway Organization, Centralization of Purchases.—By E. A. Stevens, state highway commissioner of New Jersey. Discussion opened by John S. Gillespie, Road Commissioner of Allegheny County, Pennsylvania.

State Control of Road Work as a Policy.—By A. N. Johnson, former state highway engineer of Illinois. Discussion opened by T. H. MacDonald, state highway engineer of Iowa.

Engineering Supervision of Road Construction.—By W. S. Keller, state highway engineer of Alabama. Discussion opened by R. C. Terrell, state highway commissioner of Kentucky.

Economics.—By J. E. Pennybacker, chief, Division of Economics, U.S. Office of Public Roads.

Educational Field for Highway Departments.—By Dr. Jos. Hyde Pratt, state geologist of North Carolina. Discussion opened by Col. Sidney Suggs, state highway commissioner of Oklahoma.

Heavy Traffic Roads.—By Henry G. Shirley, chief engineer, State Roads Commission of Maryland. Discussion opened by W. A. Hansell, superintendent of public roads, Fulton County, Georgia.

Grades and Excavation.—By A. D. Williams, chief road engineer of West Virginia. Discussion opened by Wm. R. Roy, state highway commissioner of Washington.

Problems of Street Construction and Maintenance.—By Charles E. Bolling, city engineer, Richmond, Virginia. Discussion opened by F. L. Ford, city engineer, New Haven, Conn.

Road Binders and Palliatives.—By chief engineer, Rhode Island State Roads Commission. Discussion opened by Chas. W. Campbell, city engineer, St. Joseph, Mo.

Possible Lines of Improvement in Contract Highway Work.—By John J. Ryan, secretary, New York State Road Builders' Association. Discussion opened by L. D. Smoot, city engineer, Jacksonville, Florida.

The elaborate exhibit of the U.S. Office of Public Roads, which is being prepared for the Panama-Pacific Exposition, will be shown intact at the Road Congress and will include not only exact models of every known type of road, and the historical development of road building from the earliest times, but will also comprise special models showing road location, the beautifying of the roadside, and mountain road construction as exemplified in the splendid Swiss roads. The New York State exhibit will include at least one example of model work, which it is claimed will prove one of the most impressive exhibits at the Congress. A number of other states will have interesting exhibits in the form of models, maps and materials.

Information about the program and the Congress in general may be obtained from I. S. Pennybacker, Executive Secretary, and concerning exhibits from Charles P. Light, Business Manager, Colorado Building, Washington, D.C. The general officers of the Congress are as follows: Austin B. Fletcher, State Highway Engineer of California, president; Edward M. Bigelow, State Highway Commissioner of Pennsylvania, vice-president; W. E. Atkinson, State Highway Engineer of Louisiana, 2nd vice-president; A. N. Johnson, Former State Highway Engineer of Illinois, 3rd vice-president; C. A. Magrath, Chairman, Ontario, Canada, Highway Commission, 4th vice-president; Lee McClung, treasurer, former treasurer of the United States; John N. Carlisle, State Commissioner of Highways of New York, Chairman, Committee on Program; the Executive Committee comprises in addition to President Fletcher, George C. Diehl, Chairman, Good Roads Board, American Automobile Association; Logan Waller Page, President, American Highway Association and Director, U.S. Office of Public Roads; Richard H. Edmonds, editor of the Manufacturers' Record, and A. G. Batchelder, Chairman, Executive Committee, American Automobile Association.

Editorial

THE TORONTO-OSHAWA ROAD.

The construction of roads and the relief for the unemployed are phrases that accompany each other in the minds of the general public to such an extent nowadays as to be safely ranked as synonymous. From all parts of the Dominion we learn that there is talk of certain highway improvements in order to provide employment for the out-of-works. No doubt as the severity of winter sets in many Canadian towns and cities will regret that their good intentions did not materialize more substantially. It is a fact, nevertheless, that a great deal of time has been spent in promoting such enterprises and in overcoming quibles of one kind and another, that have resulted. It is now over two months, for instance, since the Hamilton-Toronto highway was quoted as being an assured fact and that little remained but to place the laborers at work. No work has been provided, however, and the approach of November is a stern reminder that the season for such work is practically at an end. Insofar as the unemployed are concerned, the municipalities interested can depend but little upon the proposed highway as an immediate work-providing channel, and they must therefore look elsewhere, to remedy the condition of the dinner-pail.

The regrettable delay in the above instance is more or less typical of similar delays elsewhere. It appears that, in the majority of cases the cause for dalliance has been the same—the opposition which some town or city council puts in the way, owing to a small detail or two being apart from its liking. Thomas A. Edison, the inventor, speaking last week at Chatham, Ont., in commenting upon the large numbers of unemployed, strongly endorsed the suggestion of the governmental building of trunk roads through the country. Besides affording employment during the period of industrial paralysis, brought on by the war, the roads thus built would be of inestimable value to the communities through which they would pass. Mr. Edison's advice, we are afraid, has fallen upon already well-informed ears. What the country needs most is a practical working out of a system whereby a proposal of this kind, so undoubtedly of great need in more ways than one, may be got under way before the season for the undertaking is over.

While the Toronto-Hamilton highway scheme is still impaled on the barbs of opposition to technicalities, with evidence of little or no progress this fall, there is an abundance of interest associated with the proposal of a permanent highway east from Toronto to Oshawa. A municipal deputation has been to the government asking for an immediate survey, an estimate of the cost, with a suggested assessment on each municipality. A 16-ft. concrete road with 4-ft. gravel shoulders is mentioned, and an alternative estimate for a macadamized road is asked.

Although the Premier held out no immediate hope, as the present time is fraught by a number of difficulties in the way of raising money, he approved of the scheme on behalf of the government and stated that upon the realization of relief, which is expected early in the shape of a Federal grant for provincial highways, the matter would be proceeded with.

Further, the new Minister of Public Works assured the municipalities that the Department of Highways would make an immediate survey of the route and would shortly provide them with plans and estimates.

DEVELOPMENTS IN ELECTRIC TRACTION.

The entrance of electric power into the domain of the steam locomotive began in the early nineties with small trains in passenger service. Chicago, in 1893, where motor cars were used as electric locomotives, initiated in America the permanent invasion of the extensive steam service on elevated lines.

The earlier applications of electric power to regular steam railway service were in most cases for service in tunnels and railway terminals, with the object of eliminating the smoke and gases common to the use of steam locomotives. The Baltimore & Ohio Tunnel which commenced operation in 1895 was the first instance of electrification as applied to heavy traffic, and the first electric locomotives to successfully initiate the struggle for supremacy with steam locomotives under main line requirements.

"The electrification of main line service," states Mr. W. B. Potter, chief engineer, railway and traction department, General Electric Company, in the General Electric Review, "is no longer an experiment. The heaviest traffic can be successfully handled, and therefore there remains only the question of whether it will pay. As a rule, excepting the expense incident to the initial investment, the cost of operation with electric power will be less than with steam, and often this saving will show a handsome return on the investment. There are many instances, such as tunnels and terminals, where other considerations than the financial showing are of paramount importance. Even in such instances there are often local conditions where the value of property will be enhanced, or where territory necessary to steam service can be made available for other purposes and therefore remunerative.

"The possibility of handling heavier, or even equal trains at higher speeds is becoming better recognized as a means of increasing the tonnage over a given route, and so provide for an increasing traffic more economically than by the construction of additional lines under steam operation."

Electric locomotives for heavy traffic must be so constructed as to withstand the severe shocks and strains which occur in the handling of trains, and to facilitate inspection and maintenance the electrical and other equipment should be conveniently located. Much attention has been given to the development of different general types, and many varieties of electric locomotives differing both in mechanical design and electrical equipment have been built and tested.

Variations in the mechanical construction are influenced largely by different methods of transmitting the power from the electric motor to the driving wheels. The motor car and steam locomotive have both served as models, with innumerable variations in which their characteristics have been differently combined and in many cases with indifferent success. Geared or gearless motors mounted on the driving axle, or in special cases a combination of gearing and parallel rods, each with reference to its fitness for the particular purpose, are the most promising methods of drive. Guiding trucks will undoubtedly be used in high-speed service and doubtless at slower speeds with very heavy locomotives where the weight distribution on the track may be of importance.

The character of electrical equipment, considering the larger power required in main line service, is influenced by the problem of electric transmission to the locomotive and the collection of current from the conduction circuit. As the amount of current varies inversely as the voltage, the transmission and collection are therefore made easier at higher potentials. The development of equipment suitable for higher voltages has received much attention, and there are at present a number of important railway electrifications of this character on which alternating or direct current is used. The respective merits of alternating or direct current involve many details of which a very few are of general interest as influencing the trend of commercial development. As between the different systems the indications point strongly, however, toward the more general adoption of direct current for main line electrification and heavy railway service generally.

STANDARDS FOR THE TURBIDITY OF WATER.

In a paper read before the Illinois Waterworks Association by Francis D. West, chemist in charge of the Torresdale Laboratory, Philadelphia Bureau of Water, the author, in commenting upon the preparation of turbidity standards, regards the principle of correcting a standard determined by weight by the use of a field method as most unsatisfactory. No two laboratories nor any two persons in the same laboratory working independently in the preparation of silica standards, following the procedure outlined, will make standards exactly alike.

A field method is never accurate and the description of what is "An observation in the middle of the day, in the open air, but not in the sunlight, etc.," is a source of many possible interpretations. The amount of light, the size, shape and color of the vessel, the fineness of the material, to say nothing of the personal equation, all influence the results.

What is needed is a definite procedure by which standards can be duplicated from time to time by different chemists without variation.

Such a method has been in use in the laboratories of this bureau since 1901. It involves the use of diatomaceous earth, prepared as follows:

"Wash with water to remove soluble salts; dry and ignite to remove organic matter; treat and warm with dilute hydrochloric acid; wash until free from acid and dry thoroughly. Grind in agate mortar, sifting through 200 mesh sieve and dry in desiccator."

Take a weighed amount of finely ground material, about two grains, suspend in 500 c.c. of distilled water, shaking vigorously from time to time for two or three hours. Suspend for ten hours, decant supernatent liquid. Dry and weigh residue. The difference equals the amount in suspension. Dilute to standard and use as stock.

I have found that standards made in this way from different stocks do not differ perceptibly. All material that remains suspended for ten hours appears to be of the same degree of fineness.

We add a small amount of a saturated solution of mercuric chloride and make standards as follows: Use quart bottles of a high grade of white glass free from air bubbles. The standards are 0, 0.5, 1, 2, 3, 4, 5, 7, 9, 11, 14, 17, 20, 23, 26 parts per million silica. For readings above 26, we use a special nessler jar with a ground glass stopper. We seal these standards. The 100 c.c. standards are 26, 32, 38, 44, 50, 65, 80, 95, 120, 150, 180. For turbidities above 180, dilutions are made with clear water.

During 1913, we made over 24,000 tests with these standards. We have standards made in 1907 still in use. These have been checked from time to time and have not been found to change. We would not recommend using standards over six months without checking.

This method, while it is ideal for the preparation of standards which can always be duplicated, involves considerable labor in the preparation of the diatomaceous earth. The introduction of Fuller's earth seems to be a step in the right direction. I believe this was first brought out by Dr. E. C. Levy, of Richmond, Va., in a paper before the Laboratory Section of the American Public Health Association, although in the report for 1912, he is not given credit for it. The idea, of course, is to do away with the tedious grinding and to obtain a standard which resembles more closely the turbidity of water caused by clay.

Working, then, with two objects in view, of having a definite weight and a definite degree of fineness (obtained by suspension for a definite period) we have experimented with Fuller's earth and have prepared standards which check exactly with our standards made with diatomaceous earth. Our method follows:

If a 200 mesh sieve is not obtainable take about 20 grams of Fuller's earth; if a sieve can be obtained, take about 5 grams of the sifted material (weighing is not necessary). Place in a gallon bottle and add about a quart of distilled water, shake thoroughly, as above, and suspend for ten hours. Decant and determine the weight of the material remaining in suspension by filtering 100-200 c.c. through a weighed Gooch crucible. Dry and weigh.

It will probably be necessary to coagulate the material by the use of a known weight of hydrate of alumina or a solution of alum. In this latter case, the water should be alkaline to precipitate the alum.

The total weight will be the weight of the material in solution plus the weight of the hydrate of alumina.

We know then the degree of fineness as we have suspended for a definite period and we have a known weight. From this suspension we can make our stock for use in preparing our standards.

I do not know just how long the standards will keep, as the period elapsing since their preparation is relatively short compared with our other standards, but in any case it is a simple matter to prepare new ones.

PROGRESS ON HARLEM RIVER TUNNEL.

The sinking of the fifth and last section of the tunnel under the Harlem River, New York City, which is to be a part of the Lexington Avenue subway, has been completed. The tunnel is being built by submerging massive sections of steel tubes which, when connected in position, will be surrounded by concrete and form the bore of the completed tunnel. The procedure is similar to that followed in building the Michigan Central tunnel under the Detroit River at Detroit. The final section, now placed in position, is 250 ft. long. The other four sections are 220 ft. long. The sections are constructed on dry land, and the whole structure is floated into the river by its own bouyancy. Water is then let into the tubes, which are gradually sunk into place, two large floats being used to support the tubes as they are being lowered.

ENGINEERS' LIBRARY

Any book reviewed in these columns may be obtained through the Book Department of The Canadian Engineer.

CONTENTS.

BOOK REVIEWS.

Modern Tunneling, With Special Reference to Mine and Water Supply Tunnels. By David W. Brunton and John A. Davis. Published by John Wiley & Sons, New York; Canadian selling agents, Renouf Publishing Co., Montreal. First edition, 1914. 450 pp.; 80 illustrations; 6 x 9 ins.; cloth. Price, $3.50 net.

This book will be found of exceeding value by those who have been on the lookout for practical information concerning tunneling methods, particularly in the United States. It is confined chiefly to problems of tunneling for drainage, transportation or development, but it also includes those for water power, irrigation or domestic purposes, in which the essential features are very like those of mine tunnels. It should be stated that the book pertains almost entirely to excavation in solid rock and does not refer to soft ground, subaqueous or railroad tunneling.

Following the introduction are chapters on history of tunneling; modern mining and water tunnels; choice of power for tunnel work; air compressors; ventilation; surface equipment; rock-drilling machines; haulage; incidental underground equipment; drilling methods; blasting; methods of mucking; timbering; safety; cost of tunnel work; bibliography. The authors devote little space to the history of tunneling or to old-time methods. They enter at once upon the work of presenting up-to-date information, such as is desired by tunnel engineers who generally feel that up-to-date methods and equipment that are proving safe, efficient and economical are not as widely known as they should be.

Of great interest are the chapters devoted to a discussion of the various types of machinery, plant methods, etc. The advantages and disadvantages of many different varieties of equipment are voiced; tables are presented and the whole treated in such an exhaustive and complete manner as to leave little to be desired on the part of the reader. A chapter on "safety" supplies a very needful part of a book on this subject. The authors have treated it in a practical way that should meet with approval. The chapter on cost of tunnel work gives some excellent data covering the more important tunnels of the United States. This data has already appeared in *The Canadian Engineer* (issues of Sept. 24, Oct. 1, and Oct. 8, 1914). It had been previously collected by the authors for the U.S. Bureau of Mines. (It is in justice to the Bureau to state that the material in the book under discussion is very considerably the same matter as had already appeared in Bulletin No. 57 of the U.S. Bureau of Mines, under the same title, written, of course, by the same engineers.) The bibliography occupies 60 pages, although it has been "selected," as stated by the authors.

The Science and Practice of Management. By A. Hamilton Church. Published by the Engineering Magazine Co., New York. First edition, 1914. 535 pp.; illustrated; 5 x 7 in.; cloth. Price, $2.00.

For one who is searching for a scientific treatment of the fundamental principles and elements underlying scientific management, this volume will be found to go a long way toward analyzing and classifying the existing forms with which they are more or less familiar. The author has endeavored, according to his introductory notes, to ascertain the fundamental facts of production, not from the viewpoint of cost but from the viewpoint of management. One is accordingly impressed with his success in formulating such fundamental facts and regulative principles as may be hereafter developed into a true science of management.

The first part of the volume has to do with the science of management and Part II. with practical organization of the organic function. There are five appendices dealing with the labor question; the expense burden in relation to piecework and premium; the same in relation to bonus; the planning department; some axioms of administrations.

The reader will find the author's classification one by which the information on the subject of management may be scientifically analyzed, properly grouped and, as a result, made more useful.

Strength of Materials. By H. E. Murdock, M.E., C.E. Published by John Wiley & Sons., Inc., New York; Canadian selling agents, Renouf Publishing Co., Montreal. Second edition, 1914. 352 pp; numerous illustrations; 5 x 7 in.; cloth. Price, $2.00 net.

The first edition of this book was reviewed in *The Canadian Engineer* for Nov. 30, 1911. It is essentially a book for engineering students and has been written with the aim of making intelligible the fundamental principles of the strength of materials without the aid of the calculus. The book is replete with illustrated examples and problems. The subject is proceeded with in the following way: Materials of construction; direct stresses and applications of them; riveted joints; beams, external flexural forces and internal flexural stresses; stresses in such structures as chimneys, dams, walls and piers; graphic integration; deflection of beams; elastic curve; same determined by the algebraic method; secondary stresses; columns and struts; torsion; repeated stresses resilience, hysteresis impact; reinforced concrete beams;

reinforced concrete columns; centroids and moments of inertia of areas, (the latter as an appendix). The book concludes with numerous tables usually found in works on this subject.

Hydraulics. By Louis A. Martin, Jr., Professor of Mechanics, Stevens Institute of Technology. Published by John Wiley & Sons, Inc., New York City; Canadian selling agents, Renouf Publishing Co., Montreal, P.Q. First edition, 1914. 223+12 pages; 114 illustrations; size, 5 x 7½ in.; cloth. Price, $1.50 net.

This work appears as Volume 5, of a set of books by the same author, devoted to mechanics. The previous volumes cover statics; kinematics and kinetics; mechanics of materials; applied statics. In his preface the author states that he has sought to produce a text book which will encourage the student to think and not to memorize, to do and not simply to accept something already done for him. The fundamental principles underlying hydraulics are systematically developed and arranged, with special attention to those underlying the theory and design of impulse wheels and turbines.

The first part of the book is devoted to liquids at rest, and takes up the pressure and the force exerted by a liquid, applications, and floating bodies. Liquids in motion are dealt with in the remaining nine chapters of the book, the work being arranged as follows: The free surface of liquids moving with acceleration; the flow of liquids; flow through orifices, weirs and pipes; force exerted by moving liquids; axial-flow and radial-flow impulse water wheels; turbines.

A feature to be admired in the work is the care that has been given to the selection of exercises and examples. There is an abundance of material in this section of the book to make it of absorbing interest to the student.

Concrete Roads and Pavements. By E. S. Hanson. Published by the Cement Era Publishing Co., Chicago. Revised edition, 1914. 338 pp.; 5 x 7½ in.; illustrated; bound in cloth. Price, $1.50. The first edition of this book was reviewed in *The Canadian Engineer* for August 28, 1914.

The present volume shows one-third increase in size by the addition of seven chapters. The author has made many revisions in the older portion of the work, bringing it up-to-date in every detail. The introduction of new subjects, such as how to promote the construction of concrete roads; the economic methods of handling materials; experimental work, etc., give the book a tone of usefulness that will enhance its value considerably to the road engineer. Other subjects which were treated only briefly in the first edition of the book have been expanded into full chapters. Some new matter has been added to Chapter I., showing the advantages of concrete as a road material, and after this is a chapter discussing the various types of concrete roadways. Following this, the various steps in the construction of concrete roads and pavements are taken up in separate chapters, these covering the preparation of the sub-grade, the selection of materials, economic methods of handling materials, mixing and placing the concrete, finishing and curing. The chapter on joints has been brought fully down to date, while the chapters descriptive of work done in various localities have been considerably augmented by the addition of descriptions of recent work accomplished.

To the appendices appearing in the first edition there has been added the specifications of the American Concrete Institute. The list of specifications now includes, in addition to the above, specifications for Wayne County, Mason City, Illinois Highway Commission, Blome Granitoid and Granocrete pavements, Bitustone, Dolarway, Hassamite, Vibrolithic, bridges and culverts, sidewalks, curb and gutter.

The expansion of the book is well worth the notice, even of those already familiar with the first edition.

The Calculus. By John Graham, B.A., B.E. Published by E. and F. N. Spon, Limited, 57 Haymarket, S.W. Fourth edition. Cloth; 5 x 7 in.; 355 pages; 116 illustrations. Price, $1.25 net.

This volume is an elementary treatise on the calculus for engineering students. It covers the differential and integral calculus and the solution of differential equations. The book is very complete with numerous examples and problems worked out.

Hydraulics. By W. M. Wallace, Wh.Sc. Published by the Technical Publishing Company, Limited, 55 Chancery Lane, London, W.C. Cloth; 5 x 7 ins.; 276 pages. Price, $1.00 net.

This little volume is intended to supply the wants of the practical engineer and the student. In the first two chapters, hydrostatic principles and hydraulic machines are dealt with; the flow of water in pipes and through orifices is covered in Chapters III. and IV. Chapter V. deals with the impact of water on surfaces; Chapter VI. with centrifugal head, while Chapters VII., VIII. and IX. deal with the water turbine, the centrifugal pump and the turbine pump. The titles of the other chapters are: Chapter X., Loss of Energy Due to Shock; Chapter XI., Pumps; Chapter XII., Measuring the Flow of Water; Chapter XIII., Channel Fow; Chapter XIV., Fluid Friction; Chapter XV., Vibration and Rolling; Chapter XVI., Hydraulic Problems. This is a valuable little reference book for the engineer in practice, and a good text book for the student.

Hand Book of Construction Plant: Its Cost and Efficiency. By Richard T. Dana, M.Am.Soc.C.E. Published by Myron C. Clark Publishing Company, Chicago. 702 pp.; numerous illustrations; size, 4½ x 7 ins.; limp leather. First edition. Price, $5.00 net.

The object of this book is to furnish contractors with information in ready reference form concerning the cost, capacity, operating expenses and adaptability of equipment most generally required. Much well-arranged information is given that is invaluable to an inexperienced contractor, and that would undoubtedly be of considerable interest even to a man of broad experience. The book is especially useful to a contractor who has kept but little cost data or who is not in close touch with the costs, merits and sources of supply of equipment.

The usefulness of the volume to Canadian contractors, however, is hampered by the fact that only United States, and no English or Canadian equipment, is discussed, and the lists given of prices, makes and kinds cover only United States firms. While a vast amount of excellent equipment is bought in the United States every year by Canadian contractors, it is obvious that no Canadian contractor could afford to make any purchase without giving due consideration to the competitive merits and prices of Canadian and English goods. The book is not simply compiled from the Canadian standpoint, but will no doubt meet with a very good sale in the field which it is intended to cover.

PUBLICATIONS RECEIVED.

Philadelphia Public Works.—Annual Report (1913) of the Director, Department of Public Works, city of Philadelphia.

Timber and Soil Conditions of Southern Manitoba.—By L. G. Tilt, B.Sc.F., Forestry Branch, Department of the Interior, Canada. 36 pp.; illustrated.

Kewagama Lake Map-Area, Quebec.—By M. E. Wilson, Memoir 39, Geological Survey, Department of Canada. 140 pp.; numerous plates and illustrations.

Magnetic Occurrences near Calabogie, Renfrew County, Ontario.—By E. Lindeman, Mines Branch, Department of Mines, Ottawa, describing location, history, geology, ore deposits, etc.

Farmer as a Manufacturer.—By A. T. Stuart, B.A., assistant chemist, Department of Agriculture, Experimental Farms. An outline of some basic principles in agricultural chemistry. 16 pp.; 6 x 9 in.

Pollution of Des Plaines River.—Report of the sanitary district of Chicago. 55 pp.; 6 x 9 in.; illustrated. It outlines investigations of conditions along the river in new territory annexed by the city in 1913.

Moose Mountain Iron-Bearing District, Ontario.—By E. Lindeman, Mines Branch, Department of Mines. 32 pp., describing location, general historical and geological features, character of ore and commercial possibilities.

The Archæan Geology of Rainy Lake Restudied.—By A. C. Lawson, Geological Survey, Department of Mines. Published as Memoir 40. 115 pp.; 6 x 9 in.; plates and illustrations. A report upon investigations in Northwestern Ontario in 1911.

Gold Fields of Nova Scotia.—By W. Malcolm, Geological Survey Branch, Department of Mines. 330 pp.; 52 plates, 24 figures and 2 maps. It is a compilation of data, the result of field investigations and studies of Mr. E. R. Faribault.

Resuscitation from Mine Gases.—Technical Paper No. 77, United States Bureau of Mines, report of committee. 36 pp.; illustrated. It outlines manual and mechanical methods of artificial respiration, experiments with commercial devices, etc.

The Humidity of Mine Air, with special reference to coal mines in Illinois. By R. Y. Williams, United States Bureau of Mines (Bulletin 83). It is devoted to a resume of mine humidity investigations, methods of humidification, conclusions and suggestions.

A Study of the Oxidization of Coal.—By H. C. Porter and O. C. Ralston, United States Bureau of Mines. 30 pp.; 6 x 9 in. Rate of oxidization of different coals compared and factors affecting described. Experiments to determine nature of oxidization reactions outlined.

Valuation of Ohio Public Utilities.—Report of a joint committee of the Public Utilities Commission. 42 pp.; 6 x 9 in.; price, 50 cents. It outlines the committee's formulation of principles as applied to "Reproductive cost new, less depreciation," method of valuing public utilities.

Topographical Surveys Branch.—Annual report for 1913 of this Branch, Department of the Interior, Ottawa. 226 pp.; 6 x 9 in.; 17 maps and profiles; numerous illustrations. It contains the report of the Surveyor-General, various schedules, lists and statements, and the reports of surveyors.

Timber Conditions in Alberta.—A report on the timber conditions of Little Smoky River Valley and adjacent territory. By J. A. Doucet, Forestry Branch, Department of the Interior. 52 pp.; illustrated. It outlines general conditions, report on the country by blocks, fire protection, and the proposed forest reserve.

Telephone Systems.—The Ontario Telephone Act and Amendment thereto. Extract from report of Ontario Railway and Municipal Board for 1913. Specifications for construction of telephone systems. Forms of petition, by-laws, etc. 60 pp. Copies on application to the Ontario Railway and Municipal Board, Legislative Buildings, Toronto.

The Double-Curve Motive in Northeastern Algonkian Art.—By Frank G. Speck, Geological Survey, Department of Mines, Ottawa. It contains very interesting information respecting the occurrences of the motive among the tribes south and north of the St. Lawrence and in adjacent areas westward. There are 18 plates and 25 figures of note.

Forests, Waterways and Water-Powers.—Report of the select standing committee, Ontario Legislature. 28 pp.; 6 x 9 in. The committee's report has appended to it: (1) Conservation of natural resources in British Columbia (7 pages); Sir Richard McBride. (2) Work of the Provincial Forestry Department in British Columbia (11 pages); H. R. McMillan.

Irrigation.—Annual report for the year 1913 of the Department of the Interior. 172 pp.; numerous illustrations. It contains reports on the districts of Calgary and Maple Creek; on special inspection; on the South Saskatchewan and St. Mary River diversion projects; stream measurements; Bow River flood discharge and floods in the North Saskatchewan drainage basin.

Thermal Properties of Steam.—By G. A. Goodenough. Bulletin No. 75, Engineering Experiment Station, University of Illinois, Urbana, Ill. 69 pp.; 6 x 9 in.; illustrated. It presents a critical discussion of the experimental investigations, an outline of the thermodynamic relations that must be satisfied, and the development of a general theory of superheated and saturated steam.

Lode Mining in Yukon.—An investigation of quartz deposits in the Klondike Division, by T. A. MacLean, M.E., Mines Branch, Department of Mines, Canada. 222 pp., with 6 maps, 36 sketches and 40 photographs; size, 6 x 9 in. The report deals with the quartz deposits in the mining districts of Duncal Creek, Conrad and Dawson, with a view to describing their gold contents and reporting upon their economic value.

Water Measurement in Open Channels.—A description by C. R. Weidner, C.E., of the diaphragm method for the measurement of water in open channels of uniform cross-section. Issued as Bulletin No. 672 of the Engineering Experiment Station, University of Wisconsin, Madison, Wis.; price, 25 cents. 72 pp.; size, 6 x 9 in.; 6 plates; 30 figures. Describes the apparatus in various European stations, giving results of tests, etc.

Port Directory of the Principal Canadian Ports and Harbors, 1913-14.—Department of Marine and Fisheries, Ottawa. 305 pp.; fully illustrated; 6 x 9 in.; bound in cloth. The volume contains, in addition to the above, data respecting a large number of minor ports, wharves, depth of water, facilities for loading, etc.; also descriptions of types of aids to navigation in Canadian coastal and inland waters, navigable distances of many rivers in the north-west of Canada, and general information for mariners.

The Copper Smelting Industries of Canada.—By A. W. G. Wilson, Ph.D., chief of the Metal Mines Division, Department of Mines, Canada. 184 pp.; 6 x 9 in.; 43 plates, 4 maps and 39 illustrations. The report takes up the various smelters by provinces in Chapter 1. Following it are chapters devoted to the Canadian Copper Co., the Mond Nickel Co., Limited, the Consolidated Mining and Smelting Co. of Canada, Limited, Granby Consolidated Mining, Smelting and Power Co., British Columbia Copper Co., Tyee Copper Co., miscellaneous summaries and statistics of copper production.

CATALOGUES RECEIVED.

The World's Greatest Asphalt Plant.—The Barber Asphalt Paving Co., Philadelphia, issues a 16-page illustrated description of their plant at Maurer, N.J.

Tubular Steel Tripods.—A leaflet describing the Morris folding tubular steel tripod, issued by the Herbert Morris Crane and Hoist Co., Limited, Toronto.

Jeffrey Limestone Pulverizer.—Bulletin No. 132, of the Jeffrey Manufacturing Co., Columbus, Ohio. Describes the swing hammer pulverizer, type "D," with diagrams. 8 pp.

Synchronous Converters.—Bulletin issued by the Canadian General Electric Co., listing the ratings of standard lines of converters for various frequencies, voltages and capacities.

Morris Hand Overhead Travelling Crane.—A 4-page leaflet, issued by the Herbert Morris Crane and Hoist Co., describing a new type designed to run on the lower flange of two parallel I-beams.

Sprague Electric Monorail Cranes.—48 pp.; fully illustrated, describing the function and various types and capacities of these cranes. Issued by the Canadian General Electric Co., Limited, Toronto.

Speed Regulation.—A 4-page leaflet describing a new invention called the Douglas Speed Regulator, of interest to engineers and manufacturers. Issued by J. A. Douglas, 626 McMillan Avenue, Winnipeg, Man.

Westinghouse Turbo-Alternators.—A 40-page profusely illustrated description of various types. It traces the development of the steam turbine, of reaction and impulse turbines, and of variations in modern designs.

Temperature Control Apparatus.—A booklet descriptive of the Grundy System of automatic temperature control. Also information about heating and ventilating by electricity. Issued by A. Schonfield and Co., Glasgow.

Lackawanna Plate Sheet Piling.—Bulletin No. 107, outlining a new section just brought out by the Lackawanna Steel Co., for whom H. A. Drury Co., Limited, Montreal, are Canadian representatives. 4 pp.; illustrated.

Heavy Traffic Centres.—A descriptive publication of the Westinghouse Electric and Manufacturing Co., giving a number of interesting and instructive illustrations showing operating conditions in many large traffic centres.

Electrical Equipment for Oil Wells.—A 24-page bulletin, well illustrated and containing some instructive information on the use of electrical apparatus in the oil fields. Issued by Canadian General Electric Co., Limited, Toronto.

Drawing Tables, etc.—A 48-page catalogue, issued by Economy Drawing Table Co., Toledo, Ohio. Drawing tables, filing cases and specials for engineers, architects, contractors, manufacturers, schools, etc., are described.

Piston Rings.—A small 8-page booklet, published by the Burd High Compression Ring Co., Rockford, Ill. Reprinting an article by H. S. Whiting on "How the Efficiency of a Motor Car is Dependent upon Gas-Tight Ring Joints."

Steam Engines for Direct Connection to Electric Generators.—16 pages, describing the Chandler and Taylor engines, simple, tandem and cross compound. Issued by Canadian Allis-Chalmers, Limited, Toronto, agents for Canada.

Train Operation.—A collection of illustrations, with brief notes, showing some of the advantages of multiple-unit trains for city, suburban and interurban service. 16 pp.; 8½ x 11 in.; illustrated. Issued by the Westinghouse Electric and Manufacturing Co., East Pittsburgh.

Despatchers' Selective Signalling System.—A leaflet from the general railway signal company, Rochester, N.Y., describing a new system by means of which the despatcher can control train-order signals and take-siding signals located at various stations, and determine the indication displayed by each.

Horsfall Destructors.—A 50-page catalogue, issued by the New Destructor Co., Limited, Pershore, England, describing the features of this type of destructor and a number of the plants now in operation. Other equipment for destructor plants, such as crushing and screening plant, tin-baling machines, etc.

Marshall Traction Engines and Road Rollers.—A fully illustrated 44-page catalogue, issued by Marshall, Sons and Co., Limited, Gainsborough, England (Canadian office, Saskatoon, Sask.) It describes different sizes of traction engines and road locomotives, single and compound; road rollers, scarifiers, trailer wagons, etc.

MILITARY PROMOTION FOR C. H. MITCHELL, C.E.

Word has been received from the military authorities at Ottawa of the appointment of Major Charles H. Mitchell, of Toronto, to the important position of General Staff Officer on the Headquarters Staff of the First Contingent, and also of his promotion to the rank of Lieut.-Colonel. This appointment is one of the highest given to any militia officer in Canada. Lieut.-Colonel Mitchell is deserving of this distinction, and military men in Toronto assert that he is perhaps the best qualified Canadian officer for the position.

Lieut.-Colonel Mitchell is perhaps better known generally throughout the Dominion as "C. H. Mitchell, C.E.," of the firm of C. H. and P. H. Mitchell, Consulting Engineers, Toronto. His experience in engineering has been wide, but his activities have been chiefly in hydro-electric and hydraulic work. For the past four years he has been consulting engineer for the Dominion Government on water-power matters, particularly in Western Canada.

Lieut.-Colonel Mitchell is a member of the Board of Governors of the University of Toronto, from which university he graduated in 1892. He has also taken an active part in the advancement and improvement of the city of Toronto, and for many years has been on the Executive of the Toronto Civic Guild, of which organization he is now the President.

ST. JOHN VALLEY RAILWAY, N.B.

The Canadian Pacific and the Intercolonial have patched up their differences relative to facilities for entering the St. John Valley Railway into Fredericton. The railway will enter from the south by double-tracking the C.P.R. from Victoria Mills to the Intercolonial "Y"; thence by their own tracks. The Quebec and St. John Construction Co. may do their own double-tracking on this work or may sub-let it. As soon as this connection has been completed operation of the Valley Railway will be commenced between Frederiction and Gagetown.

It is stated in a recent communication from Fairville, N.S., that the installation of a 12-inch water main along the Sand Cove Road has been completed as far as the Fairville pl teau; that concrete sidewalk has been completed for some distance out the Manawagonish Road; and that progress on the new Government bridge over the Reversible Falls is favorable. Of the bridge construction, the granite piers which are being erected on the east side have been completed. The trestle which was built from the C.P.R. track and crosses the road overhead has been finished and the crane for hoisting the steel into position has been placed on the cliff overlooking the falls, the steel construction now being in progress.

Coast to Coast

London, Ont.—The proposed new municipal sewage disposal plant for the east end of the city has been under consideration last week and a number of suitable sites inspected.

Hamilton, Ont.—A start was made last week on the concrete foundation of the first building of the new plant of the Proctor-Gamble Co. and excavation is progressing for the other buildings. About 150 men are at work and the contractors are rushing things before cold weather sets in.

Amherst, N.S.—The Canada Car and Foundry Co. have a large number of cars of various types under construction in the passenger department. For the past few months from 350 to 500 men have been employed, and it is probable that this number will be increased from time to time during the winter.

Hamilton, Ont.—Hamilton authorities, thinking the expenditure of $328,000 for a bridge, 1,600 ft. in length, in connection with the Toronto-Hamilton highway, to be too great, have asked the Hamilton Bridge Works for plans and estimates of a bridge about 1,000 ft. in length. The purpose of this bridge is to do away completely with the Valley Inn Hill.

Moose Jaw, Sask.—Mr. Geo. D. Mackie, engineer-commissioner, owing to the shortage of the Caron water supply, due to exceptionally dry weather having reduced the flow from the infiltration galleries, recommends the use of Snowdy Springs water, which will require the use of a filter to be installed at South Hill. If the scheme is carried out it will provide the city with an additional supply of 200,000 gallons.

Kirkland Lake, Ont.—During the past week two new plants have been started in the Kirkland Lake section of Northern Ontario. At the Lake Shore Gold Mines a 3-drill air-compressor has just been installed and operations have commenced on a shaft, already sunk by hand-drill to a depth of 40 ft. A station will be established and drifting started at the 100-ft. level. The other plant is that of the Kirkland Lake Gold Fields, and will operate five drills. It is run by two boilers of 110 h.p. Sinking has been started and will be carried to 100 ft. on the continuation of the Teck-Hughes main vein, picked up some months ago on the McKane property (worked by the company) under heavy overburden.

Summerside, P.E.I.—In addition to completing that portion of the 1913 programme of steel and concrete bridge construction which had to be left unfinished, the provincial department of public works has built a number of other bridges this year. Of last year's work the most important is the big bridge over the Cardigan River. This structure comprises two steel spans of 280 feet in length, clear of the approaches. The bridge has a concrete roadway and a 4-foot sidewalk, the width of the bridgeway being about 16 feet. This bridge was commenced last fall, and at present the entire superstructure, including the concrete roadway, has been completed; while the construction of the approaches is now under way. It is expected that it will be opened for traffic in the course of another month. A concrete culvert bridge was also erected near Cardigan this year. At Wigginton's a 35-foot steel bridge has been erected in the place of the previously existing wooden one. Fortune bridge of two 120-foot steel spans has been completed, this permanent structure also replacing a wooden bridge. A Mink River, a 100-foot steel span bridge has been erected; near Crapaud another 35-foot steel bridge; while one with 25-foot steel spans is in course of erection at Ahearn's, Tignish.

PERSONAL.

A. T. ENLOW, sales manager of the Pedlar People, Limited, Oshawa, Ont., has resigned.

A. I. DAVIS, B.A.Sc., has been appointed mining engineer for the United States Gypsum Co. at Fort Dodge, Iowa. Mr. Davis is a graduate in mining of the University of Toronto.

W. N. ASHPLANT, city engineer of London, Ont., has applied for service in the second Canadian contingent. Mr. Ashplant is a South African veteran and a lieutenant in the 17th Fusiliers, London.

GEO. W. COBURN, district engineer for the Canadian Pacific Railway Co. at Souris, Man., has been transferred to Brandon, Man., where he will serve in the same capacity. Mr. Coburn has been with the C.P.R. since 1896.

Prof. GEO. A. GUESS, of the Department of Metallurgy, University of Toronto, is at present in Anyox, B.C., where he has been engaged for a short time in a consulting capacity by the Granby Co. in connection with their new smelter.

E. MAERKER, A.Sc., of Toronto, has accepted a position with the Winnipeg River Power Co., at Winnipeg, and assumes his duties next week. Mr. Maerker was previously designing engineer with the Toronto Power Co. on high-tension transmission work.

Hon. T. CHASE CASGRAIN, K.C., chairman of the Canadian section of the International Joint Commission, has been appointed Postmaster-General for Canada. His successor on the Commission will likely be appointed forthwith, as the Commission meets in Detroit on November 10th.

F. N. SMITH, resident engineer of construction, Canadian Northern Pacific Railway, Henningsville, B.C., and D. R. WEBER, assistant superintendent, Grant Smith and Co. and McDonnell, Limited, Revelstoke, B.C., have recently attained associate membership in the American Society of Civil Engineers.

OBITUARY.

Hon. COLIN H. CAMPBELL, formerly Minister of Public Works for the Province of Manitoba, died at his home in Winnipeg on October 24th after an illness of about 2 years.

TORONTO BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

On Wednesday, Oct. 28th, the Toronto Branch of the Canadian Society of Civil Engineers met at the Engineers' Club to hear an address on "Naval Architecture," delivered by Prof. J. R. Cockburn, of the University of Toronto. The meeting was largely attended. Mr. Cockburn also illustrated by a number of slides the various types of vessels employed by the British Admiralty.

On Saturday, Oct. 31st, members of the Branch, accompanied by members of the University of Toronto Engineering Society, will take a trip over the new Welland Ship Canal work. Sections 1, 2 and 3 present many important and instructive engineering features that will be of special interest to the visitors, who will be shown over the work by Mr. J. L. Weller, chief engineer of the canal, and his engineering staff.

In order to see all the work under construction open street cars will be hauled over the track on the west bank of the canal. Arrangements also provide for inspecting the harbor work at Port Weller. Luncheon will be served in one of the construction camps. In the evening the ladies of St. Catharines will provide a dinner, the proceeds of which will go to the Patriotic Fund.

The library committee of the Branch has announced the addition since the last annual meeting of a considerable number of valuable series of transactions, proceedings, journals and reports as well as some 80 engineering treatises and text books. These new books comprise the most recent works on bridge engineering, cement and concrete, ceramics, chemical engineering, electrical engineering, foundations, heating and ventilating, highway engineering, hydraulics, mechanical engineering, metallurgy, railway engineering, sanitary engineering, steam engineering, structural engineering and water supplies. The usefulness of the periodic literature in the library has also been considerably increased. The committee consists of Messrs. W. A. Hare, A. L. Mudge and Prof. C. R. Young, chairman.

HIGHWAY STUDY AT COLUMBIA.

The non-resident lecturers in the graduate course in Highway Engineering at Columbia University appointed for the 1914-1915 session are as follows: John A. Bensel, New York State Engineer; Edward D. Boyer, Cement and Concrete Expert, the Atlas Portland Cement Company; Sumner R. Church, Manager, Research Department, Barrett Manufacturing Company; William H. Connell, Chief, Bureau of Highways and Street Cleaning, Philadelphia; W. W. Crosby, Chief Engineer, Maryland Geological and Economic Survey, and Consulting Engineer; Charles Henry Davis, President, National Highways Association; Arthur W. Dean, Chief Engineer, Massachusetts Highway Commission; John H. Delaney, Commissioner, New York State Department of Efficiency and Economy; A. W. Dow, Chemical and Consulting Paving Engineer; H. W. Durham, Chief Engineer of Highways, Borough of Manhattan, New York; C. N. Forrest, Chief Chemist, Barber Asphalt Paving Company; Walter H. Fulweiler, Chief Chemist, United Gas Improvement Company; D. L. Hough, President, the United Engineering and Contracting Company; William A. Howell, Engineer of Streets and Highways, Newark; Arthur N. Johnson, Highway Engineer, Bureau of Municipal Research, New York; Nelson P. Lewis, Chief Engineer, Board of Estimate and Apportionment, New York; Philip P. Sharples, Chief Chemist, Barrett Manufacturing Company; Francis P. Smith, Chemical and Consulting Paving Engineer; Albert Sommer, Consulting Chemist; George W. Tillson, Consulting Engineer to the President of the Borough of Brooklyn, New York; and George Warren, President, Warren Brothers Company.

G.T.R. MASTER MECHANICS.

The following Grand Trunk staff changes have been announced: J. Markey is appointed master mechanic of Ontario lines with headquarters at Toronto, and J. R. Donnelley is named as assistant master mechanic of Ontario lines with headquarters at Allandale, the title of master mechanic of the northern division being abolished. T. McHattie is appointed master mechanic of eastern lines with headquarters at Montreal, and the title of master mechanic of the Ottawa division is abolished. W. H. Sample is appointed master mechanic of western lines with headquarters in Battle Creek, Mich.

CANADIAN ENGINEERS AT THE FRONT.

In addition to the list of graduates and undergraduates of the University of Toronto who are now in England with the first Canadian expeditionary force there should be added the names of Messrs. P. J. McCuaig, '09; H. N. Klotz, '09, and W. J. Baird, '10.

We announced Mr. H. F. H. Hertzberg, chief engineer of the Canadian Bridge Co., Walkerville, as a member of the contingent. As many of our readers are aware, this should have read, "Mr. H. F. H. Hertzberg, engineer of the Trussed Concrete Steel Co. of Canada, Walkerville, Ont."

THE CANADIAN SOCIETY OF CIVIL ENGINEERS.

On Thursday, Oct. 22nd, a largely attended meeting of the Canadian Society of Civil Engineers was held in the Society's headquarters, 176 Mansfield Street, Montreal, Walter J. Francis, C.E., presiding. A paper, illustrated by slides, and entitled "The System of Unit Construction in the Concrete Power House at Cedars, P.Q.", was read by Mr. J. E. Conzelman, chief engineer of the Unit Construction Co., Montreal. The speaker dealt in detail with the use of reinforced concrete in the construction of large industrial and similar buildings. The application of the "unit construction" to the power house of the Cedars Rapids Manufacturing and Power Co., as described by Mr. Conzelman, aroused a good deal of discussion and was of great interest.

Another paper, entitled "Mushroom Construction," by Mr. C. A. P. Turner, had to be postponed until a later meeting as the discussion following the first paper occupied the greater part of the meeting.

CHANGE OF ADDRESS.

The Ottawa Branch of the Canadian Society of Civil Engineers has changed the address of its headquarters from 177 Sparks Street to 128 Queen Street, Ottawa.

COMING MEETINGS.

NORTHWESTERN ROAD CONGRESS.—Annual Convention, to be held at Milwaukee, Wis., October 28th to 31st. Secretary, J. P. Keenan, Milwaukee.

AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—Charles Carroll Brown, Secretary, Indianapolis, Ind. Meets at Somerset Hotel, Boston, Mass., October 21st, 22nd and 23rd.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

WASHINGTON STATE GOOD ROADS ASSOCIATION.—Convention to be held at Spokane, Wash., November 18th, 19th, and 20th. Secretary, M. D. Lechey, Alaska Building, Seattle, Wash.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

AMERICAN ROAD BUILDERS' ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

Volume 27. Toronto, November 5, 1914 Contents of this issue on page 3

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

Fig. 1.—The Harbor Under Construction at Port Weller.

WELLAND SHIP CANAL CONSTRUCTION

NOTES ON THE SEASON'S ACTIVITIES IN THE CONSTRUCTION OF CANADA'S $50,000,000 WATERWAY BETWEEN LAKES ERIE AND ONTARIO, UNDER THE DIRECTION OF THE DEPARTMENT OF RAILWAYS AND CANALS, OTTAWA.

THE present season has been one of remarkable activity along the line of the proposed New Welland Ship Canal. The northern portion of the route has been converted into a scene of constructional development embodying works whose proportions and involved methods of construction are on a scale with which few of our Canadian enterprises are comparable, and certainly far beyond anything of a similar nature ever attempted in this country.

For general information respecting the new route, and essential features of design, the reader is referred to an article which appeared in *The Canadian Engineer* for August 21st, 1913. Briefly, it is to replace the present Welland Canal whose length of 26¾ miles from Port Colborne on Lake Erie to Port Dalhousie on Lake Ontario, provides, through 25 locks, the only existing means of water transportation in this section of the Great Lakes' route. The old canal, with locks 45 feet in width, afforded some 14 ft. of water over the sills. The new canal will be 25 miles in length, from lake to lake, overcoming a difference of level of 325½ feet. There will be seven locks, each of 42½ ft. lift, 80 ft. width, and of sufficient length to accommodate a vessel 800 ft. long. The present construction is to provide a depth of 25 ft. over the sills; this to be ultimately deepened to 30 ft., according to the design.

Fig. 2.—Drag Line Excavator in Lock No. 1, Port Weller.

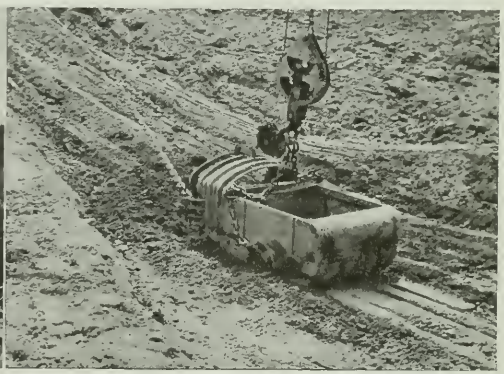

Fig. 3.—Drag Line Bucket at Work on Site of Lock No. 1.

The work has been divided into nine general sections and up to the present contracts have been let for Sections 1, 2, 3, 5, and a portion of Section 4, called 4A.

Section 1.—The contract for Section 1 was let on August 1st, 1913, to The Dominion Dredging Company, Limited, Ottawa, at about $3,500,000. It extends from deep water about 1½ miles from the Lake Ontario shore line to Sta. 150, about 1½ miles inland. The contract includes the construction of Lock 1, the lower end of which is about 2,500 ft. from the shore line. There is a lock wall about 800 ft. in length and an entrance wall also 800 ft. long. The inland part of this section entails a large amount of dry excavation. The contract also includes sub-structures for two bridges. One of these will be situated over the head of Lock 1 and will be for the electric line to Niagara, of the Niagara, St. Catharines and Toronto Railway. This will comprise a bascule lift bridge over the Canal proper with 95 ft. clear span, and a reinforced concrete approach of six spans over the regulation weir on the east side. The two outer spans will be 41½ ft. and the four central spans 40 ft. in length. The contract calls for the complete construction of this approach.

The other bridge, No. 2, will also be a bascule lift highway bridge, but of 200 ft. span. It will be situated about a mile south of bridge No. 1, and will lie between the second and third concessions of the Township of Grantham.

A considerable part of The Dominion Dredging Co.'s contract consists of the construction of a harbor at Port Weller. This harbor is to be formed by two earth dykes about 500 ft. in width and extending, as stated, 1½ miles from shore line. These dykes each carry a temporary trestle used in their formation. This trestle carries the tracks of a railway to be described later. Here all the surplus material from Sections 1 and 2 and the lower end of Section 3 is being dumped. At present the trestle on the west side extends over half way out and that on the east side is almost as far advanced.

It is expected that the side embankments of the harbor will eventually be three or four hundred feet in width at the top at the narrowest point, and considerably wider toward the shore. The material dumped into these embankments washes away to a very small extent under normal conditions, and even during storms no great quantity has so far been taken out. When the earth filling is completed rock will be brought from Section 3 to roughly rip-rap the outer slopes.

The work in the lake includes dredging a 25-foot channel from deep water to the shore line, the material being cemented gravel and hard-pan overlying shale rock. Some of the latter will also be removed.

The harbor work includes the building of 55 cribs, each weighing about 2,000 tons, to be placed at the entrance piers and at the east docking and gate yard slip, near the shore line. Each is 110 ft. in length, 38 ft. wide and 34 ft. deep and contains 18 compartments, each 12 x 18 ft. The exterior walls are 18 in. wide at the bottom, tapering to 12 in. at the top. The base and top widths of the interior walls are 14 and 10 in. respectively. There is an offset at the bottom of each compartment providing a seating for a movable timber bottom. When the cribs are floated to position they are sunk by the removal, by chain operation, of these bottoms. When sunk they will be filled with earth. One of the cribs has already been constructed and floated out into the lake and temporarily rests on bottom pending the dredging of a deeper channel and the preparation of the site. The bottoms of the compartments of the crib are, as stated, removable, and will be used over and over in the construction and placing of the different cribs. When sunk, the top of the cribs will reach water level. They will extend for a distance of 700 feet on either side of the harbor entrance. Upon such cribs also will be placed the concrete superstructure forming the lines of docking at the shore end of the harbor.

The entrance wall to Lock No. 1 involves some interesting construction. The steel frame work, 41½ ft. in height, and a large part of the steel reinforcing has already been placed and considerable concreting has been done. The entrance wall extends from near the lake to the foot of the lock and is of reinforced concrete, buttress type. In the use of the structural steel frames, one in each counterfort, a departure from ordinary design has been made. These frames are for the purpose of supporting the reinforcing rods, many of which pass through holes punched through the framework, and also for supporting the concreting forms. The illustrations of this

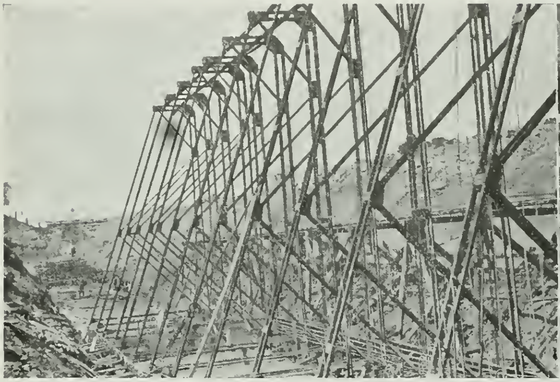

Fig. 4.—End Section of Steel Frame for West Entrance Wall at Port Weller, Before Placing Reinforcing Steel.

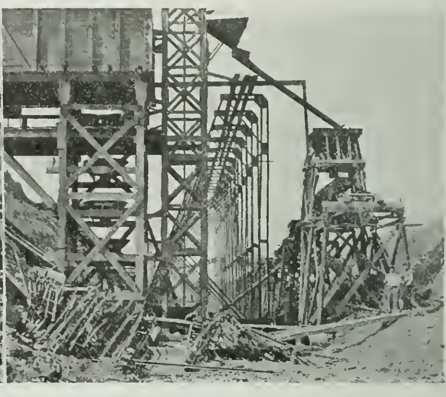

Fig. 5.—Part of the Concreting Plant at the South End of the Retaining Wall.

wall show some interesting reinforcing work. The wall has a rock foundation. The reinforced concrete crib docking, mentioned above, will extend from its outer extremity into the harbor.

At work in the harbor is a sounding scow about 40 feet square, and provided with 4 large spuds or anchors. This scow was built for the general purposes of the survey staff in connection with the harbor work, but principally for ascertaining the elevation of the surface of the rock beneath the overlying material. As it was liable to be caught out in rough weather before the piers were extended as far as they are into the lake, and as sometimes a perfectly steady platform is required, the scow is arranged with a heavy engine on each spud, by means of which the scow is enabled to hoist itself completely out of the water and above the reach of wave action, which will thus have only the four spuds to strike against. When it is required to move the machine the scow is lowered into the water and the spuds lifted up clear of the bottom by the same machinery.

A reinforced concrete scow, built in 1910, is also engaged on the work.

Up to the end of September the work done on Section 1 of the Canal included about 300,000 cubic yards of dredging from the harbor and about 1,000,000 cubic yards of dry excavation from the lock division. This material has all been used in the embankment construction.

Section 2.—This was let by contract on December 31st, 1913, to Baldry, Yerburgh & Hutchinson, an English firm with an office in St. Catharines. It extends from Sta. 150 to Sta. 380, approximately 4⅓ miles, and includes the construction of Locks 2 and 3, with necessary entrance walls, regulating and supply weirs. Substructures for three bridges will be required in addition to road diversions, etc. Bridge No. 3 will be an 80-ft. bascule bridge to be used for highway purposes and will be situated over the head of Lock 2. The contract requires the construction of a reinforced concrete approach of six spans, each 40 ft. in length and 21½ ft. wide.

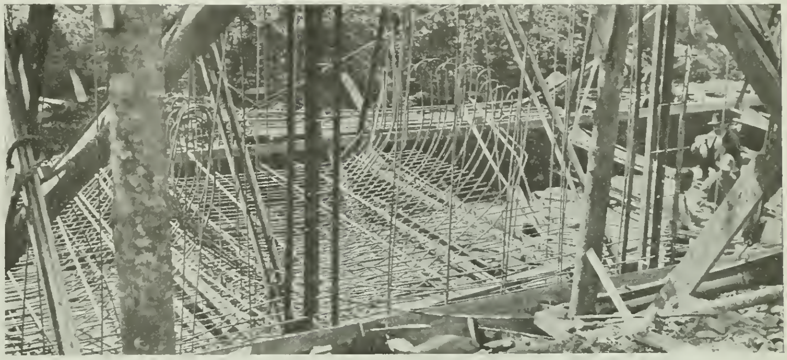

Fig. 6.—Reinforcing Steel at the Base of One of the Counterforts—West Side Entrance Wall, Port Weller.

Bridge No. 4, to be also of bascule lift type, will have a 200-ft. span with earth approaches. It will be over the Queenston Road and about midway between Locks 2 and 3. The location of bridge No. 5 is on the St. David's-Merritton Road, near the boundary line of Sections 2 and 3 of the canal. It will also be a bascule lift bridge with a span of 200 ft.

In Section 2 there will be a crossing of the present and new canals. The water in both is to be at the same level thereby affording vessels an alternative passage to or from Lake Ontario by way of Port Dalhousie. This will probably be taken advantage of largely by smaller craft.

Fig. 7.—Grader and Mule Outfit Working on a Watertight Embankment, Section 2.

During the season the embankments for a pondage of 200 acres required for Lock No. 2 have been in progress, east of the canal bank. About half a mile of it is completed. Six elevating graders have been employed on the work. A dam is also being built to the east of Lock 3, to form an equalizing basin. Lock 1 will also have a pond. These basins are necessary in order to prevent fluctuations in the levels when a lock is filled or emptied, as the filling of a lock would lower the water in a 70-acre pond one foot. It is therefore advisable to have these ponds as much over 70 acres as possible.

At the site of Lock No. 2, the excavation for a heavy breast wall is in progress. A cavity about 175 ft. long and 25 ft. wide has been made and enclosed in sheet piling 45 ft. in length, driven to refusal and supported by wooden bracing. Excavation will be carried to a depth of 60 ft. to solid rock, whereupon the pit will be filled with concrete, thus forming the breast wall for Lock No. 2.

Fig. 8.—Rock-cut on G.T.R. Relocation, 3rd Curve. Thorold (Section 3).

This method of construction was adopted in order to conserve the ground above the breast wall in its natural state, as, had the lock pit been excavated in the usual manner, it would have been open for a couple of years, during which time a slope probably flatter than 1 to 1 would have formed above the breast wall, as well as along the sides of the pit. The present method will leave the material above the breast wall intact.

The contractors had completed on September 30th, 1914, a total of 1,500,000 cubic yards of dry excavation in Section 2. All this material, with the exception of that required for grading the construction railway, has been transported to the harbor site and used in the construction of the dykes. The section involves the excavation of about 6,000,000 cu. yds. of earth. This part of the work has proceeded very rapidly by means of heavy steam shovels, drag-line excavators and several mule outfits operated in connection with grading machines. The embankments are being built by mule teams hauling wagons from the grading machines to the different banks, where it is placed in layers and compacted after being watered.

Section 3.—The contract for Section 3 was let on October 4th, 1913, to O'Brien & Doheny, Montreal, and Quinlan & Robertson, Toronto, in combination, the price being approximately $9,500,000. It extends from Sta. 380 to Sta. 490 and includes the twin Locks Nos. 4, 5 and 6 in flight, single Lock No. 7, and guard gates. A part of the contract is the diversion of the Welland Division (to Port Colborne) of the Grand Trunk Railway. At present this line extends along the right-of-way of the canal. The relocation is along the west side for a distance of about 3 miles, and extending into Section 4. The part of this work included in Section 3 is practically completed. Some particularly heavy rock excavation and earth cutting were encountered, as the railway here climbs the Niagara escarpment. The location of the line at this point was a difficult matter on this account. Over 500,000 cu. yds. of material have been removed from this cutting within a length of 1½ miles.

There is also a diversion of the main double-track line of the G.T.R. to Niagara Falls. This line crosses the right-of-way at the foot of Lock 4. The diversion has required the erection of a bridge of 4 truss spans, already supplied and erected by the Hamilton Bridge Works Company. This diversion is only temporary, and the bridge will be removed when the canal is nearing completion, whereupon it will be available for use elsewhere. The pier for the ultimate structure is to form a part of the centre wall of twin Lock No. 4. The final bridge will consist of a bascule lift span on either side of this pier. This diversion allows free passage for the excavated material from the lock pits to the stone crushing plant, and to Port Weller. In order that the diversion might be finally disposed of and cause no further trouble to the Grand Trunk Railway or to the contractor, the centre pier upon which one end of the steel spans rest has been sunk through earth and rock, a depth of 90 ft., to the level of the foundations of the locks, and, as stated, it will be eventually incorporated in the centre wall of the locks. The side piers have been sunk to about two-thirds of this depth, to the surface of the rock below. This will allow the contractors to excavate the lock pit completely and the lock walls to be built without interfering with the bridge. It will be noted that instead of building double-track spans, two single-track spans have been constructed, the idea being that they will be more easily disposed of, upon the completion of the work, than a double-track structure.

In addition to the above, which in reality calls for two bridges, the contract includes the substructures for four others. One of these is bridge No. 7 on the St. David's-Thorold Road in Thorold. It consists of a reinforced concrete bridge 99 ft. in length, and a double bascule bridge over the canal. The contract requires the complete construction of the former and the foundations for the latter. The Hamilton Bridge Works Company has recently finished the erection of a steel bridge for the Welland division of the Grand Trunk Railway. This consists of two deck plate girder spans and one through girder span. It is located close to the guard gates above Lock No. 7.

Fig. 9.—Department's Main Crushing Plant, Section 3.

A highway bridge, No. 8, over the railway cutting at Peter Street, Thorold, will consist of a bascule lift bridge, 80-ft. span, over the canal, and a reinforced con-

crete bridge of 3 spans, each 36½ ft. c. to c. of piers, over the G.T.R. right-of-way. It has a 16-ft. roadway and 6-ft. sidewalk.

Bridge No. 9, for the Niagara, St. Catharines and Toronto Railway, will be a swing span of 222 ft. 11 in., with a reinforced concrete skew approach, the centre spans of which are 46 ft. 9 in. c. to c., while the end spans next and farthest from the canal bridge are 11 ft. 7 in. and 28 ft. 6 in. in length respectively.

These bridge structures and diversions are really incidental to the general scope of the contract, and have been mentioned first as the work they involve is encountered at an early stage. There are about 3,500,000 cu. yds. of earth, 2,500,000 cu. yds. of rock and 1,500,000 cu. yds. of concrete masonry on this section. The 3 twin locks in flight are to be built, the lower end of twin Locks No. 4 being located under the Grand Trunk Railway main line, where the 4 large steel spans noted above carry the diverted railway. These three locks will lift a vessel 139½ feet to a regulating basin which will be formed by a large dam now in course of construction, on the east side at the head of Lock No. 6. Above this pond will be built single Lock No. 7, the head of the lock being located at Peter Street in Thorold, where a swing bridge crosses the present canal at the head of Lock 24.

The dam at the head of Lock No. 6 is an interesting and important part of the section. It is of earthen construction, having a concrete core wall extending from the rock surface to an elevation about 30 ft. below the top of the dam. The latter will be 75 ft. in height at its highest point, and the core wall is built in a trench in the clay overlying the rock, varying in depth from 5 to 30 feet. The good earth from the excavation has been dumped on either side of the dam site, and is now being re-handled into the work. The seat of the dam was carefully prepared by removing all loam and other loose material and by benching all sloping surfaces. A toe trench was then excavated along the full length of the dam for a few feet in depth into the solid material, and the dam has been built up in layers of approximately 8 to 12 in., each layer being carefully spread, watered and compacted by rolling. This process will be continued to the top. A heavy stone talus consisting of rock from the excavation will then be placed on the downstream side of the dam to add weight and to prevent sliding, and earth will be dumped on the upstream side after the water has been let in, to reduce the depth of water in the pond to about 10 or 12 feet.

The construction of this core wall and watertight embankment will provide a pondage covering 84 acres, for Lock No. 6. The core wall, which has been completed, is irregular in alignment. For a distance of approximately 500 ft. it projects from the canal wall at an angle of 45°. Then its direction changes through an angle of 49°, and for a distance of about 675 ft. it extends outward from the canal and at nearly right angles to it. The centre line of the dam extends from the terminus of the core wall at this point at an angle of nearly 30° for a distance of about 400 ft. where a backward sweep of about 67° occurs. This new line is followed for the remaining portion of the embankment, approximately 650 ft. The thickness of the core wall varies from 5 to 10 ft., depending on the depth, tapering at the top with a batter of 1 to 6 to a uniform width of 3 ft. At any vertical cross-section the thickness is uniform from the taper to the base of the wall.

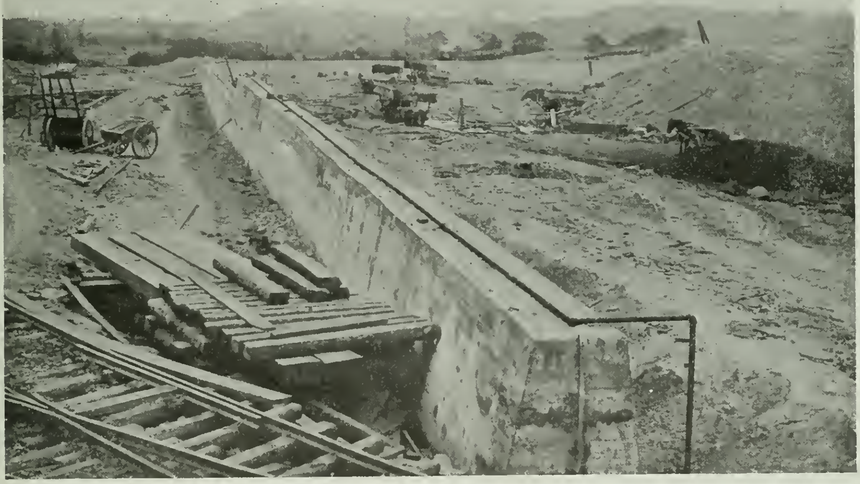

Fig. 10.—Core Wall of Dam at Head of Lock No. 6, Section 3.

Two drag-line excavators are re-handling the material that has been dumped along the side of the proposed dam from the stripping of the site of the flight locks, and from railway cuttings in the vicinity. The watertight embankment has been completed to a depth of about 6 ft.

It should be stated that the location of these flight locks, as well as the diversion of the Welland division of the G.T.R., is in the heart of the town of Thorold and

that these undertakings have involved the removal of a number of houses. The stripping has been done and at present Keystone and Cyclone drills, operated by electricity, are working on the site of Lock 5, drilling blast holes from 30 to 40 feet in depth into the rock.

The contractors for this section of the canal are required to provide crushed rock for the concrete work, not only for this section but for Sections 1 and 2. This has necessitated the installation of a large rock-crushing plant which is located east of Merritton and north of the G.T.R. line. The capacity of this plant is such as to provide 2,000 cu. yds. of crushed rock per day for each of Sections 1 and 2, besides the amount required for Section 3. The arrangement is described more fully later, in connection with the construction railway.

Fig. 11.—Reinforcing Work for the Supply Weir. Section 4 A.

Section 5.—The contract for this section was let to the Canadian Dredging Co., Midland, Ont., on December 22, 1913, the price being approximately $1,950,000. The section is about 2½ miles in length, from Sta. 636 to Sta. 774. It consists of widening the present canal between Allanburg and Port Robinson and dredging the channel to the proper depth of 25 ft. The widening is being effected by removing the west bank of the present canal. The contract calls also for the foundation work for one bascule lift bridge over the canal at Main Street, Port Robinson. It will have a span of 200 ft.

Up to September 30, 1914, the contractors had handled about 700,000 cu. yds. of excavation. Five steam shovels have been steadily employed on the work all summer. The material is being disposed of on dumping grounds provided on the west side between the present and old canals, opposite Section 4. Provision is made there for dumping the entire excavation from Section 5, which will aggregate about 5,000,000 cu. yds., practically all earth.

Section 4 A.—The contract for this division of the work was awarded on May 6, 1914, to Maguire & Cameron, St. Catharines, Ont., at about $80,000. It consists chiefly of the construction of a supply weir near the boundary of Sections 3 and 4 to furnish water to the old canal through an existing channel connecting with the present canal. Two culverts for drainage purposes under the dumping grounds mentioned above are also necessary and included in the contract.

Construction Railway.—As mentioned elsewhere, a double-track standard gauge construction railway has been built on the west side of the canal. As noted above, the contractor for Section 3 supplies the crushed stone required for the three sections, there being plenty of rock on Section 3, but none on Sections 1 and 2. A short distance from the crushing plant, track scales are being constructed which will weigh a train of cars 150 feet in length. These scales will weigh all the crushed stone leaving the plant for Sections 1 and 2. When the contractors for these sections require it, they will send their cars to this source of supply and the cars will be loaded by the contractor for Section 3. It is expected that the big plant will be in full operation within a few weeks.

The railway extends from these scales to Lake Ontario, a distance of about six miles. It is carried over the present canal, about a mile north of the crushing plant, by means of a double-track steel swing bridge, recently completed. It was built, and is maintained by the Department of Railways and Canals, under whose direction a superintendent, dispatchers and switchmen control all the operations on the road. The contractors for Sections 1, 2 and 3 are entitled to the free use of this road for the purpose of moving crushed stone from the crushing plant to their respective works, and for the purpose of removing excavated material from their respective works to the service ground fills in Lake Ontario. A complete interlocking plant and block signal system is being installed. The ballasting of the line was done by the contractors for Section 2.

Near the shore line the railway branches and each harbor embankment has its own tracks, supported by temporary wooden pile trestles that are being built out into the lake in advance of the dumps. In order to give the piles of these trestles a firm bearing and more stability than would ordinarily be the case, under-water embankments are being built in advance of the trestles. These are formed by dumping the scows of excavated material from the dredges on the line of the trestles till the scows will no longer float over it, and through this dump the piles are driven.

Up to September 30th approximately 2,500,000 cu. yds. of excavation had been transported to the harbor embankment since the completion of the railway to this point.

Sub-contracts.—The Dominion Dredging Company have sublet several portions of their work in connection with Section 1. The locks, retaining walls and other concrete work has been let to Lane Bros., while the J. H. Tromanhauser Co., Toronto, has the construction of the 55 cribs for the entrance piers and gate yard slip. On Section 2 Baldry, Yerburgh & Hutchinson have sublet portions of the excavation work to Yale & Reagan, Chicago, Ill; Hill-Leonard Engineering and Construction Company, Toronto, and to Stein & Reade, Merritton, Ont. The construction of embankments has been sublet to Michael Conroy, Chicago, who has about 50 mule teams on the work. Jos. Battle, Thorold, Ont., has already finished a small concreting sub-contract; Ernest Bennett, St. Catharines, will construct a number of culverts, while Jos. Riley, St. Catharines, has the contract for sodding the finished slopes of the canal in Section 2. As the work proceeds on the several sections the slopes are being

sodded. This will tend to prevent washing out and thereby materially reduce the cost of maintenance of the canal, besides adding to the appearance of the canal banks.

No contracts have been sub-let on Section 3. On Section 4 A, the 2 culverts will be built under sub-contract, while on Section 5, J. H. Corbett & Company, of Moncton, N.B., has the dry excavation work.

Synopsis.—The general dimensions of the canal are as follows:—

Length, lake to lake	25 miles
Bottom width	200 feet
Width at water line	310 feet
Depth of canal	25 feet
Depth on lock sills	30 feet
Number of lift locks	7
Usable length of locks	200 feet
Usable width	80 feet
Height of lock walls above sills	81.5 feet
Lift of each lock	46.5 feet

All the work is being executed under the direction of J. L. Weller, C.E., Mem. Can. Soc. C.E., chief engineer of the canal for the Department of Railways and Canals, Ottawa.

STEAM TURBINE POWER PLANT AT KAMLOOPS.

THE city of Kamloops, B.C., has recently completed a municipal power plant which, while it is smaller than some other Canadian municipal plants, differs in some respects from the ordinary steam turbine plant because of a combination of conditions which controlled the design.

The following description of the plant, written for the "Municipal Journal" by H. W. Beecher, M.E., will be found of interest:—

The city, which is located at the junction of the North Thompson and South Thompson rivers, and is on the Canadian Pacific Railway, has been growing rapidly and promises to continue to do so, and this has required provision for water supply and street lighting plants of much greater capacity than were originally constructed. The water supply is drawn from Thompson river and pumped to reservoirs on neighboring hills. Several years ago it seemed to city officials that this offered an excellent opportunity for combining pumping and electric power plants, the former being used to fill in the times between peak loads and thus keep the load more uniform. H. K. Dutcher, of Vancouver, was employed to report upon the proposition, and located a power site on the Barriere river about forty miles north of Kamloops, where an ultimate development of 16,000 h.p. was possible. The municipality voted $475,000 for the project and proceeded to carry it out. The present plans call for only 2,200 h.p. installation, but provision is made for the ultimate development of the entire power available.

The plant on the Barriere river now nearing completion will consist of two 1,100 h.p. Victor-Francis turbines made by the Platt Iron Works Company, of Dayton, Ohio, and supplied through Charles C. Moore & Co., engineers, of Seattle; and two Westinghouse water wheel type generators direct connected to the turbines. The turbines will operate at 720 r.p.m., will be of the single-runner scroll-case Francis type and will be provided with outside gate mechanism and direct-acting Lombard governor.

To provide for accidents to the power plant, and especially on account of the long transmission line, it was considered necessary to install an auxiliary steam plant in the city. As the demand for increased power was immediate, and the steam plant could be constructed more quickly than the hydraulic works, it was decided to build the steam plant as quickly as possible so that it could be used while waiting for the completion of the hydro-electric system. The engineers prepared plans for a combination steam plant, sub-station and pumping plant, and this has recently been completed and is the most interesting feature of the municipal installation.

On account of the shifting bed of the Thompson river, it was considered advisable to construct the main power house some distance from the river, where suitable foundations could be secured, and place an auxiliary pump house at the river's edge. The plan provided also for the future construction of filters to receive the discharge from the auxiliary pumps, from which the effluent could flow by gravity to the pump well of the main pumps.

The auxiliary pump house contains two vertical centrifugal pumps operated by vertical motors placed above the highest known water level. Water is brought to the pumps through long intake pipes which terminate in a screened inlet located in the middle of the river. The inlet pipes terminate at the pump house in gate valves, hand-operated. After leaving these pipes the water passes through a double system of screens into the suction chamber. The pumps are operated from the main switchboard, one by a standard hand-operated starter and the other by an automatic patent starting device controlled by a float switch which maintains at a given level the water in the suction chamber. By proper regulation of the inlet valves this automatic pump is kept in practically uniform service. The pump house is of concrete heavily reinforced throughout.

Power House and Plant.—The main building is of reinforced concrete, 90 x 75 feet ground plan, divided into boiler room, turbine room and high-tension sub-station. In the basement at the extreme west end is located a reservoir from which the pumps take their suction, and here also are located the condenser and condenser auxiliaries. The basement under the turbine room is on the same level as the boiler room floor. The suction well is connected to the auxiliary pumps on the river's bank by about 600 feet of 6-inch mains. The roof over the boiler room is supported by trusses and that over the turbine room and switchboard by deep web I-beams. The horn gap structure for the high-tension lines allows them to come in through roof cones, well within the confines of the plant.

The boiler room contains four Babcock & Wilcox water tube boilers of 250 h.p. each. Each boiler contains ten sections of ten 4-inch by 18-foot tubes, mounted under one 54-inch steam and water drum. They are designed to operate at 160 lbs. pressure. The pumps were manufactured in the Renfrew, Scotland, factory of the Babcock & Wilcox Company, and are arranged so that superheaters can be added later if conditions warrant. Shaking grates for hand firing are used, but the plant can readily be converted to an oil-burning plant. Coal is brought direct from the mines in bottom-dump cars and dumped from an overhead spur into the coal bunkers just outside the building. From the bunkers it runs by gravity onto the firing floor through chutes in the rear wall of the boiler room, from which point it is fed by hand into the furnaces. Ashes are raked into the boot or hopper of a motor-driven conveyor elevator of the endless chain type, which discharges them on the ground about 40 feet east of the boiler room. The chimney is 89 inches in diameter and 180 feet high above the boiler room floor. It is

heavily reinforced with ⅝-inch steel rods and is of the tapering or coniform type. The boiler feed pumps are of the Smith-Vaile outside end packed plunger type, 6 x 4 x6 inches, manufactured by the Platt Iron Works. They receive water from a Stilwell open type heater. This type of heater is advantageous because it permits the settling out in the filter beds in the bottom of the heater of sediment contained in the river water which is used for boiler purposes. In the heater the water drips over a large tray surface and then passes into the settling chamber and filter.

The boiler branches leading from the four boilers are each provided with automatic steam stop and check valves at the boiler nozzles and a double wedge gate valve at the header. The header is carried on the boiler room side of the partition between that and the turbine room, branches to the turbine being carried through openings left in the concrete wall. Gate valves are placed on each turbine branch. An auxiliary header is installed within the turbine room, from which branches are carried down to the air pumps and circulating pumps.

The generating equipment consists of two Curtis turbo-generators of 600 kw. capacity built by the General Electric Company. They are wound for 2,200 volts three-phase 60-cycle and operate at 3,600 r.p.m. The governor mechanism operates six inlet valves, giving very close speed regulation. Each unit has an electric speed-changing device and over-speed safety trip. The speed of the turbo-generator is thus controlled by the switchboard operator, materially facilitating the paralleling of the machines at the time of bringing the machine onto the line. A 20-kw. G.E. motor generator exciter running at 1,200 r.p.m. is provided, and for breakdown service and for starting a 15-kw. Curtis steam turbo-generator exciter.

The turbines exhaust through corrugated copper expansion joints into cylindrical surface Wheeler condensers equipped with steam turbine-driven circulating pumps and Edwards suction valveless air pump. Each condenser contains 1,440 square feet of cooling surface of ¾-inch brass tubes, secured in brass sheets by ferrules and packed joints. The air pumps are single cylinder, single acting, 7-inch steam cylinder and 16-inch air cylinder with 10-inch stroke. The suction valveless feature makes it possible to use the one pump for handling both air and condensate and maintain a high vacuum. The condensed steam and non-condensible vapors flow continuously by gravity from the condenser to the base of the pump and are removed by a conical piston, which projects the water without shock at high velocity through ports in the sides of the working barrel. The condensing equipment is arranged to produce between 28 and 28½ inches of vacuum and was furnished by the Wheeler Condenser and Engineering Company.

Waterworks Equipment.—The waterworks pumping plant consists of two Platt 2-stage centrifugal pumps of the horizontal split casing type, fitted with bronze runners and arranged for motor drive. Their efficiency is 72 per cent. They are driven by two 200 h.p., 1,760 r.p.m. induction motors manufactured by the Canadian General Electric Company. A third pump, manufactured by the Platt Iron Works, is steam-driven, of the 2-stage type, operated by a 200 h.p., 2,200 r.p.m. Kerr economy type condensing turbine, exhausting into a Wheeler waterworks type condenser with Edwards air pump. The condenser has 1-inch tubes and is placed in the suction of the pump so that no circulating pump is necessary. Each of these three pumps has a capacity sufficient to supply the city consumption if operated twenty-four hours a day, but all three can be operated at once, the large reserve capacity being considered advisable to insure adequate fire protection in the business section. Each pump has a capacity of 1,200 Imperial gallons per minute against a head of 350 feet.

The steam turbine-driven pump is found to be very economical, owing to its being operated condensing, the greatest efficiency being obtained with 28 inches vacuum.

Water from these pumps is discharged into a reservoir about a mile away and about 320 feet above the pumps. The main between pump and reservoir serves also as distribution main.

The discharge from the pumps is measured by a Simplex venturi meter located just outside the building wall, the recording and integrating apparatus being placed in the corner of the turbine room.

There is an elaborate switchboard of natural slate containing 22 panels. All high-voltage connections on switchboard leads which would prove dangerous to the operators are on a structure placed some distance to the rear of the switchboard and operating by remote control. There is no apparatus on the panels at a potential above 110 volts. The switchboard consists essentially of a station lighting panel box, three generator panels (one blank as yet), 2 station power panels and 2 incoming high-tension line panels, the balance being feed panels. At the extreme end of the board are located the constant current panels for controlling the constant current tubs on the series arc lighting system of the town. The voltage on the system is kept constant by a Tirrell automatic voltage regulator. The high-voltage apparatus for the proposed high-tension lines from the hydro-electric plant are behind and above the switchboard, partitioned off from the rest of the equipment. It consists essentially of oil switches, aluminum lightning arrester and static transformer, which reduces the voltage from 44,000 to 2,200. Under the transformer are provided suitable oil tanks and water piping to cool the oil in the transformer.

A 10-ton hand-operated traveling crane which runs over the entire turbine and pump room is provided for handling heavy machinery parts. A transfer car permits the transformers to be wheeled out under the crane to facilitate handling their cores for inspection or repair.

This plant, during the short time which it has been operated, has shown a material saving of fuel as compared to the old plant which it supplants. A still greater saving is anticipated when the new hydro-electric plant comes into service and the steam station is held as an auxiliary only.

HUMIDITY OF COAL MINE AIR.

The fact that dry bituminous coal dust will explode under certain conditions has been proved both by the experience of the past and by laboratory tests and is now generally admitted by all coal men.

That coal dust may be rendered inert by the proper application of moisture has been shown both by laboratory tests and by the absence of explosions at mines in which moisture is present in the proper proportion to the quantity of dust produced. The result of an investigation in Illinois, of the humidity of mine air, carried out by the United States Bureau of Mines, leads to the belief that steam may be applied to the intake air in such a way as to offer the most economical and efficient method of dampening coal dust.

The Panama Canal was closed to traffic five days, October 15-20, by a landslide in Culebra Cut. Fifteen ships were detained one or more days each, and will have claims on the government for demurrage.

DESIGNING SMALL WATERWORKS SYSTEMS.*

By William S. Johnson.

IN Massachusetts there are 215 water supply systems, and of these, 152 were installed before the population of the towns they supply was 5,000, and 111, or more than half, are now still supplying towns of less than 5,000. In fact, the opportunity seldom comes to design a complete system of works for a large community, the larger systems being extensions of the system designed for the small town. As there are only four towns in Massachusetts having a population of more than 3,000, which remain unsupplied with water, it is likely that, in that State at least, the problems arising in small systems will be more numerous than the problems connected with the larger systems, although, perhaps, not so interesting to any but those immediately affected.

It has been my lot to put in a number of small waterworks plants, and it has surprised me to see how easily 10 per cent. of the cost of construction may be saved by a thorough study of the problem. I have also found that many problems over which I have worked have been solved by others, who have kept the results to themselves, not because of unwillingness to part with the information, but because the matter seemed too small to be of general interest. It is with a view of encouraging the discussion of the problems connected with small waterworks installations, as well as to give a few of the results of my own experience that this paper is presented.

Provision for Future Requirements. — The works should be designed for a long time in the future, but the design should provide for as little immediate construction as is possible except where the cost of extensions or increased capacity will be much more than the cost of doing the work in the beginning.

To build works for a long time in the future assumes a power of prophecy which most of us do not possess. It is impossible to foretell the future growth of the whole or any part of the community. The advancements in the art of water supply engineering are so rapid that portions of the plant are likely to become obsolete before they are worn out. The requirements of the public which uses the water are changing very rapidly. For these reasons it is desirable to build only for the immediate future, and to plan for additional works to be constructed as they become necessary.

Fire Protection Requirements.—The capacity of the distributing system is determined, in the case of the small town, by the fire-protection requirements solely. One good, effective fire stream will use water at as great a rate as the ordinary town of 5,000 inhabitants will require for domestic purposes during the hours of maximum draft.

The quantity of water which will be drawn from the sources of supply depends upon the population to be supplied, the character of the residences supplied, the care taken to prevent leaks and other wastes, and the use of water for manufacturing or mechanical purposes. It is exceedingly difficult to evaluate these factors, since it is impossible accurately to forecast the industrial development or retrogression of the average small community. The population to be served depends primarily upon the growth of the community's industries. A future per capita domestic consumption of from 75 to 100 gallons per day for ordinary small towns does not seem unlikely, and in the case of towns having large estates and a large area of well-kept lawns the consumption may be much larger.

Metcalf, Kuichling and Hawley, in a paper before the American Waterworks Association, state that "the cost of the portion of the waterworks plant involved by fire protection probably constitutes from 60 to 80 per cent. of the entire cost of the physical property in the case of communities having less than 5,000 population." This is undoubtedly true except in those places where it is necessary in order to secure water of sufficient purity for domestic purposes, to go to a large expense in obtaining it or in its purification.

In a small town it is usually necessary to depend entirely on hydrant streams without the use of steamers, and it is essential, therefore, that the works, either by themselves or assisted by some outside source, should furnish both the requisite quantity of water and the proper pressure with which to fight the greatest conflagration which is likely to occur, and to do this under the most unfavorable conditions in regard to domestic consumption and quantity of water in reservoir or standpipe.

Fire Streams.—The standard fire stream is now considered to be that thrown by a 1⅛-inch smooth nozzle, discharging 250 gallons per minute, and it is generally considered by the insurance engineer that a hose stream which does not throw 200 gallons per minute is not a good stream. There are many cases, however, where smaller streams throwing from 150 to 175 gallons per minute would furnish reasonable protection, and this is all that a town would be justified in providing in some districts. In the outlying sections of small towns any fire which gets sufficient headway in the ordinary building so that it cannot be controlled with two streams of 150 to 175 gallons each is not likely to leave much of value if it is extinguished by using six streams. In such cases the value of the water is chiefly in saving adjacent buildings, and for this purpose even small streams are of great value. For streets in a district where the houses are small and occupy comparatively large lots with no prospect of any considerable increase in density of population, and where extensions of the mains are not likely, a hydrant which will furnish 300 gallons per minute under a suitable head to any building in the territory supposed to be covered by this hydrant will be good fire protection. More is desirable, but the advantages are not sufficiently great to warrant the expense of larger mains to secure it. In a district where the houses are nearer together, but where there are no business blocks, apartment houses or other large buildings, it should be possible to get 500 or 600 gallons per minute at any point. Where there are business blocks and other large buildings and where the buildings are very close together, as they frequently are in the centre of a small village, it should be possible to get 1,000 gallons per minute. Where there are factories or other special fire risks a much larger quantity may be necessary, and a special study should be made of each case.

Pressure and Hydrant Spacing.—The pressure required at the hydrants while the hydrants are being used should be great enough to force the water through the greatest length of hose which will be used and throw it to a sufficient height to cover any building. The hydrant spacing and the pressure should, therefore, bear some relation to each other. Table I., from E. B. French, gives the limit of a good, efficient fire stream with different lengths of good, rubber-lined cotton hose, with a constant pressure of 60 lbs. at the hydrant, with moderate wind. Table I. also gives the corresponding amount of water which would be discharged.

* Read at a meeting of the New England Waterworks Association.

Table I.—Height and Volume of One $1\frac{1}{8}$-Inch Stream Flowing from a Smooth-Bore Nozzle.

Length of hose, ft.	Limit of height, ft.	Discharge, gals. per min.
100	67	250
200	59	222
300	52	206
400	44	188
500	40	178
700	33	158
1,000	25	140

Table I. shows the importance of having hydrants near the buildings to be protected. Unless the hydrants are near enough to furnish water at the fire under a good pressure, the expense of large pipes and a high reservoir is largely wasted. The cost of a two-way hydrant in place is about $40, and in the ordinary distribution system about eight hydrants are required per mile of street main to keep the hydrants within 250 feet of every building in the territory covered; so that the expense of hydrants is very small compared with the expense incurred in other parts of the system to obtain efficient fire protection. In general, hydrants should not be more than 500 feet apart in the outlying sections. In the more closely built-up sections they should be so spaced as to make it possible to get the number of streams which are considered necessary at any particular point with the use of not more than 300 feet of hose for each stream. This figure may be modified, however, if the pressure is unusually high, and should be if the pressure is unusually low.

The minimum pressure desirable for good fire protection with hydrants spaced as suggested is about 50 pounds per square inch at the hydrants when they are in use. This pressure will give, with 300 feet of best quality hose and a $1\frac{1}{4}$-inch nozzle, a stream of 185 gallons per minute, which can be thrown to a height of 44 feet. With 200 feet of hose the quantity thrown would be about 200 gallons per minute, and the height would be increased to 50 feet. There are cases where in the higher sections of the town these pressures are almost impossible, and in such places the hydrants should be so located as to require as little hose as possible. In the case of thickly built-up villages, the pressure should be 60 pounds per square inch at the hydrant when the water is being drawn at the maximum rate. This pressure will give a stream of more than 200 gallons per minute with 300 feet of hose, and with 200 feet of hose will throw 222 gallons per minute to a height of about 60 feet.

Size of Mains.—The size of the mains depends entirely on the requirements determined on to give fire-fighting facilities and on the head available. When these are known the system can readily be designed. Generally, however, the head which can be secured is not fixed, but can be made whatever is desired by going to additional expense, and the determination of the most economical arrangement of height of reservoir, size of pipes and spacing of hydrants is a matter for careful study. The rule adopted in many places to put in no street main less than 6 inches in diameter in most cases works out properly, but there is no excuse for it as an arbitrary rule. A short street will many times be better served with a 4-inch pipe than other streets in the same system with 6-inch mains, and the money saved by using the smaller pipe could well be expended in strengthening those parts of the system which are weaker. The standard should be the quantity of water the pipe will deliver and the head under which it delivers this amount. If a 4-inch pipe will do this satisfactorily, there is no good reason why it should not be used.

The loss of head due to friction in a 6-inch pipe which has been in the ground for some time, when water is being drawn at the rate of 300 gallons per minute, is about 10 feet per 1,000 feet of length, and this figure, together with the required pressure at the hydrant of 50 pounds per square inch, should, in general, determine the allowable length of 6-inch pipe as a dead end.

The maximum desirable pressure is a matter on which there is much disagreement, but the limit is constantly being extended. If it should prove to be more economical to have a system where the pressure runs up to 150 pounds, there would seem to be no good reason why this should not be done in a new system of waterworks, and it would be likely to prove much more satisfactory than to maintain two levels. In 86 small towns in Massachusetts the average static pressure in the central portion of the town is 79 pounds per square inch. Nine of these towns have pressures of less than 50 pounds; 33 have pressures of from 50 to 75 pounds; 21 from 75 to 100 pounds, and in 13 the pressure is more than 100 pounds.

Pumping Engines.—The development of the oil and gasoline engine has done much to make waterworks systems for small places financially possible. When the only available pumping machinery was the steam pump, the cost of installation of pumps and boilers, the cost of the pumping station to house them, and the cost of maintaining the plant made waterworks practically out of the question unless a gravity supply could be secured. With the new form of engine, however the conditions are quite different. The cost of the machinery has been greatly reduced, the cost of the station is much less, and the cost of operating is reduced to a minimum on account of the fact that with oil or gasoline there is no consumption of fuel except while work is being done, while with a steam plant a large proportion of the coal is used in banking the fires and getting up steam. Electricity is also becoming an important factor in connection with small pumping plants, although the cost of current is so great (in New England) that there are few places where oil or gasoline are not more economical except for auxiliary plants used only occasionally.

Pumps should usually be designed for the greatest economy in doing the work which they are called upon to do regularly in supplying the domestic needs of the town without regard to their use for fire protection purposes. It is seldom feasible in the small system to have pumps of sufficient capacity to be of very great value in case of fire, and dependence for fire protection should be placed on water stored in a reservoir or large standpipe or tank, or on some connection with factory pumps through which a large supply of water can be quickly secured. With increased size of pumps it is necessary to have a larger force main, a larger suction pipe, more wells, if the supply is taken from driven wells; in fact, a considerable portion of the plant must be increased in size and made more expensive in order to operate large pumps. Large pumps are somewhat more efficient than small ones, and if an attendant remains at the station while the pumps are in operation there is a saving in the shorter hours required with the large pump. With the oil engine, however, or with electricity, constant attendance is unnecessary, especially in the case of the smaller plants.

Pumping machinery should always be provided in duplicate, and works, although designed to run most

economically when one unit is in operation, can be operated, if necessary, at double capacity with a somewhat reduced efficiency. A plant designed for a community which will use from 100,000 to 150,000 gallons per day, should generally have a capacity of about 250 gallons per minute for each unit. This would mean the operation of one of the pumps for from six to ten hours each day. Such a plant would give two large fire streams in case of fire by starting both of the pumps. Many pumping plants are undoubtedly of too large capacity for economy, and the tendency in recent years has been to make them smaller, especially when the power used is some form of internal combustion engine.

Distributing Reservoir.—The design of the distributing reservoir is affected chiefly by the topography, the requirements for fire protection and by facilities for pumping. In a much less degree it is affected by the consumption of water. The effect of the topography upon the design is generally to change the reservoir from what is desirable to what is practicable. In a comparatively flat community it is practically impossible to store as much water at so great an elevation as is desirable, and in such cases the distributing reservoir must be cut down and other portions of the system must be designed to do the work which should properly be done by the distributing reservoir.

When the topography is such that it is feasible to build a reservoir of any desired size and any height, the design is dependent almost entirely upon the requirements for fire protection. Generally, it is found that the desirable static pressure from the reservoir at the point where there is likely to be the greatest demand for water is from 80 to 100 pounds, depending to a large extent upon the distance from the reservoir to the centre of distribution. The reservoir should be, if practicable, large enough to hold at the required elevation, in addition to the domestic supply for 24 hours, a sufficient quantity of water with which to fight any fire which is likely to occur. A fire in the built-up portion of a village may take about 1,000 gallons per minute, or 60,000 gallons per hour. In general, the time during which this quantity will be required will not be more than from two to four hours. Applying this rule to the ordinary town with no large fire risks, the capacity of the reservoir to standpipe should be from 300,000 to 400,000 gallons.

Pipe Thickness.—The part of the design in which theory plays the smallest part, and in which even experience is likely to count for little, is in the determination of the thickness and weight of cast-iron mains. The static pressure which pipes have to withstand and the breaking strength of the cast-iron are the only elements in determining the proper thickness of the pipes which are even approximately known, and determining the thickness from these elements alone would give pipes of about the thickness of cardboard.

The formula used by the New England Waterworks Association is:—

$$t = \frac{pr}{1/5\ (16,500)} + \frac{p'r}{1/5\ (16,500)} + 0.25$$

where t is the thickness of the shell in inches; r, is the radius of the pipe; p, the static pressure in pounds per square inch; p', an assumed water hammer in pounds per square inch; 16,500 is the breaking strength of cast-iron; and 5 is a factor of safety.

The chief uncertainties in the determination of the proper thickness of pipes are the water hammer, the effect of corrosion, the possibility of breakages in handling, the strains due to imperfect foundations or unequal settlement, and the eccentricity of castings and other imperfections in the pipe. There is no reason why the water hammer in a small system should not be kept below the figures ordinarily used in the formula. There are few, if any, authentic cases where corrosion of a cast-iron pipe has caused its failure. In fact, if a pipe has been in the ground long enough to corrode, it seldom fails from any cause. The strains due to imperfect foundation and settlement, in the case of small pipes, can be neglected if proper precautions are taken during construction. The difficulties due to imperfections in the casting and to the handling of thin pipes are the most serious, and to overcome these is the duty of the founders. That they will be overcome, if the engineers insist on light pipes, there is no doubt, for already much has been done along these lines; the cost per ton may be somewhat increased if lighter pipes are used, but this increased cost will be nothing like the saving accomplished by the use of the lighter pipe.

In my own practice I have put in many miles of Class C pipe where the pressures run up to 115 pounds per square inch and have never known of a failure which would have been prevented by using thicker pipe. The breakage in the handling may be or may not have been greater. In any case, it was not excessive. For the ordinary conditions in a small town I would never use a heavier pipe than the Class C, and lighter pipe may safely be used in many cases.

Depth of Cover for Pipe Lines.—The depth to which street mains should be laid has been investigated by a special committee of the New England Waterworks Association (see report presented at November, 1909, meeting), and the experience of the cold winter of 1911-12 has given valuable experience to those who have had charge of waterworks. The depth determined on affects the cost of the works materially, especially if rock is encountered, and if it is safe to reduce the depth it certainly should be done.

Theoretically, street mains might be laid at different depths in different soils, being a foot nearer the surface in clay than in gravel, but in the average New England town there are so many soils that it is not wise to make any distinction. The only discrimination which it would appear safe to make is in the case of places where the ground water always stands near the surface; here the pipes may be laid in shallow trenches. The freezing of the pipes is such a serious matter that it would seem to be unwise to take any chances in an attempt to save money on trench excavation. The best practice seems to be, for a climate like that of Massachusetts, to have the centre of the pipe from 4.75 to 5 feet beneath the surface.

OPPORTUNITIES FOR EXPORT OF RAILWAY MATERIAL.

German exports of rails to South Africa last year were valued at $300,000, and that of rolling stock at $120,000, according to a report of the Department of Trade and Commerce. Canada should make progress in both these items in the future. Under the item of locomotives, Germany's trade for 1913 was only $22,000. In addition to the railway material imported under the general heading, there were also imported in 1913 for the Union Government: rails, $1,315,000; sleepers, $897,000; locomotives, $570,000; rolling stock, $1,742,000, and under the item, all other, $329,000. The only line which Germany shipped was under all other, and her total was only $15,000. This year a number of locomotives and cars were ordered in Germany and under normal conditions she would have figured both this year and next in the Union Government's imports.

TRANSMISSION LINE CHARACTERISTICS.

By E. Maerker, A.Sc.
Designing Structural Engineer, Toronto.

(Continued from October 15th issue.)

An article on transmission line characteristics by the same author appeared in the issue of October 15th, dealing with 250,000 C.M. copper wire and 400,000 C.M. aluminum wire, both for 600-ft. spans. In transmission line work the standard span (of, say 600 feet) cannot always be adhered to, due to river crossings, railways, highways, etc. For this reason a chart comprising various spans would be of great value. Furthermore, since Charts I. and II., in previous issue, give a complete picture of the behavior of the wire under different loadings and for different temperatures, a chart with no ice and no wind acting on the wire, would be more useful for stringing purposes, including, of course, the usual range of temperature.

Chart III. has been drawn up for this purpose for a 250,000 C.M. copper wire, ranging from a 200-ft. span to a 1,000-ft. span, with no ice and no wind acting on the wire. It is to be understood that all these spans pull up to 5,900 lbs. at 0° F. with ½ inch of ice and 8 lbs. per square foot of wind pressure on the wire, as explained in previous article. In Charts I. and II. the points of intersection were solved graphically by assuming values for S_1, the sag, and computing the corresponding values for P_1, the tension. In Charts III. and IV. all points of intersection will have to be solved algebraically and then plotted.

Following equations of previous article are employed:

Modified equation (2) $L_1 - L_0 = L_0 \alpha t + \dfrac{P_1 - P_0}{a E} L.$

Equation (4) $P_1 = \dfrac{w_1 l^2}{8 S_1}$

Solving for P_1 in the former equation, we have:

$$P_1 = \frac{L_1}{L_0} a E - [a E (1 + \alpha t) - P_0]$$

and substituting for L_1 and L_0 its equal $l + \dfrac{8 S_1^2}{3 l}$ and $l + \dfrac{8 S_0^2}{3 l}$ respectively, we obtain:

$$P_1 = \frac{3 l^2 + 8 S_1^2}{3 l^2 + 8 S_0^2} a E - [a E (1 + \alpha t) - P_0]$$

$$= \frac{3 l^2 a E}{3 l^2 + 8 S_0^2} + \frac{8 S_1^2 a E}{3 l^2 + 8 S_0^2} - [a E (1 + \alpha t) - P_0]$$

but $S_0^2 = \dfrac{w_0^2 l^4}{64 P_0^2}$ and substituting this in above:

$$P_1 = \frac{3 l^2 a E}{3 l^2 + \dfrac{w_0^2 l^4}{8 P_0^2}} + \frac{8 S_1^2 a E}{3 l^2 + \dfrac{w_0^2 l^4}{8 P_0^2}} - [a E (1 + \alpha t) - P_0]$$

Rearranging and simplifying terms:

$$P_1 = \frac{a E}{\dfrac{l^2}{8}\left(3 + \dfrac{w_0^2 l^2}{8 P_0^2}\right)} S_1^2 + \frac{a E}{\dfrac{1}{3}\left(3 + \dfrac{w_0^2 l^2}{8 P_0^2}\right)} - [aE (1 + \alpha t) - P_0]$$

Eliminating P_1 by using equation (4):

$$\frac{w_1 l^2}{8 S_1} = \frac{a E}{\dfrac{l^2}{8}\left(3 + \dfrac{w_0^2 l^2}{8 P_0^2}\right)} S_1^2 + \frac{a E}{\dfrac{1}{3}\left(3 + \dfrac{w_0^2 l^2}{8 P_0^2}\right)} - [a E (1 + \alpha t) - P_0] \quad (6)$$

Equation (6) is a reduced cubical equation of the form

$$x^3 + px + q = 0$$

S_1 being the unknown quantity. All other quantities are constants for a definite span and temperature.

Table VII. has been compiled to solve equation (6).

$a E = .19635 \times 16,000,000 = 3,141,600$; $\alpha = .0000096$
$w_1 = .762$
$w_0 = 1.788$
$w_0^2 = 3.1969$
$P_0 = 5,900$
$P_0^2 = 34,810,000$

With these values substituted in equation 6, we are now able to solve for the sag, S_1. This is easily accomplished by trial with two sets of slide rules, as follows:

Let it be desired to find the sag for a 400-ft. span at 90 degrees F. With values substituted from Table VII., equation 6 will reduce to $\dfrac{15,240}{S_1} = 52.3\,S_1^2 + 3,139,678 - 3,138,415$, and finally $\dfrac{15,240}{S_1} = 52.3\,S_1^2 + 1,263.$

With the left-hand side of the equation operated by the setting of one slide rule and the term $52.3\,S_1^2$ operated by the setting of the other, the value for S_1 will soon be found by successive trials. In this case we have, assuming $S_1 = 5.43$ ft., $\dfrac{15,240}{5.43} = 52.3 \times 5.43^2 + 1,263$ or $2,810 = 1,545 + 1,263 = 2,808$, which gives the sag sufficiently accurate.

Table VIII. has been figured accordingly and the values for P_1 computed from equation 4 $P_1 = \dfrac{w_1 l^2}{8 S_1}$.

Chart III. has been drawn up with the tension as the horizontal axis and the sag as the vertical axis. Any values for spans between those shown, can be interpolated with sufficient accuracy.

Chart III. is indispensable for the purpose of stringing wire at any temperature. It brings out a very important factor which, to the author's knowledge, has been disregarded in the construction of many transmission lines.

Coupling a 600-ft. span with a 200-ft. span, it is seen that at 120 degrees F. the tension for the 600-ft. span is 2,465 lbs., and for the 200-ft. span 2,350 lbs., a difference of 115 lbs. in favor of the longer span. At -30 degrees, the 600-ft. span has a tension of 4,110 lbs. and the 200-ft. span a tension of 6,400 lbs., a difference of 2,290 lbs. in favor of the shorter span. These 2,290 lbs. represent a dead pull along the line and too great a stress on the insulator and the supporting structure, especially if this particular tower should happen to be at an angle, in which case the insulator would have to bear the stress due to the angle in addition to the stress of 2,290 lbs., as mentioned above.

It will be noticed here that, although a maximum tension of 5,900 lbs. is specified at 0° F., with ice and wind, the tension for a 200-ft. and 300-ft. span at -30°

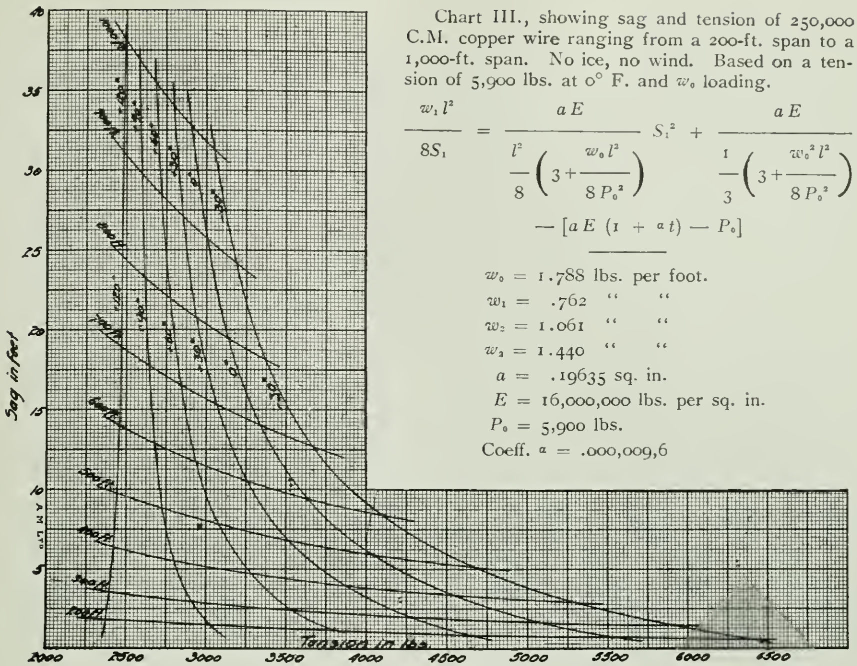

Chart III., showing sag and tension of 250,000 C.M. copper wire ranging from a 200-ft. span to a 1,000-ft. span. No ice, no wind. Based on a tension of 5,900 lbs. at 0° F. and w_0 loading.

$$\frac{w_1 l^2}{8 S_1} = \frac{a E}{\frac{l^2}{8}\left(3 + \frac{w_0 l^2}{8 P_0^2}\right)} S_1^2 + \frac{a E}{\frac{1}{3}\left(3 + \frac{w_0^2 l^2}{8 P_0^2}\right)} - [a E (1 + \alpha t) - P_0]$$

w_0 = 1.788 lbs. per foot.
w_1 = .762 " "
w_2 = 1.061 " "
w_3 = 1.440 " "
a = .19635 sq. in.
E = 16,000,000 lbs. per sq. in.
P_0 = 5,900 lbs.
Coeff. α = .000,009,6

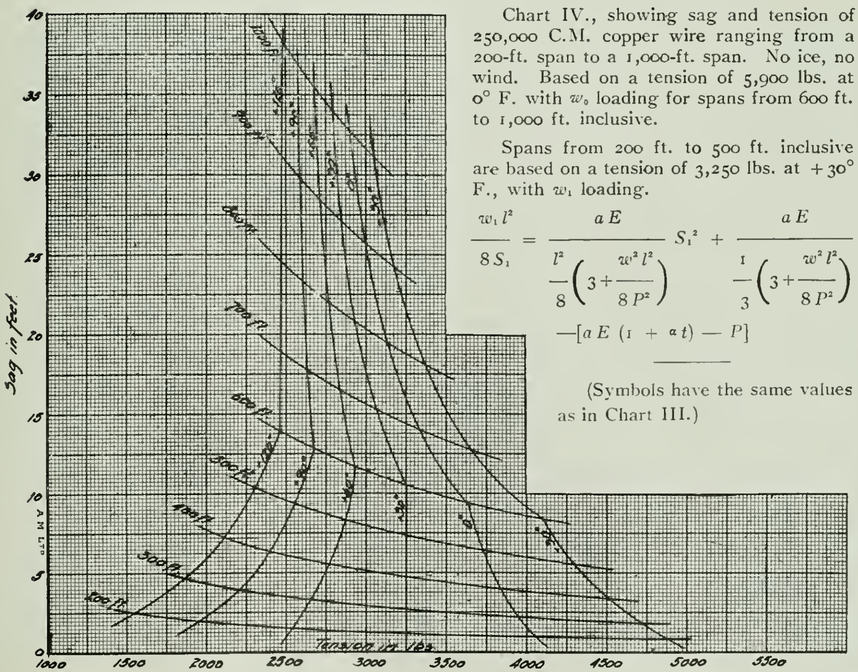

Chart IV., showing sag and tension of 250,000 C.M. copper wire ranging from a 200-ft. span to a 1,000-ft. span. No ice, no wind. Based on a tension of 5,900 lbs. at 0° F. with w_0 loading for spans from 600 ft. to 1,000 ft. inclusive.

Spans from 200 ft. to 500 ft. inclusive are based on a tension of 3,250 lbs. at +30° F., with w_1 loading.

$$\frac{w_1 l^2}{8 S_1} = \frac{a E}{\frac{l^2}{8}\left(3 + \frac{w^2 l^2}{8 P^2}\right)} S_1^2 + \frac{a E}{\frac{1}{3}\left(3 + \frac{w^2 l^2}{8 P^2}\right)} - [a E (1 + \alpha t) - P]$$

(Symbols have the same values as in Chart III.)

with no ice and no wind is exceeding this value and the computation for these two spans would have to be based on 5,900 lbs. at -30° F. with no ice and no wind. Since the stringing of all spans is usually based on the same assumption, *i.e.*, maximum tension at a low temperature under maximum loading, there is bound to be a dead pull along the line with unequal spans, as seen from Chart III. The author has seen cases where the line turned a slight angle and a standard tower was found sufficiently strong to resist this additional sidepull. However, a short span was used on one side of the tower, toward the angle, presumably to counteract the sidepull. This, of course, made matters worse and added to the pull on the insulator and tower, instead of relieving the stress.

The influence of the temperature in the tension is much greater for short spans than for long spans. It is

not always sufficient to base all computations on a maximum loading at 0 degrees F., but investigate the tension at the lowest temperature with a w_3 loading, especially for short spans. (See Charts I. and II. in previous article.) Since unequal spans cannot be avoided in transmission line work, the absolute pull along the line can be lessened materially. This is accomplished by reducing the tension for the shorter spans, *i.e.*, by altering the assumed basis of maximum loading at 0 degrees F. The ideal condition would be to have a +45 degrees temperature curve run vertically and the intersection points for all spans equidistant from this line (Chart III.). This would distribute the stress equally. From Chart III. we notice that at +30 degrees and a 600-ft. span, the tension is, say 3,250 lbs. By producing this +30 degree temperature curve vertically down and rectifying all curves below this point accordingly, we are able to distribute the stress more equally. The new basis to work from now is 3,250 lbs. at +30 degrees F. with no ice and no wind for spans ranging from 200 ft. to 500 ft. inclusively. The values for this new basis of w_1 loading (no ice and no wind) and 3,250 lbs. tension at +30 degrees F. will have to be substituted in equation 6.

w_1 is to be substituted for w_0, and 3,250 lbs. for P_0, and the temperature is to be based on +30° instead of 0° as before.

Table IX. shows these corrections and substituted in equation 6, we again solve for values of S_1 and P_1.

Table X. gives these new values for the sag and the tension, and plotted, we obtain the rectified curves for spans from 200 ft. to 500 ft., as shown on Chart IV.

It will be noticed that the tension for the 200-ft. span has been reduced to 4,880 lbs. at –30 degrees F.

If we attempt to couple this span with a 600-ft. span, we have a difference of 4,880 — 4,110 = 770 lbs. at —30° F. in favor of the short span and at 120° F., a difference of 2,465 — 1,545 = 920 lbs. in favor of the longest span, against a former difference of 2,290 lbs.

By proper substitutions we can figure what tension these spans would reach at 0° F. and maximum loading, and also at —30° F. and w_3 loading. The latter being the critical value. By substituting for this critical value in equation 6, we find a maximum tension of 5,520 lbs. for a 200-ft. span, which is less than the allowable tension of 5,900 lbs. In conclusion, it might be said that Chart IV. gives all necessary information to the engineer in the field for stringing wire according to the best engineering practice.

CEMENT AND PLASTER OF PARIS.

In 1912, Australia imported 2,603,792 cwt. (of 112 lbs.) of cement (Portland) to the value of £261,680. Of the quantity stated, Germany was the country of origin of 1,393,456 cwt., valued at £144,564, while Belgium contributed 269,760 cwt., valued at £25,879. Favorable freight rates and the quality of brands established on the market for many years were contributing factors to this trade. Australian manufacturers of cement have notified an increased output, but when present stocks of imported cement are exhausted there should be a market available for Canadian manufacturers, established near shipping port, to exploit.

In 1912, the imports of plaster of Paris, approximately, were 251,051 cwt., valued at £39,104, of which Germany contributed 116,659, valued at £17,184. This item is of particular interest to the manufacturers of plaster of Paris in Nova Scotia and New Brunswick, one brand of which is becoming favorably recognized in Australia. The plaster must be dead white to meet the requirements of the trade and any pink shade in the material will condemn it.—Canadian Trade and Commerce Report.

STANDARDS WITH REFERENCE TO SEWAGE TREATMENT.

By R. O. Wynne-Roberts,
Consulting Engineer, Regina.

IN the latest issue of the Public Health Journal there appears the paper on the above subject, which Mr. T. Aird Murray read at the Public Health Convention held in Regina in September, 1913. His paper was relegated to the tail end of the convention, and it was with regret that many found the time too limited for a full discussion.

Mr. Murray started by stating that engineers, when called upon to design sewage treatment work, will naturally "ask the Provincial authority to state what it expects and will insist upon with reference to the degree of purification and manner of sewage treatment." This would be an excellent procedure, but he further on states that it is "impossible to adopt any general standard of required degree of purity, and that each case under consideration requires separate adjustment with reference to local conditions and requirements." This places the engineer in an anomalous position, for he is left in doubt as to what may be required.

It should, however, be possible to give the engineer some indication as to what will be demanded to satisfy the provincial authorities as regards design, capacity and degrees of purification under certain specific conditions. Such requirements cannot, of course, be rigid or stereotyped, but should possess sufficient elasticity.

Mr. Murray next referred to the standards suggested by the Royal Commission on Sewage Disposal in their fifth report. These standards were revised in the eighth report and bear little resemblance to those quoted.

The revised standards are, that the effluent should not contain more than 3 parts of suspended matter per 100,000 parts, and with the suspended matter should not take up more than 2 parts of oxygen per 100,000 at 65° F. in 5 days. If the dilution is very low, then it is proposed to make the standard more stringent. If the dilution is from 150 to 300 volumes, the dissolved oxygen test may be omitted and 6 parts of suspended matter per 100,000 permitted. If the dilution is from 300 to 500 volumes, the suspended matter may be 15 parts per 100,000, and when the dilution is over 500 volumes crude sewage may be discharged into the stream after the coarser particles have been removed by detritus tanks and screens.

Mr. Murray appears to consider the British standards as inapplicable to Canadian conditions. It may be that they are less stringent than is desirable here, but that is only a question of degree of purification. These standards, however, afford the basis for others more or less stringent, and have been favorably considered by American authorities, for expert chemists, bacteriologists, sanitarians and engineers recognize that the purity of the effluent must be based upon the dissolved oxygen tests, the character of the bacteria, and the quantity and nature of the sediment contained in such effluent.

To ensure as uniform a quality of effluent as possible, it is necessary to conduct regular tests, and this entails the employment of chemists and bacteriologists as well as engineers, which would mean a heavy charge in the case of the smaller towns and cities. Even the employment of chemists and bacteriologists to conduct daily investigations will not obviate the discharge of unsatisfactory effluents, because sewage disposal plants are subject to disturbances, such as failure of pumping ma-

chinery, surcharging due to storms, fluctuation in flow of sewage, and to the frailty of human agencies in the management of such works.

The following extract from the report of the Royal Commission on Sewage Disposal was quoted by Mr. Murray: "That any authority taking water from such rivers for the purpose of water supply must be held to be aware of the risks to which the water is exposed, and that it should be regarded as part of the duty of that authority, systematically and thoroughly, to purify the water before distributing it to their customers." Bearing in mind the contingencies inherent to works of this kind, operated under such fluctuating and variable conditions, and by agencies which are inevitably more or less inconstant, the above advice is as reasonable in Canada as anywhere else. The risks are too great to allow of any town consuming water which is liable to contamination. The discovery of contamination is often subsequent to an outbreak of disease, and to depend on effectual purification of sewage effluent before its discharge into a stream is a risky procedure. Sewage treatment is one which varies hourly and daily. It is affected by climatic and meteorological influences, and by manufactural wastes. Its final oxidation by effectual dilution is affected by the fluctuating river flows, by varying velocities of the recipient stream, by the nature of the stream beds and surroundings, by seasons, and by the means adopted for dispersion and diffusion of the effluent.

Dr. Dunbar, when dealing with the pathogenicity of effluents, remarked that "in the case of rivers which serve as sources of water supply, attempts should be made to restrict the infection to a minimum." Whilst this advice is good, it introduces an interesting point, namely, the possibility of pathogenic germs surviving in sewage-polluted waters. Dr. Houston, the Director of Water Examination to the Metropolitan Water Board of London, England, has for many years been conducting a series of researches in this connection. His report may be consulted by anyone interested in this matter. It is the Ninth Research Report, published in April, 1913.

It is not necessary to enter into the details, but it may be stated that 28 samples of crude sewage-polluted waters—one set of which was purposely infected with typhoid bacilli and the other set was not inoculated—were examined according to the most approved method recognized by specialists. The average number of excremental bacteria, as judged by the bile-salt-agar test, was 1,155,040 per c.c. of sewage. Five thousand four hundred and eighty-five colonies recovered from each set of samples were studied, but not one of the colonies from the non-infected samples gave the characteristics of typhoid bacillus, but in the case of the infected samples, out of an average of 205 typhoid bacilli added per 0.01 c.c. of sewage, an average of 20 were afterwards isolated. "The positive result with one set and a negative result with the other justifies the conclusion that whatever number of typhoid bacilli were added to one set of samples, that number could not have been present in the other." Dr. Houston also states that the Thames water in its present condition does not, on the average, contain one single typhoid bacillus per 24 c.c. of water. Over 50 per cent. of the raw water samples contain B. Coli in 0.1 c.c., and less than 25 per cent. of the filtered water samples had B. Coli in 100 c.c.; so, generally speaking, he "concludes, on the basis of the test, that the purification process improves the water at least 1,000 times," and that it requires some imagination to conjecture the possibility of an ordinary consumer of London water imbibing an infective dose of typhoid malarial from this source, always assuming the absence of any accidental infection of the water between the works and the tap."

Like Worcester, Hereford, Shrewsbury and other towns in England, drawing water from contaminated streams, London depends on its supply of water from the Rivers Thames and Lea, both of which are observably contaminated with more or less sewage from a large number of towns, yet the typhoid fever death rate is only 3.3 per 100,000. The water is, of course, carefully stored and filtered before being distributed to the consumers.

The typhoid bacillus is rarely found in sewage, but, assuming a stray one does survive, Dr. Houston submits that it is difficult to believe that "the ingestion of a solitary typhoid bacillus would be likely to produce typhoid fever, even in a highly susceptible individual."

The above named authority, when discussing the incidence of typhoid fever in North America, which is usually attributed to the consumption of impure water, suggests that it may be due to accidental pollution by typhoid "carriers," of whom it is estimated there are about 3 or 4 per 1,000 inhabitants. Dr. Houston submits that the discharge of one person is potentially more dangerous than that of a community. As an instance of this the writer may refer to an epidemic of dysentery which occurred about eight years ago at Simon's Town, South Africa. When it was investigated it was discovered that a Kaffir suffering under that ailment had been employed on the watershed near the head works, and that on the next day there was a heavy rainfall, which evidently washed the filth into the water mains with the above result.

The writer may at a future date further discuss the incidence of typhoid fever from the engineer's point of view, but the foregoing will suffice to indicate that the problem of sewage treatment is one, the principal function of which is to safeguard the health of the public, as far as it is possible. But it is unwise to depend on such treatment to assure a pure water supply, even though thorough sterilization of the effluent is effected. In some parts it is difficult to secure an outfall which will not affect the water supply of a neighboring district. On the other hand, certain towns have contaminated streams or lakes as the most available source of water supply. The duty which devolves on the city authorities is to attain the highest possible efficiency in the treatment of sewage and in the purification of water. There nevertheless remains a duty on the provincial authorities to formulate a standard, and whilst some governmental officials consider it impossible to establish regulations as to the degrees of purification of sewage necessary under different conditions, it is becoming recognized that certain standards, subject to modifications to meet different requirements, can be formulated.

The Royal Commission on Sewage Disposal has published its proposed standards, which have already been quoted in the foregoing.

The authorities in Lancashire, Derbyshire and Yorkshire have their standards. Prof. Phelps submitted in connection with New York sewage disposal that the recipient waters should contain 70 per cent. of possible saturation of dissolved oxygen. Mr. Soper, chairman of the New York Sewerage Commission, considers that a definite standard of cleanness should be established as a guide for future operation. Dr. Winslow expressed an opinion that arbitrary standards are not feasible or desirable, but it is feasible to formulate standards as guiding principles, to be intelligently interpreted in the light of available knowledge in individual cases. He submits that the dissolved oxygen content of recipient waters

should not be less than 50 per cent saturation. There should be no effervescence, marked discoloration, decided turbidity, oily, sleek, floating, solid sewage material deposits of sludge or other conditions offensive to sight or smell.

With regard to the purification of polluted water, the International Joint Commission re Pollution of Lakes report that the number of B. Coli per 100 c.c. should be expressed as annual average, that the safe limit of loading water purification plants is exceeded when the annual number of B. Coli in the water delivered to the plant is higher than about 500 per 100 c.c., or when in 0.1 c.c. samples of water B. Coli is found over 50 per cent. of the time.

ELECTROLYTIC TREATMENT OF SEWAGE.

THE purification of sewage by electrolytic treatment has received considerable investigation during the past season by the Borough of Queens, New York City. A plant was installed at the Elmhurst disposal plant on March 26, 1914, for the purpose of observing the effect of the electrolytic and electro-chemical method devised and patented by Mr. C. E. Landreth, of Philadelphia. The process is being introduced by the Electro-Chemico Corporation of New York. It includes screening, passage through an electrolytic machine with addition of lime, and sedimentation for about half an hour. The sludge is dried by filter press. Both the tank effluent and the water extracted from the sludge are stated to be clear, almost devoid of bacteria, and non-putrescible. A report has recently been issued upon the operation and results obtained. From this report, written by Elmer W. Firth, C.E., Ph.D., Engineer of Maintenance, the following information is presented:

The sewage reaching this plant is very variable in composition. Cesspool wastes are permitted to be emptied from tank wagons into a sewer manhole adjacent to the receiving well. The capacity of these wagons varies from 400 to 1,040 gallons and on some days nearly a hundred loads of this strong sewage are added to the normal flow. This contribution will run from 10,000 to 60,000 or more gallons per day in a normal sewage flow of about 800,000 gallons. On the other hand, storm water and ground water render this sewage at times very dilute. The contribution of this cesspool waste has greatly increased the difficulty of treatment by the old methods.

History of Electrolytic Treatment of Sewage and Water.—It should be noted at the start that the present investigations were undertaken with full knowledge of the history of electrolytic appliances as they have heretofore been employed for sewage and water purification; their limitations and failures, the employment of correct principles and on the other hand the unscientific and ridiculous attachments which have from time to time been tried and then discarded as useless. All this, as recorded in the literature on the subject, has been sufficiently discouraging to serve as a warning against blinding enthusiasm for new methods. A brief review of previous efforts in this line will be helpful in comparing the process under consideration with its forerunners.

Electrolytic phenomena have been employed in two ways: First, by the immersion of electrodes in the sewage or water to be treated, and second, by the production of hypochlorites from salt solutions, to be subsequently added to the liquid under treatment.

William Webster, of England, appears to have been the first to utilize the principle of electrolysis in the purification of sewage about 1889, when it was tested on a small scale at Crossness and at other places. His patented process consisted in passing sewage through flumes in which iron or aluminum electrodes were immersed, and he called attention to the oxidizing and precipitating effect and suggested also the production of hypochlorite, which idea was developed three or four years later by Hermite, of France, and Woolfe, of America, in the manufacture of hypochlorite from common salt solution, or from sea water. These two similar ideas could not successfully compete with the cheaper production of hypochlorites on a larger scale and often as bi-products, and their processes appeared to have no advantage beyond the action of the disinfectant. The Woolfe "Electrozone" was used at Brewster, New York, and for a while at Danbury, Conn. The Hermite process was used at Ipswich, England, where the liquid hypochlorite was run into the main sewer. This was abandoned in 1905, after about ten years' operation, because the results obtained were not commensurate with the cost.

It is now recognized that where disinfection alone is desired, the expense is much reduced by applying the reagent as a finishing process after much of the organic matter has been removed from the sewage by sedimentation or filtration. It will, therefore, be perceived that these two processes showed no advance over the Webster process toward the complete purification of sewage.

Under the Harris patents, which were similar to the Webster process, experiments were made on Passaic River water about 1893, and the system was tested again at Louisville, Ky., by Mr. George W. Fuller, in 1896, and his report, "The Purification of the Ohio River Water at Louisville," refers to it as a complete failure. Harris had introduced magnets and a "sparking drum" for passing high-tension electric currents through the liquid, and notwithstanding Mr. Fuller's conclusion that they were absolutely useless, these features were again employed at Santa Monica, Cal., in 1908, but were finally abandoned, resulting in a return to the simple principles utilized by Webster. Alternate iron and aluminum electrodes were used at Santa Monica, spaced about ⅝ in. centre to centre, until it was found that the plates lasted only about three weeks. Later the electrodes used were all iron and they were bound on top with strips of copper in an attempt to lengthen the life of the plates, and it was claimed that the production of copper sulphate helped in the treatment. The Harris patents were later taken up by The Electro-Sanitation Company of Los Angles, which company secured new patents stripped of all useless devices that had been discarded after trial, and in this form the system was again installed at Oklahoma City in 1911.

Experiments were recently made at Toronto on electrolytic apparatus fashioned on the lines of the Oklahoma plant, and the degree of purification effected, according to the published analyses, is not calculated to engender confidence in the process.

All the processes thus far mentioned have relied on the consumption of the iron electrodes by the action of acid ions liberated from any electrolytes normally present in the water or sewage. These acid ions attacking the iron plates produce a certain amount of ferric hydrate, which serves as a coagulant, but in the presence of carbonic acid much of this is dissolved and passes on in solution as ferrous carbonate. Other soluble ferrous salts, such as iron chloride and iron sulphate formed by the attacking ions, constitute additional drains on the metallic iron. This accounts for the failure of the processes mentioned to effect a removal of the suspended matters in the

sewage proportionate with the great amount of iron wasted.

It was concluded from the Louisville experiments that atmospheric oxygen served to oxidize the ferrous to ferric salts, thus airing the formation of coagulants, but that atomic oxygen, produced electrolytically, tended to oxidize the iron plates, thus constituting a serious disadvantage in the waste of electric power and metallic iron, and further, that atomic or nascent oxygen did not result in the destruction of bacteria or organic matter. This was all doubtless true of the processes then under observation.

Electro-Chemical Process.—These deficiencies have all been fully met in the process employed at the Elmhurst plant by what will now appear a very simple conception, namely, the introduction of lime with the sewage or water under treatment. The lime solution is added in sufficient quantity to neutralize the free and half-combined acid present and render the liquid slightly alkaline to phenolphthalein. The lime solution serves three purposes: 1st—It prevents the waste of iron electrodes by neutralizing the attacking acid ions; 2nd—The calcium hydroxide, being readily ionized, liberates nascent oxygen from the hydroxyl, while the positive calcium at the cathode reunites with water to form calcium hydroxide again; 3rd—A bulky hydrated calcium carbonate is produced which with any ferric hydrate formed furnishes a remarkable coagulant which settles out in a few minutes, carrying with it most of the suspended matter.

The notable effect of the nascent oxygen in the destruction of organic matter and bacteria is evident from the analyses made.

The first bacteriological tests made on samples taken from the electrolytic machine and from the small sedimentation tank in unsterilized bottles and placed an hour later in the laboratory, showed amazing results in that only one plate out of twelve made with gelatine and agar developed two or three colonies, the rest remaining sterile. Fermentation tubes also showed no gas production in 48 hours, while gas was formed from sewage samples in full quantity in 24 hours and the sewage plates were overgrown with colonies. These results inspired a more careful and systematic study of the effects produced under the conditions adopted for operation.

It has been suggested by some of the engineers and scientists who have inspected this plant that lime alone would have a sterilizing effect, but Dr. Samuel Rideal has observed that "caustic lime used even to the extent of 60 to 70 grains per Imperial gallon (860 to 1,000 parts per million) of sewage is inefficient in sterilization," so that the bacteriacidal effect must be due to the ionization of the calcium hydroxide.

The suggestion has also been made that lime itself has sufficient coagulating effect, without the use of electrolysis, but observations made at the Columbus, Ohio, experimental station showed that 5.87 grains of lime and 5 grains of copperas, with 8 hours retention in tanks, removed only 52% of the suspended matter, and 11% of the dissolved volatile matter, and that the dissolved mineral matter was increased 3% and the bacteria 18%. The statement was also made that 8 hours was insufficient to effect complete coagulation with this amount of coagulant, or to allow for the sedimentation of the precipitant formed in this time. The lime in the Columbus experiments was then increased to 20 grains per gallon and a satisfactory clarification was obtained, but it is stated that a sedimentation period of at least 24 hours following the application was required to prevent the escape of hydrated coagulant from from the precipitation tank. According to a recent report by Sir M. Fitzmaurice, Chief Engineer of the London County Council, lime is held to be of little benefit as applied to London sewage.

In the face of this evidence a single observation of the wonderful coagulation and rapid sedimentation produced immediately with the use of lime in the Elmhurst electrolytic installation will convince the most skeptical of the unique advantage secured by electrolyzing this coagulating agent. The effect is to be ascribed to the hastening of chemical reactions under electric current.

No doubt the colloidal matters which may be assumed to be held in suspension by mutual repulsion of the microscopic particles, due to electric charges of similar polarity, owe their coagulation and precipitation, to a large extent, to neutralization of these charges by means of the current.

The conservation of the metallic iron of the electrodes is shown by the absence of color in sample of the effluent and by the small increase in the iron content, as shown by analysis. Inspection of the electrodes from time to time when the machine has been opened for the observation of visitors, showed no apparent corrosion, oxidation, or fouling, after 2½ months' use. The edges of the plates are still as sharp as when they were cut.

Other difficulties recorded both in the report on the Louisville experiments and in the application of electrolysis elsewhere, are: 1st—Polarization, and 2nd—The waste of iron electrodes even when the current is turned off, with the formation of deposits on the plates, which increase the power consumed in starting the process after a rest. The first of these difficulties is here overcome by the use of rotating elements in the form of paddles continuously operated between the electrodes. These serve several purposes, namely the prevention of polarization, the breaking up of solids in suspension, the cleaning of the plates, the mixing of the reagents produced electrolytically, and the bringing of all portions of the sewage into contact with the electrodes. It is hardly necessary to elaborate these suggestions, as the mechanical advantages will be apparent. It may, however, be well to explain that polarization is due to the tendency of ions to part with their electric charges more or less reluctantly, the positive ions attracted to the negative pole, for example, tend in some degree to remain positive and thus repel the following positive ions, which would otherwise be attracted. These are swept away by the revolving paddles. The breaking up of solids is important in view of the fact that sterilizing agents require some time to penetrate large masses or gelatinous membranes. The only other point which it seems necessary to note is that certain strata in the sewage flow tend to pass between the electrodes without coming in contact with them where the paddles are not used.

The second difficulty mentioned above, namely the waste of iron when the current is turned off, arises from reverse currents set up in the machine, which in the Elmhurst apparatus are taken care of by simply short-circuiting the iron electrodes with a zinc plate. The zinc being positive to iron attracts the current, thus saving the iron from decomposition and preventing the increased resistance observed in starting the electric current through the older devices.

Ten carbon electrodes which are placed in the Elmhurst machine at the point of entrance of the sewage, being electro-chemically passive, serve to utilize the common salt or other electrolytes normally present in the sew-

age, for the production of hypochlorite with its sterilizing effect. It will be noted that the lime solution used is introduced at a point above the carbon and just below the iron electrodes, for the reason that the electric current passes by way of the electrolyte which predominates, or which is more easily ionized, and the presence of the lime in the passive carbon electrodes would result in the dissociation of calcium hydroxide, rather than the sodium chloride, and no sodium hypochlorite would be liberated.

Description of Electro-Chemical Apparatus.—In the old process the sewage on entering the receiving well at the Elmhurst plant passes through a perforated metal screen with ⅝ in. circular openings, and is pumped to the level of the sedimentation tanks, from which it flows by gravity to sand filter beds. There are four of these old sedimentation tanks used in series, each holding about 65,000 gallons, and enclosed under the roof of the building.

In preparing for the tests on the new electrolytic process, the apparatus was placed on a temporary platform built over one end of the first tank in the old series above mentioned. This platform has a floor area of 18 x 24 ft., which provides sufficient room for a 2-in. centrifugal pump and motor, the electrolytic machine, lime solution tank, effluent sedimentation tank, platform scale and laboratory table. The pump was required only for the purpose of lifting the sewage treated to the higher level above the flow of the old tanks. A ⅜-in. perforated screen is used on the suction line of this pump. The electrolytic machine used is erected vertically, the sewage flowing through the bottom to top, the electrodes being entirely enclosed. It stands 7 ft. 3 in. high from the floor to its outlet pipe flange and is 24 in. x 18 in. in cross-section. The cypress frame enclosing the electrodes is 4 ft. 10 in. high, sets on a cast iron base, which holds also the motor-generator set, is capped with the outlet casting which is bolted through to the base by outside bolts at the four corners. The electrodes are set horizontally one above the other. At the bottom of the electrolytic machine one bank of 10 carbon plates, or electrodes, are placed and connected in series, and above this are four banks, each consisting of 12 iron electrodes. The alternate iron electrodes are connected in groups of three and these groups are then connected in series. The one bank of carbon plates is parallel with the whole set of iron electrodes, so that 9/10 of the current is taken by the carbon and 1/10 by the iron electrodes. The iron plates are connected so as to be automatically short-circuited to a zinc plate in the top when the operating current is shut off. A volt meter and an ammeter are attached to the front of the machine. The motor of the generator set furnishing direct current for the electrodes also rotates two ¾-in. vertical square steel shafts connected by gearing to the motor shaft. These vertical shafts carry paddles which operate between the electrodes continuously. The shafts are made in sections just long enough to pass through a single bank of electrodes and the sections are keyed together in the spaces between each bank. This arrangement supplies two paddles in each space between the electrodes and they are rotated in opposite directions, one slightly in advance of the other, with high mechanical efficiency since the water pressure generated by one aids in driving the other. The paddles are made of material which is non-absorbent, non-conducting and very durable. In this machine they are 9 in. long, ¼ in. thick and 2¼ in wide at the centre, tapering to 1⅛ in. at each end, while the shaft opening at the centre is a ¾ in. square.

The iron electrodes are made of a certain grade of low carbon steel and are 10 in. x 16 in. x 3/16 in. thick and spaced ⅜ in. apart. An opening is left at one end of the lower plate in each bank for the entrance of the sewage or water, which then is divided by the plates into thin films as it passes on to the next bank of electrodes. A space of 3 inches between each bank or section of electrodes facilitates the connection of the paddle shaft sections as they are inserted with each tank of plates when the machine is erected.

Lime Tank.—The lime solution tank used is 3 ft. x 5 ft. and 3 ft. deep, holding about 336 gallons. Lime solution is introduced into the electrolytic machine just above the carbon electrodes and mixes with the sewage as it passes from the carbon to the iron plates. In this instance a small plunger pump electrically driven was used to inject the lime, as there was not sufficient head room to secure a gravity flow into the machine. From the electrolytic machine the sewage flows through a weir box to provide means of measuring the quantity treated. This box is 23 in. x 37 in. x 17 in. deep, with a 3-in. pipe outlet into the sedimentation tank.

Sedimentation Tank.—A small sedimentation tank is provided to take the flow from the electrolytic machine. Its outside dimensions are 11.5 ft. x 7 ft. x 5 ft. and was built as a two-story tank with a false bottom sloping from a line 2 ft. below the top on one side, down to the front bottom edge, but as septic action plays no part in this process, the effluent is permitted to pass through the sedimentation slot and emerge from the 6-in. space between the side of the upper compartment and the outside wall of the tank. This space is usually provided for the escape of septic gases in biological processes when it would be filled with decomposing sewage. Notwithstanding the unsuitableness of the design, this tank has served as well as any, inasmuch as any form of tank properly baffled and with convenient means for removing the sludge, is all that is needed. Its effective capacity is only 1,550 gallons, which, at the rate of 25,000 gallons per day, gives a theoretical retention period of ½ hour. However, tests have shown that the clarified effluent leaves this tank in from 10 minutes to 1 hour. This was conveniently tested by the introduction of phenolphthalein, which holds its pink color in the slightly alkaline effluent throughout the flow through the tank. The strongest traces of color usually emerge in about ½ hour.

The time of flow through the electrolytic machine when 25,000 gallons per day were being treated, averaged about 2 minutes, though the first traces of color showed in 1 minute and all color of the indicator used had disappeared in 3 or 4 minutes.

The weir box was calibrated by means of a scale fastened to the inside. The flow was measured by weighing the effluent on a platform scale, and a curve was plotted to indicate the number of gallons treated per day for each reading on the scale in the weir box.

The quantity of sewage treated was generally held at 25,000 gallons per day to suit the capacity of the lime tank and the small sedimentation tank and also to maintain uniform character in the effluent, which, after settling in the small tank, was run into the large plant tank below, and there retained for observation.

Amount of Lime Required.—The amount of lime used will vary in each case with the normal free and half-combined carbonic acid contained in the sewage. The softer the water of the public supply, the less the amount of lime required for purification. The lime used at Elmhurst averages about 1,200 lbs. per 1,000,000 gal.

As shown by the analyses, the hardness of the Elmhurst water supply is 102 p.p.m., total hardness, and the lime necessary to overcome this is 496 lbs. per 1,000,000 gal. of sewage. Analysis of the effluent shows that the hardness is reduced 50%.

In treating the sewage of the Borough of Manhattan only 180 lbs. of lime per 1,000,000 gal. would be required to overcome hardness, since the total hardness of Croton water is only 40 p.p.m. This would indicate that only 941 lbs. of lime would have to be used per 1,000,000 gal. in the electro-chemical treatment of sewage in Manhattan.

Power Used.—The electric power supplied to this plant is alternating current, 2-phase, 220 volts, 60 cycle. The current used for electrolysis on a flow of 25,000 of sewage daily is 18 to 20 amperes, with a pressure of 7½ volts, or a power consumption of 135 to 150 watts, which is about 1/5 h.p. The carbon electrodes take about 9/10 of the current, the balance going to the iron electrodes; hence out of 20 amperes 18 go to the carbon and the remaining 2 amperes are seriesed 8 times on the iron plates, giving an efficiency of 16 amperes on the iron. Estimating the power required per million gallons from the above figures, and remembering that with the increase of plate area in larger machines, the voltage required to put through a given amperage is proportionately reduced, about 6 kw. should be sufficient to effect the high degree of purification obtained in these tests.

Where an electrolytic machine designed to treat 1,000,000 gallons is installed, and a similar reserve unit is added, the utilization of both machines simultaneously for the million-gallon flow should cut the voltage required in half, since the plate area is doubled and the amperage remains the same. This would also halve the cost of power, which is the product of the voltage by the amperage.

Improved Electro-Chemical Machine for Sewage Treatment.—The electrolytic machine tested here was designed primarily for water purification. An improved type for sewage purification is now being built. It is designed to be installed horizontally, with the electrodes in a vertical plane and set longitudinally to secure the advantage of having the grit drop to a bottom trough. This also minimizes wear on the electrodes due to the grinding of grit by the rotating paddles, which in the new arrangement will, of course, turn in a vertical plane. In the vertical machine tested at Elmhurst this wear, however, has been hardly appreciable, notwithstanding the surface of the electrodes underneath the paddles are more subjected to it. The large machines are about 20 ft. long and 3 ft. square. As is usual with most mechanical and electrical devices, higher efficiency may reasonably be expected with increasing size.

Effects produced.—The effluent from the electrolytic machine shows immediate coagulation and when taken in a glass and held to the light the flocculent precipitate is seen to increase rapidly in bulk and starts to settle immediately. The liquid between the coagulated particles at once appears clear. Grease is rapidly saponified by the lime under the hastening action of the electric current and precipitates out as lime soap. This effect can be illustrated by the simple experiment of adding lime to a soap solution and holding two carbon electrodes in it for a moment.

Grease is one of the most disturbing elements in the purification of sewage by biological processes, on account of its tendency to clog bacterial filters and dosing devices, and the difficulty with which it is decomposed and mineralized by bacteria. Electrolytic treatment is well suited to handle sewage of this character.

Nitrogenous organic matter in the sewage becomes highly oxidized in this process, and this, together with the dissolved oxygen produced, yields an effluent of very high stability and as it leaves the small sedimentation tank after about ½ hour's retention, it is clear, colorless and without odor. The removal of bacteria is close to 100%. Disease-producing germs and allied species, outside of the body, are destroyed more readily than the ordinary bacteria of decomposition and hence if a few bacteria survive electrolytic treatment, they will not be pathogenic germs. This is borne out by observations on cultures made to identify this class of bacteria.

Storage of the Effluent for Observation.—From the small settling tank the clear effluent was run into the large concrete sedimentation tank, over which the electrolytic apparatus was erected. This tank has a capacity of about 67,000 gallons and is one of the four regular sedimentation tanks built with the Elmhurst plant. Chemical and bacterial observations made from time to time on the liquid stored in this tank showed some very interesting results. The bacterial content remained very low and the fixation of nitrogen, as shown by the increase in the nitrites and nitrates on standing, is remarkable, notwithstanding the fact that the tank is open to contamination from the air and by birds which nested in the rafters of the roof. This tank was kept full for 66 days. When emptied, a light deposit, about ¼ inch thick, was found at the bottom. This was light colored and inoffensive and was composed largely of calcium carbonate. The clear appearance of the water in this tank made interesting contrast to the dark septic sewage in the adjacent tank, with its deposited sludge continually forced to the surface in large masses by the rising gases of decomposition.

Sludge.—The flocculent precipitate in the machine effluent after sedimentation in the small tank was drawn from the bottom of this tank through 2-inch outlet pipes and forced into a filter press under about 25 pounds pressure by means of a small water-feed pump. At this pressure about 20 pounds of liquid sludge, containing about 95% moisture, could be dehydrated per hour, per square foot of filter area, based on the operation of a large press. The percentage of moisture remaining was from 55 to 60%. The filtrate from the sludge is quite odorless, colorless and has sufficient available oxygen to remain nonputrescible. The sludge has no odor, except possibly a very slight suggestion of ammonia.

The extraction of this readily settling sludge from the electrolytic machine effluent, by a process other than sedimentation in tanks, is now being considered, but on account of the short period of sedimentation required the elimination of a small tank area would be important only under exceptional conditions.

Cost.—Without including pumpage, the necessity of which would have to be determined at each point of treatment, according to topography, the cost of electricity for electrolysis at the rate of six kilowatts per million gallons at a cost of 3c. per kilowatt hour is 6 x 24 x .03 = $4.32

Lime 941 lbs. x .003 = $2.83

$7.15

Disastrous fires at the docks along the Seattle waterfront have led to an ordinance providing that all docks constructed hereafter shall be provided with fire walls spaced not further apart than 500 ft. on centres and fire stops not more than 100 ft. apart. These provisions are not required in structures fully equipped with automatic sprinklers.

Editorial

THE WORDING OF SPECIFICATIONS.

One of the most frequent causes of trouble between owners, engineers and contractors is the inability of some engineers to express their requirements clearly, concisely and in plain, unequivocal English, so that all concerned may read and know what their specifications mean and call for. Most of this trouble can be ascribed to the practice of copying specification provisions from some other person's work or from some ancient specifications with no regard or consideration as to whether the class of materials is the present market classification or whether even obtainable except at an exorbitant price. Such specifications usually contain ambiguous phrases which have been rightly named "club" or "big stick" clauses, unfair to all parties, and which create the impression that the engineer himself does not know what he wants, and that he expects to cover up his deficiency by other common phrases such as "the decision of the architect as to the true construction and meaning of the drawings and specifications shall be final"; "that all work and materials must be to the entire satisfaction of the engineer"; "that all materials must be of the best quality"; "that all work must be done in the best manner as the engineer shall direct," etc. Nor do these expressions always accomplish the expected result. Some examples that well illustrate this were enumerated by Wm. L. Bowman, C.E., LL.B., in a paper entitled "The Engineer and the Law," read before the Harvard Engineering Society, of New York. One instance he cites was where a contract for a heating plant provided for a "complete and perfect job, even though every item required to make it such is not specially noted in the drawings or these specifications"; also that the contractor "shall furnish all labor, tools, and appliances necessary to complete his work according to these specifications, and shall perform his work in a true workmanlike manner in every particular, and thus provide the building with a durable and mechanically perfect system"; it was held that the contractor was not required to improve upon the plans in order to make a mechanically perfect system.

Another example given by Mr. Bowman was where a contract required the construction of a cellar according to specifications, it was held that an additional requirement that "the whole to be perfectly watertight and guaranteed" only bound the contractor so far as his own work was concerned, and that he was not held to guarantee that the plans would produce a watertight job. In another instance, where a tin roof of the "best quality" was called for, the trial justice in charging the jury held that such a requirement was satisfied when the roof as finished "was equal to the standard contemplated by the contract." In another contract a reservoir was required to be built according to definite plans and specifications, and the contract further provided that "the work contemplated . . . is the construction of a watertight reservoir," and it was held that that did not impose upon the contractors the responsibility of making the reservoir watertight, because consideration of the entire terms of the contract showed that they had no discretion as to the method or means of doing the work.

These numerous examples are given because of the tendency on the part of some architects and engineers to reject work under such circumstances, involving all concerned in expensive and needless litigation, and opening themselves to severe and sometimes well-merited criticism.

CO-OPERATION BETWEEN SCIENCE AND BUSINESS.

Professor Ed. D. Jones, in his new book on business administration, makes some interesting allusions to the fruitful co-operation of men of widely differing talents, in business. He shows clearly how industry and science agree in making extensive use of that simple form of co-operation, commonly known as division of labor, by which men of unlike genius are united in the same enterprise for the accomplishment of different functions. He turns first to pure science of modern times and displays a striking instance, in the life history of two noted men, of the benefits of individual co-operation. Tycho Brahe, the leading astronomer of the latter half of the sixteenth century, was a nobleman of proud spirit and, by reason of a certain dramatic talent which attracted attention, able to secure from his royal patrons large grants for astronomical apparatus. He was an expert instrument maker, and an accurate observer. His life was spent largely in compiling tables of observations of planetary movements. Kepler, who came under his patronage, and who worked with him for many years, was a poor observer, suffering from defective eyesight. He was awkward in his movements and possessed little mechanical ability. He was, however, a good mathematician, and he possessed the rare ability to become enthusiastic over statistical calculations. The five laws of planetary motion which Kepler discovered, and the Rudolphine tables which he completed, are monuments to a splendid and devoted co-operation between two geniuses of entirely different endowments.

As for applied science, the writer reverts to the more familiar case of Isaac Watt and Matthew Boulton. Watt has described himself in the following words: "I am not enterprising. I would rather face a loaded cannon than settle an account or make a bargain; in short, I find myself out of my sphere when I have anything to do with mankind." Boulton was a man of affairs, full of energy and common sense, and possessed of property. He is remembered because he was able to perceive and respect the talent of a man entirely different from himself, and because he tenderly encouraged and courageously defended that genius through manifold attacks and disappointments, to the lasting benefit of the world.

Professor Jones treats the subject in a manner that permits of but brief mention here. One observation of his will bear frequent repetition, however. It is this: "There are even enough men of wealth ready to enter into an arm's-length alliance with science and education, by means of a cold bequest. But there is a waiting opportunity for men of affairs to go into living, daily partnership with the arts and sciences, by entering into close personal relationships with men who need help of a natural administrator to make their contribution to progress. A good many captains of industry might weave their names firmly into the fabric of history, as did Boulton, by aiding some delicate flower of genius with energetic counsel and a wise corrective influence.

PERMEABILITY OF GRAVEL CONCRETE.

THE following is a summary of tests that have been under way at the Engineering Experiment Station, University of Wisconsin. They were recently described in a paper read by Prof. M. O. Withey, before the Western Society of Engineers.

1. None of the concretes tested were absolutely watertight if we consider continuous flow into the specimen as proof of permeability, but the majority of the mixes (varying from 1 : 1 to 1 : 3 : 6) were so impervious that no visible evidence of flow appeared. For most purposes such mixes can be considered watertight.

2. The visibility of dampness on the bottom of the specimens increased with the humidity of the air and the non-homogeneity of the concrete. The minimum rate of flow for which leakage was indicated was 0.00011 gal. per sq. ft. per hr.

3. In tests of nearly all of the properly made mixes of 1 :7 proportions, or richer, the rate of flow for a 50-hr. period was less than 0.0001 gal. per sq. ft. per hr. under a pressure of 40 lb. per sq. in.

4. Through increasing the fineness of the cement a reduction in the rate of flow and a considerable increase in the strength of a 1 : 9 mix were secured.

5. By grading the sand and gravel in accordance with Fuller's curve it was possible to obtain practically watertight concrete of 1 : 9 proportions under pressures less than 40 lb. per sq. in. To secure such results, however, requires great care and careful supervision in mixing, in determining the proper consistency, in placing, and in curing the concrete.

6. In the proportioning of such materials as these, volumetric analysis coupled with a determination of the density and air voids yields very valuable information concerning the best proportions of sand and gravel for a given proportion of cement. If proportions must be selected arbitrarily a 1 : 1½ : 3 mix, by volume, is very impervious.

7. The use of the proper amount of water necessary to produce a medium or mushy consistency is one of the most important conditions in securing impervious concrete, especially when lean mixtures are used. Dry mixtures cannot be sufficiently compacted in the molds and are more difficult to cure properly than the mushy mixtures. Although the use of a wet consistency does not materially affect the imperviousness of very rich mixes, such as 1 : 1½ : 3, it greatly increases the flow through a lean mix.

8. For lean mixes made from damp sand it seems advisable to mix longer than is now common practice. These tests would indicate that for a mixer running at 30 r.p.m., a period of one and one-half to two minutes is required to secure thorough mixing of a 1 : 9 concrete. For a rich 1 : 1½ : 3 mix a one-minute period appears to be sufficient. The method of mixing in which water is first admitted to the mixer is to be condemned. A preliminary period of dry mixing lasting from 15 to 30 sec. seems desirable.

9. No stage or process in the making of impervious concrete is of more importance than curing. The results of these tests clearly demonstrate that premature drying destroys the imperviousness of 1 : 9 mixes, seriously impairs that of the 1 : 2 : 4 mixes and somewhat diminishes that of the 1 : 1½ : 3 mixes. For thin sections, not over six or eight inches thick, the curing conditions should be such that a lean concrete will be kept damp for a period of one month and a rich concrete for at least two weeks. Even after a month of proper curing, complete desiccation of a lean mix composed of these materials produces an increase in permeability, but the effect on a rich mix is not marked.

10. In these tests the imperviousness of the concrete increased rapidly with the age of the specimens for the first month; thereafter the change was not marked.

11. From the tests thus far made it seems probable that the permeability of lean concrete in a direction normal to the pouring is greater than in the direction of pouring.

USE OF CONCRETE IN WATERWORKS CONSTRUCTION.*

THE author does not pretend to advance any new theories, but rather endeavors to present in convenient form the general principles involved in the use of concrete in such structures as may be employed in connection with waterworks. There is no recognized standard test or specifications now in use for concrete. There has not as yet been developed a set of standard tests or specifications, the use of which will in cases guarantee entirely satisfactory finished work. That the cement and aggregate stand the laboratory tests is no guarantee that the workmanship will give the best of results.

Neither sharpness nor excessive cleanliness in the sand is worth seeking after if it involves much expense. Tests have shown conclusively that sand with rounded grains makes quite as strong a mortar, other things being equal, as does sand with angular grains. Comparative sand tests of cement-sand mortar should be based on compressive strength values instead of tensile strength values. The strength of all sand mortars is affected by the amount of water used over that required for normal consistencies. The more water used the greater will be the loss in strength at early periods. A fine sand takes much more water to produce a certain consistency of mortar when mixed with cement than does a coarse sand. A fine sand makes a weaker mortar than a coarse, because of the lower density. The only substitute for natural sand for concrete that need be considered is pulverized stone, either dust and fine screenings produce in crushing rock or an artificial sand made by reducing suitable rocks to powder. The danger of using stone dust is failure to secure the proper balance of large size grains. The coarseness as well as the fineness of a good concrete sand is limited. The best sands will show not more thon 40 per cent. retained on a No. 10 sieve, and not more than 5 per cent. passing a No. 80 sieve.

Upon large or important structures it pays from an economic standpoint to make very careful studies of the materials of the aggregates and their relative proportions. W. B. Fuller has shown that by changing the ordinary mixture of watertight concrete, which is about 1 :2½ :4½, and which requires 1.37 barrels of cement per cubic yard of concrete, by carefully grading the materials by methods of mechanical analyses he was able to obtain watertight work with a mixture of about 1 :3 :7, thus using 1.01 barrels of cement per cubic yard of concrete. This saving of 0.36 barrel is equivalent, with Portland cement at $1.60 a barrel, to 58 cents per cubic yard of concrete.

A better and more uniform concrete can be made with a good machine mixer than by hand. A plastic con-

* Abstract of a paper by Edgar B. Kay before American Water Works Association.

crete of jelly-like consistency always produces stronger concrete than a wet mix and is preferred where conditions will admit of its use. It is absolutely necessary, however, in reinforced concrete to employ a consistency sufficiently wet to flow around the steel and into the corners of the forms and in rubble concrete, to flow around the large stones.

Concrete should never be placed in running water.

It is almost impossible to satisfactorily plaster a face of hardened concrete.

A wall of concrete may be rendered watertight in various ways:

1. By accurately grading and proportioning the aggregates and the cement. The proportions employed to resist the percolation of water usually range from 1 : 1 : 2 to 1 : 2½ : 4½, the most common mixture being 1 : 2 : 4 or 1 : 2½ : 4½. With accurate grading by scientific methods, watertight work may be obtained. For maximum watertightness, a mortar or concrete may require a slightly larger proportion of fine grains in the sand than for maximum density or strength. In general it may be stated that in monolithic construction a wet mixture, a rich concrete and an aggregate proportioned to secure great density will in the majority of cases give the desired results. It is impossible to specify definite thicknesses of concrete to prevent percolation under different heads of water, because of variations in proportions and methods of laying.

2. By special treatment of the surface of the concrete. Various methods have been employed, such as plastering the surface of concrete with rich Portland cement mortar in proportions 1 : 1 or 1 : 1½. Watertightness may also be secured by the use of a granolithic finish; by troweling the surface so as to produce a hard finish. Layers of waterproof paper or felt cemented with asphalt or bitumen or tar are extensively used, and sometimes asphalt alone. A mixture of alum and lye has also been used.

3. A waterproof concrete can be prepared by the application of fluates. The operation, however, requires a great deal of time and labor. By the application of an 8 per cent. solution of potash soap, instead of water, in mixing, the concrete can be rendered waterproof, so as to fulfil all requirements as to permeability of water.

The first method suggested is unquestionably the best to secure permanent watertightness, and the writer is not in favor of using waterproofing ingredients or of making surface applications except in cases where such may be required by reason of imperfections in the original concrete.

NEW BUILDING FOR THE HYDRO-ELECTRIC POWER COMMISSION.

A new office building, to cost approximately $200,000 is to be erected by the Hydro-Electric Power Commission of Ontario on a newly-purchased site on University Avenue. The building will be 6 stories in height, with white stone frontage and will be constructed of brick. Its floor dimensions are to be 63 x 83 ft. The whole of the building will be used by the Commission. Contracts for the exterior work were let last week to Messrs. Witchall and Sons, Toronto.

Agents of the Grand Trunk Pacific are taking measures to get Belgian settlers for the territory opened by the company's lines in western Canada. It is expected that the European war will result in a rush of settlers to Canada. Belgian farmers are very thrifty people. It is hoped to settle a large tract in the Stuart River district.

Coast to Coast

St. Andrews, N.B.—Plans for the rebuilding of the C.P.R. Algonquin Hotel, burned last April, have been prepared by Barrott, Blackader and Webster, architects, Montreal. A reinforced concrete structure is contemplated.

Sault Ste. Marie, Ont.—The third lock of the St. Mary's Falls canal was formally opened to traffic last week. It is 1250 ft. long, 80 ft. wide and 23 ft. deep. Its construction began in 1908, and has cost $6,250,000. It is rated the longest lock of its kind in the world.

St. Vital, Man.—The Manitoba Engineering and Construction Company, of Winnipeg, were awarded, last September, the contract for the construction of a 12-inch cast-iron water main to extend from the pump-house at this point to a reservoir in the National Transcontinental Railway yard at Transcona. This is being proceeded with, and is giving employment to quite a number of laborers. The estimated cost of the line is $87,000.

Brandon, Man.—Last week Mr. J. G. G. Sullivan, chief engineer of western lines for the C.P.R., made the announcement that 350 miles of double-tracking had been completed during the season between Brandon and the Pacific coast. Prior to this year the road had been double-tracked from this point to Fort William, which makes a distance of 909 miles completed to date. The entire distance between Fort William and Vancouver is 1908 miles. It is expected that the line of the C.P.R. between Swift Current and Bassano will be completed in a few days

Montreal, Que.—As announced in another department of this journal, the Grand Trunk Pacific Railway is going ahead with the construction of terminals in British Columbia. Contracts to the value of $300,000 at the four divisional points, viz., Prince George, Smithers, Pacific, and Endako, have recently been let. They include the construction of roundhouses, machine shops, and other railway facilities, and will require the services of large numbers of mechanics and laborers during the winter months. It is to be noted that large oil storage buildings are included, indicating that the company may have under consideration the use of oil-burning locomotives on its fast transcontinental service.

Montreal, Que.—No sooner had the contractors placed the roof on a large extension to the Ross Rifle factory than work was commenced on a second extension, which will double the size of the present factory, and more than double its capacity. The output of the enlarged factory will be at least 500 rifles per day. The contractors for the new structure, the C. E. Deakin Co., of Montreal, have been urged to rush the work, and the concrete foundations are already being placed. The building, which will be of brick construction, is to be handed over on December 1st, ready for the installation of machinery. It is also understood that the Quebec Railway, Light and Power Company has signed up a contract with the Ross factory for a large block of additional power. The machinery and equipment for the extensions are on the way from England.

St. John, N.B.—Several large steel bridges are now under construction in this Province. The spandral arch bridge at St. John, which bridges the Reversing Falls, and which will be utilized for street car and general traffic, is well advanced, and the remaining work will be completed in time for use next spring. The new steel bridge, which the provincial government is constructing at Grand Falls, is almost completed, and in a few days the finishing touches will have been made to the magnificent new bridge

which crosses the Miramichi river at Newcastle. In addition to these splendid structures two large steel bridges for the use of the Valley Railway are in contemplation. The C.P.R. also has under consideration the building of a new cantilever bridge, of a somewhat different type from that now used by the railway, at the Falls, St. John.

PERSONAL.

J. J. McNIVEN, B.Sc., of Vancouver, has been appointed assistant inspector of gas and electricity in that city.

JOHN T. MATTHEWS, of St. John, N.B., has been appointed inspector of boilers and machinery and of hulls and steamboat equipment at Edmonton, Alta.

R. A. ROSS, consulting engineer, Montreal, has been retained by the city of Peterborough, Ontario, as its representative in the settlement of the taking-over of the plant of the Peterborough Light and Power Company by the city.

T. R. DEACON, C.E., whose second term as Mayor of the city of Winnipeg is drawing to a close, has announced that he will not seek re-election to the office. Mayor Deacon's work in connection with the Greater Winnipeg Water District has been of such a nature as will for all time associate his name with the supply of good water to the city of Winnipeg. It was to further the scheme that he permitted himself to be chosen as head of the civic administrative board, and the present extensive construction work on the 95-mile aqueduct bespeaks the fruits of his great service to the city.

H. S. VAN SCOYOC, A.M. Am. Soc. C.E., has been appointed chief engineer of the Toronto-Hamilton highway, on which work is to start at once. Mr. Van Scoyoc has been inspecting engineer of the Canada Cement Co., Limited, at Montreal, for the past few years, and is thoroughly familiar with the construction of concrete roads. The Toronto-Hamilton Highway Commissioners chose Mr. Van Scoyoc in order to make the Canada Cement Co. more definitely responsible for the success of the road than the company would be if the engineer in charge were not practically one of its own men.

OBITUARY.

The death has been announced of Mr. E. R. BABINGTON, a well-known architect of Toronto. The deceased started his profession in 1874, and, after twenty-three years of active professional work, he became an instructor in the Toronto Technical School, which position he held until forced by ill-health to resign.

INSPECTION OF NEW WELLAND SHIP CANAL.

As intimated in last issue, a tour of inspection was made over the sections of the new Welland ship canal now under construction, by members of the Toronto branch of the Canadian Society of Civil Engineers, and of the University of Toronto Engineering Society, on Saturday, October 31st. Several hundred took advantage of the opportunity afforded them by Mr. J. L. Weller, chief engineer of the Canal, to examine closely the enormous equipment and methods, somewhat unusual to Canadian construction, that were to be seen on Sections 1, 2 and 3.

The party was divided into groups, each looked after by several members of the engineering staff of the Canal. Beginning at Thorold, the various features of the work, outlined in the leading article of this issue, were examined, every development of interest between that town and the harbor at Port Weller receiving the attention of the closely interested engineers. Luncheon was served at one of the construction camps; electric cars, drawn by one of the locomotives, conveyed the party along the department's construction railway. At the close of the day a dinner was held in St. Catharines, the party returning to Toronto by special train.

EDMONTON BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

The Edmonton Branch of the Canadian Society of Civil Engineers held their regular meeting on Oct. 22nd. An informal dinner was served to about forty-five guests. Following the dinner, the gathering was addressed by A. M. Calderon, F.R.A.I.C., and J. L. Cote, M.P.P., on the Military Engineers' Corps, which is now established in the city. Several military engineers who were present also gave short addresses on various aspects of military engineering. The members of the Branch, who strongly favored the movement regarding the formation of a local corps of military engineers, unanimously passed the following resolution: "Whereas there are a large number of qualified engineers having headquarters at Edmonton who are desirous of putting their scientific training and practical experience at the service of the Empire; be it resolved that the Secretary of the Branch be instructed to communicate with the District Officer commanding this military district, urging upon the Militia Department the desirability of authorizing an engineering unit in Edmonton."

The chair was occupied during the evening by Professor Edwards, of the University of Alberta. Mr. L. B. Elliot is the secretary of the Branch.

COMING MEETINGS.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

WASHINGTON STATE GOOD ROADS ASSOCIATION.—Convention to be held at Spokane, Wash., November 18th, 19th, and 20th. Secretary, M. D. Lechey, Alaska Building, Seattle, Wash.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

AMERICAN ROAD BUILDERS' ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

AMERICAN WATERWORKS ASSOCIATION. — The 35th annual convention, to be held in Cincinnati, Ohio, May 10th to 14th, 1915. Secretary, J. M. Diven, 47 State Street, Troy, N.Y.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.—Annual meeting to be held at the Iowa State College, Ames, Iowa, June 22nd to 25th, 1915. Secretary, F. L. Bishop, University of Pittsburgh, Pittsburgh, Pa.

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

THE FILING OF ENGINEERING LITERATURE

THE DEWEY DECIMAL SYSTEM OF CLASSIFICATION IN ENGINEERING AND ITS EXTENSION TO COVER MUNICIPAL ENGINEERING.

By R. DeL. FRENCH, Assoc. Mem. Can. Soc. C.E.; Assoc. Mem. Am. Soc. C.E.
Lecturer in Municipal Engineering, McGill University, Montreal.

IN every engineering office there are catalogues, photographs, pamphlets, drawings, books, clippings, etc., which, to be of the greatest use, must be filed so as to be kept in order and yet to be easily accessible. In addition to such matter, the engineer should keep a list of references to articles in the engineering periodicals and in the proceedings of the engineering societies which are of particular interest to him.

The actual filing of such matter is probably best accomplished by the use of the familiar vertical system, and the index to the contents of the files is most conveniently kept on standard cards, 3 in. x 5 in. in size. Many systems of indexing have been devised which are more or less satisfactory. Any alphabetical system is open to the objection that it requires copious cross-indexing to make it of much value. The numerical systems are, therefore, the more popular, and justly so.

The Dewey decimal system, developed by Melvil Dewey, formerly director of the New York State Library, is probably the best of the numerical systems. It is in great favor with library workers and is used in the majority of the public libraries of the United States and Canada.

The following explanation of this system is based on that given in "An Extension of the Dewey Decimal System of Classification Applied to the Engineering Industries" by Breckenridge and Goodenough, of the Engineering Experiment Station of the University of Illinois at Urbana. This bulletin, as well as one giving a similar extension of the system to cover architecture and building, may be obtained from the Director of the station for a low price.

The essential characteristic of the Dewey system is its method of division and subdivision. The entire field

of knowledge is divided into nine chief classes numbered by the digits from 1 to 9. A tenth class for matter too general in nature to fall in any one of the other nine is numbered 0. The following are the primary classes:

0 General works.	5 Natural sciences.
1 Philosophy.	6 Useful arts.
2 Religion.	7 Fine arts.
3 Sociology.	8 Literature.
4 Philology.	9 History.

Each of these classes is again divided into nine divisions with a tenth for general matter, and each division is separated into nine sections. The sections are again subdivided, and the process may be carried as far as is desired. To show clearly the workings of the system, the divisions of Class 6 (useful arts) and the sections of Division 2 of this class (engineering) are given below:

600 Useful arts.	620 Engineering.
610 Medicine.	621 Mechanical.
620 Engineering.	622 Mining.
630 Agriculture.	623 Military.
640 Domestic science.	624 Bridge and roof.
650 Communication and commerce.	625 Road and railway.
660 Chemical technology.	626 Canal.
670 Manufactures	627 River and harbor.
680 Mechanic trades.	628 Sanitary.
690 Building.	629 Other branches.

It will be seen that the first digit gives the class; the second, the division; and the third, the section. Thus, 625 indicates Section 5 (road and railway engineering) of Division 2 (engineering) of Class 6 (useful arts). Further subdivision is indicated by the digits following the decimal point, which is placed as a matter of convenience after the section digit. For instance, 625.7 indicates highway engineering; 625.75, highway construction equipment; 625.753, highway consolidating machinery; 625,753.2, road rollers; 625.753.23, steam road rollers, and finally, 625.753.231, steam road rollers for macadam.

Following the classification list herein is the relative index, in which the terms of the classification are arranged alphabetically, each with its proper number. This index is manifestly incomplete, as it is impossible to include in it every subject that might come up in engineering practice. The skeleton is there, however, and the user may extend it further if he finds it advisable.

There are certain modifications in the use of the Dewey system. To avoid the writing of long numbers, a single letter may be used for the first three or four digits. Thus "H" might be used by a highway engineer in place of 625, "W" by a waterworks man in place of 628.1, and so forth.

Another modification consists in the use of an alphabetical arrangement for certain subsections where it is convenient, while retaining the decimal arrangement for the main divisions. For instance, under 625.821 (stone for macadam highways) the various varieties might be arranged alphabetically if desired. This is most useful where there are a large number of such minute divisions.

The use of "form divisions" is another useful modification. There are certain set forms, given on page 631, which are used throughout the range of the Dewey system. They may be still further extended thus:

064 Exhibits (under societies)
072 Laboratories (under universities)

They are usually enclosed in parentheses and annexed to the usual class number. Thus 62(07) indicates engineering education and 628.184(008) refers to patents regarding water sterilization and disinfection. If an engineer were particularly interested in patents, for example, he could reverse the usual manner of writing the class number and write it thus, (008)628.184, so that all the cards referring to patents would come together in his index.

Fig. 1 shows a set of cards for indexing a book or pamphlet and comprises both author and subject cards. These would be arranged alphabetically in the card drawers. To distinguish two cards having the same number, it is customary to write under the class number the initial or first two or three letters of the author's or publisher's name, though there are elaborate numerical lists published for this purpose.

625.892.212*

Gutter Construction for Streets and Road. T. Hugh Boorman. (Granite curbing and vitrified brick gutter)

Canadian Engineer. Sept. 14, 1914. XXVII. 473.

625.892.22*

Gutter Construction for Streets and Roads. T. Hugh Boorman. (Standard type of combined concrete curb and gutter.)

Canadian Engineer. Sept. 14, 1914. XXVII. 473.

625.95*

Gutter Construction for Streets and Roads. T. Hugh Boorman. (Preparation of curb and gutter construction materials: concrete, asphalt, brick, wood or stone.)

Canadian Engineer. Sept. 14, 1914. XXVII. 473.

Fig. 2.

For references to articles in the engineering press, the writer uses the form shown in Fig. 2. These cards are arranged numerically in the drawers, and it is necessary to find the class number of subject under investigation before referring to them. This class number may be found in the relative index. The asterisk after the class number indicates that the article in question is in the writer's clipping file.

Three years' experience with the system outlined has convinced the writer that it is as near perfection as it is possible to get. It requires some intelligent attention to keep it in shape, but that is true of any system. It is hoped that the lists herein will be of value to city engineers, superintendents of waterworks, streets and sewers and others in municipal engineering work.

Extension of the Dewey Decimal System of Classification to Cover Municipal Engineering.

FORM DIVISIONS.

01 Philosophy; theory.
02 Compends; text books; hand books; manuals.
03 Encyclopedias; dictionaries.
04 Essays; addresses.
05 Periodicals.
06 Societies.
07 Education; teaching; schools; colleges; universities.
08 Tables; diagrams, computations; tests; miscellanies.
09 History; progress; development.

001 Statistics; quantities.
002 Construction methods; costs.
003 Contracts; specifications.
004 Designs; drawings.
005 Executive; accounts; financial.
006 Working; maintenance.
007 Laws; rules; regulations; court decisions.
008 Patents.
009 Reports.

CLASS NUMBERS.

625.7 HIGHWAYS, ROADS AND STREETS.

.71 **Varieties.**

.711 Country roads.
.711.1 For heavy traffic; trunk highways.
.711.2 For medium traffic; inter-village roads.
.711.3 For light traffic.

.712 City streets.
.712.1 Thoroughfares.
.712.2 Minor streets.
.712.3 Streets for special purposes; motor roads; speedways.
.712.4 Alleys; lanes.
.712.5 Squares; public gardens.

.72 **Traffic.**

.721 Weight.
.722 Distribution.
.723 Effects.
.724 Censuses; counts.

.73 **Surveys and Designs.**

.731 Preliminary surveys; reconnaisances.
.732 Location surveys; staking out.
.733 Profiles.
.734 Curvature.
.734.1 Widening.
.734.2 Superelevation.

.74 **Features.**

.741 Alignment.
.742 Cross section.
.743 Crown.
.744 Slopes.
.745 Drainage.
.746 Accessories.
.746.1 Gutters; catch basins; gullies; inlets.
.746.2 Retaining walls; guard rails; parapets.
.746.3 Bridges; culverts.
.746.4 Milestones; signs; mirrors.
.746.5 Lighting; lamp posts.
.746.6 Other features.

.75 **Construction Equipment.**

.751 Excavating and grading machinery.
.751.1 Hand tools.
.751.2 Scrapers.
.751.3 Drags.
.751.4 Plows; scarifiers.
.751.5 Elevating graders.
.751.6 Trenching machinery.
.751.7 Power shovels.
.751.8 Other appliances.

.752 Hauling machinery.
.752.1 Wheelbarrows.
.752.2 Wagons; carts.
.752.3 Auto trucks.
.752.31 Steam.
.752.32 Gasoline.
.752.33 Electric.
.752.4 Cars.
.752.41 Dumping.
.752.42 Non-dumping.
.752.5 Locomotives.
.752.51 Steam.
.752.52 Gasoline; oil.
.752.53 Electric.
.752.54 Compressed air.
.752.6 Tractors.
.752.61 Steam.
.752.62 Gasoline or oil.
.752.7 Tractor wagons.
.752.8 Other machinery.

.753 Consolidating machinery.
.753.1 Tampers.
.753.11 Hand.
.753.12 Power.
.753.2 Rollers.
.753.21 Hand.
.753.22 Horse.
.753.23 Steam.
.753.231 Macadam.
.753.232 Asphalt.
.753.24 Gasoline or oil.
.753.241 Macadam.
.753.242 Asphalt.

.754 Quarrying and stone working machinery.
.754.1 Hand tools.
.754.2 Drills.
.754.3 Derricks.
.754.4 Cableways.
.754.5 Hoists.
.754.51 Hand.
.754.52 Horse.
.754.53 Steam.
.754.54 Gasoline or oil.
.754.55 Electric.
.754.56 Compressed air.
.754.6 Block splitters.
.754.7 Other appliances.

.755 Crushed stone, gravel and sand machinery.
.755.1 Hand tools.
.755.2 Crushers.
.755.21 Gyratory.
.755.22 Jaw.
.755.23 Rotary.
.755.24 Hammer or impact.
.755.3 Screens.
.755.31 Rotary.
.755.32 Shaking.
.755.33 Stationary.
.755.4 Washers.
.755.5 Heaters.
.755.6 Bins.
.755.7 Other appliances.

.756 Brick machinery.
.756.1 Clay mills.
.756.2 Brick machines.
.756.3 Dryers.
.756.4 Kilns.
.756.5 Other machinery.

.757 Concrete machinery.
.757.1 Mixers.
.757.11 Continuous.
.757.12 Batch.
.757.13 Gravity.
.757.2 Conveyers.
.757.21 Buggies; wheelbarrows.
.757.22 Buckets.
.757.23 Continuous; belts; pneumatic.
.757.3 Other appliances.

.758 Asphalt machinery.
.758.1 Hand tools.
.758.2 Mining appliances.
.758.3 Refinery appliances; stills; tanks.
.758.4 Hot mixers.
.758.5 Kettles; heaters.
.758.6 Other machinery.

.759 Wood block machinery.
.759.1 Hand tools.
.759.2 Special saws, etc.
.759.3 Dry kilns.
.759.4 Tanks.
.759.5 Treating cylinders.
.759.6 Pumps.
.759.7 Conveyers; transporters.
.759.8 Other appliances.

.76 **Maintenance.**

.761 Dragging; scraping.
.762 Rolling.
.763 Sprinkling.
.763.1 With water.
.763.2 With chemical solutions.
.764 Oiling; tarring.
.765 Treating with other materials.
.766 Sweeping.
.766.1 Patrol system.
.766.2 Horse or auto brooms.
.767 Vacuum cleaning.
.768 Flushing.
.768.1 With hose by hand.
.768.2 With horse or auto flushers.
.769 Miscellaneous methods of maintenance.
(For repairs, see under paving material in question).

.77 **Cultivation.**

.771 Tree planting
.771.1 Species.
.771.2 Arrangement.
.771.3 Care; maintenance.

.772 Boulevard space; parking.
.772.1 Lawns.
.772.2 Flower beds.

.773 Flower boxes.
.773.1 On electric light or trolley poles.

.78 **Sanitation.**

.79 **Other General Matter.**

625.8 PAVING MATERIALS.

.81 **Earth.**

.811 Sand-clay; top-soil.
.812 Gravel.
.813 Burnt-clay; ballast.
.814 Other earthy materials.

.82 **Macadam and Telford.**

.821 Stone.
.821.1 Trap.
.821.2 Limestone.
.821.3 Granite.
.821.4 Basalt.
.821.5 Porphyry.
.821.6 Other stones.

.83 **Stone Blocks.**

.831 Stone.
.831.1 Granite.
.831.2 Sandstone.
.831.3 Limestone.
.831.4 Basalt.
.831.5 Lava.
.831.6 Porphyry.
.831.7 Other stones.

.832 Joint fillers.
.832.1 Sand.
.832.2 Pitch; coal tar products.
.832.3 Asphalt.
.832.4 Cement grout.
.832.5 Wood.
.832.6 Other materials.

.84 **Brick.**

.841 Ordinary brick.
.842 Vitrified brick.
.843 Vitrified block.
.844 Scoria block.
.845 Other similar materials.
(For jointing materials see under 625.832 above).

.85 **Wood Block.**

.851 Wood.
.851.1 Yellow pine.
.851.2 British Columbia or Oregon fir.
.851.3 Norway deal.
.851.4 Jarrah.
.851.5 Karri.
.851.6 Other woods.

.852 Preservation.
.852.1 Creosoting.
.852.2 Kyanizing.
(For jointing materials see under 625.832 above).

.86 **Concrete.**

.861 Cement.
.862 Sand.
.863 Gravel.
.864 Crushed stone.
.865 Water.
.866 Joints.
.866.1 Protection devices.

.867 Surfacing materials.
.867.1 Asphalt.
.867.2 Coal tar products.
.867.3 Mortar; granolithic.
.867.4 Other materials.

.868 Reinforcement.
.868.1 Bars.
.868.2 Fabric.

.87 **Asphalt and Bituminous Macadam**

.871 Asphalt.
.871.1 For sheet asphalt.
.871.2 For asphalt blocks.
.871.3 For mixing method.
.871.4 For penetration method.

.872 Coal tar products.
.872.1 For mixing method.
.872.2 For penetration method.
.873 Fluxes.
.874 Crushed stone.
.875 Gravel.
.876 Sand.

.88 **Other Paving Materials.**
.881 Shells.
.882 Slag.
.883 Cinders.
.884 Other materials.

.89 **Sidewalks and Curbing.**
.891 Sidewalks; crosswalks.
.891.1 Arrangement.
.891.11 Slope.
.891.12 Grade.
.891.13 Width.
.891.14 Position.
.891.2 Materials.
.891.21 Earth; gravel; cinders.
.891.22 Wood.
.891.23 Brick; tile.
.891.24 Stone; flagging.
.891.25 Concrete; artificial stone flags.
.891.26 Asphalt; coal tar products.
.891.27 Other materials.

.892 Curbing.
.892.1 Arrangement.
.892.11 Size.
.892.12 Shape.
.892.2 Materials.
.892.21 Stone.
.892.211 Limestone.
.892.212 Granite.
.892.213 Sandstone.
.892.214 Other stones.
.892.22 Concrete.
.892.221 Corner protection.
.892.222 Reinforcement.
.892.23 Wood.
.892.24 Vitrified clay.
.892.25 Other materials.

625.9 CONSTRUCTION.

.91 **Subgrade.**
.911 Excavation.
.912 Consolidation.
.913 Ditching and drainage.

.92 **Foundation.**
.921 Preparing material.
.921.1 Telford.
.921.2 Macadam.
.921.3 Concrete.
.921.4 Other materials.
(For methods of mixing, placing, spreading, consolidating, etc., see under 625.942 and 625.945, and so forth).

.93 **Cushion.**
.931 Sand.
.932 Mortar.
.933 Other materials.

.94 **Wearing Surface.**
.941 Earth.
.941.1 Gravel.
.941.2 Sand-clay; top-soil.
.941.3 Burnt-clay; ballast.
.941.4 Other earthy materials.
1 Spreading; 2 Shaping; 3 Rolling; tamping; 4 Finishing.

.942 Macadam; telford.
.942.1 Spreading stone.
.942.2 Consolidating.
.942.3 Sprinkling.
.942.4 Accessory construction.

.943 Block paving; stone; brick; wood block; asphalt block.
.943.1 Distributing blocks.
.943.2 Placing blocks.
.943.3 Consolidating blocks.
.943.4 Jointing blocks.

.944 Asphalt; bituminous macadam.
.944.1 Mixing material.
.944.2 Distributing material.
.944.3 Consolidating material.
.944.4 Sprinkling with oil, tar or asphalt.

.945 Concrete.
.945.1 Mixing materials.
.945.2 Distributing materials.
.945.3 Consolidating materials.

.946 Other kinds of paving.

.95 **Sidewalks and Curbing.**
.951 Preparing materials.
.952 Placing.
.953 Jointing.
.954 Other operations.

.06 **Street Railways.**
.961 Preparing the foundation.
.962 Laying the track.
.963 Paving between and adjacent to rails.

628. **SANITARY ENGINEERING.**

628.1 WATER SUPPLY.

.11 **Sources of Supply.**
.111 Lakes and ponds.
.111.1 Quality.
.111.11 Physical.
.111.12 Chemical.
.111.13 Bacteriological.
.111.14 Protection of quality; prevention of pollution.
.111.15 Other data.

.112 Flowing streams; rivers; brooks; creeks; impounding reservoirs.
.112.1 Quality.
.112.11 Physical.
.112.12 Chemical.
.112.13 Bacteriological.
.112.14 Protection of quality; prevention of pollution.
.112.15 Other data.

.113 Underground waters; springs; wells; galleries.
.113.1 Quality.
.113.11 Physical.
.113.12 Chemical.
.113.13 Bacteriological.
.113.14 Protection of quality; prevention of pollution.
.113.15 Other data.

.114 Yield.
.114.1 Rainfall.
.114.11 Amount.
.114.12 Rate.
.114.13 Distribution.
.114.14 Other data.
.114.2 Evaporation.
.114.21 From land area.
.114.22 From water surface.
.114.23 Other data.
.114.3 Percolation.
.114.4 Runoff.
.114.5 Underground waters.
.114.51 Pumping tests.
.114.6 Other data on yield.

.115 Consumption.
.115.1 Domestic.
.115.11 Amount.
.115.12 Variation.
.115.13 Other data.
.115.2 Industrial.
.115.21 Amount.
.115.22 Variation.
.115.23 Other data.
.115.3 Public (except fire).
.115.31 Amount.
.115.32 Variation.
.115.33 Other data.
.115.4 Fire protection.
.115.41 Amount.
.115.42 Other data.
.115.5 Waste.
.115.51 Amount.
.115.52 Detection.
.115.521 By inspection.
.115.522 By metering.
.115.523 By Deacon meter.
.115.524 By pitometer.
.115.525 By pulsograph.
.115.526 By other methods.
.115.53 Prevention.
.115.531 By inspection.
.115.532 By metering.
.115.533 By other methods.
.115.6 Total consumption.
.115.61 Quantity.
.115.62 Variation.
.115.621 Hourly.
.115.622 Daily.
.115.623 Weekly.
.115.624 Monthly; seasonal.
.115.625 Annual.
.115.63 Other data.

.116 Pressure.
.116.1 For domestic use.
.116.2 For industrial use.
.116.3 For public use.
.116.4 For fire protection.
.116.5 For other purposes.
.116.6 Gauges.
.116.61 Indicating.
.116.62 Recording.
.116.7 Other data.

.12 **Hydraulics.**
.121 Of canals; conduits; pipe lines.
.122 Of fire streams; hose; nozzles.
.123 Of distribution system.
.124 Of pumping machinery.

.125 Measuring devices.
.125.1 Weirs.
.125.2 Orifices.
.125.3 Meters.
.125.4 Pitometers; pitot tubes.
.125.5 Other devices.

.126 Other hydraulic questions.

.13 **Collection of Water.**
.131 Impounding reservoirs.
.131.1 Dams.
.131.11 Earth.
.131.12 Rock fill.
.131.13 Masonry; concrete.
.131.14 Wood.
.131.15 Steel.
.131.16 Other materials.
.131.2 Outlets.
.131.21 Tunnels.
.131.22 Towers.
.131.23 Other devices.

.132 Diversion.
.132.1 Dams.
.132.11 Earth.
.132.12 Rock fill.
.132.13 Masonry; concrete.
.132.14 Wood.
.132.15 Steel.
.132.16 Other materials.

.133 Underground water collection.
.133.1 Wells.
.133.11 Shallow.
.133.111 Large open.
.133.112 Driven.
.133.12 Deep.
.133.2 Springs.
.133.21 Spring basins.
.133.3 Galleries.
.133.4 Other devices.
.134 Other adjuncts.

.14 **Pumping.**
.141 Intakes.
.141.1 Cribs.
.141.2 Towers.
.141.3 Screens.
.141.4 Other devices.

.142 Suction wells.

.143 Steam plant.
.143.1 Boilers.
.143.11 Fire tube.
.143.12 Water tube.
.143.13 Other types.
.143.2 Fuel handling machinery.
.143.21 Cars.
.143.22 Trolleys.
.143.23 Conveyers.
.143.3 Chimneys.
.143.4 Forced and induced draft apparatus.
.143.5 Feed pumps.
.143.6 Condensers.
.143.61 Surface.
.143.62 Jet.
.143.63 Barometric.
.143.64 Air pumps and auxiliaries.
.143.7 Engines.
.143.71 Reciprocating.
.143.711 Low speed.
.143.712 High speed.

.23 **Design.**
.231 Size.
.231.1 Sanitary sewers.
.231.2 Storm water drains.
.231.21 Formulas.
.231.22 Rational methods. (For rainfall data see 628.114).
.231.3 Infiltration; leakage.
.231.4 Other data.

.232 Shape.
.232.1 Circular.
.232.2 Egg-shaped.
.232.3 Horseshoe.
.232.4 Parabolic; semi-elliptical; catenary; basket handle.
.232.5 Rectangular.
.232.6 Other shapes.

.233 Velocity.
.233.1 In sanitary sewers.
.233.2 In storm water drains.
.233.3 Erosion.
.233.4 Grades.
.233.5 Other data.

.234 Ventilation.
.234.1 Sewer air; "sewer gas"; explosions.
.234.2 By omitting house traps.
.234.3 By use of perforated manhole covers, etc.
.234.4 By special shafts, etc.
.234.5 By connection to chimneys.
.234.6 By mechanical methods; fans.
.234.7 By other means.

.24 **Sewer Sections.**
.241 Pipe.
.241.1 Clay.
.241.2 Concrete.
.241.3 Jointing materials.
.241.31 Cement.
.241.32 Asphalt.
.241.33 Sulphur and sand.
.241.34 Cement and tar.
.241.35 Other materials.
.242 Brick; stone.
.243 Concrete.
.244 Wood.
.245 Other materials.
.246 In combination with other structures.

.25 **Appurtenances.**
.251 Manholes; lampholes; ventilating shafts.
.251.1 Regular.
.251.2 Drop.
.251.3 Special.
.252 Catch basins; gullies; inlets.
.253 Flush tanks.
.254 House connections.
.255 Outlets.
.256 Other appurtenances.

.26 **Special Structures.**
.261 Stream crossings.
.261.1 Bridges.
.261.2 Inverted siphons.
.262 Overflows.
.262.1 Weirs.
.262.2 Regulators.
.262.3 Other types.
.263 Flood and tide gates.
.264 Reservoirs; tank sewers.
.265 Pumping stations.
.265.1 Automatic.
.265.11 Compressed air.
.265.12 Electric.
.265.13 Other types.
.265.2 Non-automatic.
.265.21 Steam.
.265.22 Electric.
.265.23 Gas, gasoline or oil.
.265.24 Other types.
.266 Other special structures.

.27 **Special Construction Appliances.**
.271 Excavators.
.272 Material handling devices.
.273 Forms; centres.
.274 Jointing appliances.
.275 Unwatering devices.
.276 Other appliances.

.28 **Operation and Maintenance.**
.281 Cleaning.
.281.1 Scraping.
.281.11 Hand.
.281.12 Power.
.282 Flushing.
.282.1 Tank carts.
.282.2 By hand with hose.
.282.3 By damming sewage.

.29 **Other Material Regarding Sewerage**

628.3 SEWAGE DISPOSAL.

.31 **Composition of Sewage.**
.311 Physical.
.312 Chemical.
.313 Bacteriological.
.314 Other data.

.32 **Disposal by Dilution.**

MAIN PEDESTALS, QUEBEC BRIDGE

NOTES ON THE DESIGN OF THE FOUR 400-TON SHOES TO TRANSFER THE LOAD FROM THE CANTILEVER AND ANCHOR ARMS TO THE MAIN PIERS—METHOD OF FABRICATION AND ASSEMBLAGE.

By H. P. BORDEN,
Assistant to Chief Engineer, Quebec Bridge.

Each of the four main shoes of the new Quebec Bridge are designed to transfer the following loads:

Main vertical post	26,600,000 lbs.
Cantilever arm chord	29,600,000 lbs.
Anchor arm chord	24,100,000 lbs.
Cantilever arm Compression diagonal	7,820,000 lbs.
Anchor arm compression diagonal	7,810,000 lbs.

Resolving the above, this pedestal supports a maximum vertical and horizontal reaction of 55,000,000 and 32,000,000 lbs. respectively. Owing to the unprecedented size of the members required to transfer these loads to the shoe and the necessarily unusual proportions of the shoe itself which is required to distribute these loads to the masonry, the design of this member probably entailed more investigation and study than any other single detail in connection with the bridge.

The shoe is 26 ft. 4 in. x 20 ft. 10 in. at the base and 19 ft. high. To facilitate fabrication, shipping and erection, it is constructed in three stories. The lower story, or base, is 4 ft. high and is composed of 4 steel castings. These castings probably constitute a record for weight and size of steel castings in Canada, weighing over 40 tons each. These members have webs and flanges ranging from 2½ in. to 3 in. in thickness, the webs being supported by cross diaphragm walls of the same thickness, at frequent intervals. These castings are planed on a machine designed especially for this purpose, great care being taken to get a uniform depth for each of the 4 castings. When erected in place they are bolted together with 2½-in. bolts through exterior flanges, thus forming a base through which the vertical and horizontal reactions from the upper portions of the shore are transmitted to the masonry. The horizontal reactions at the

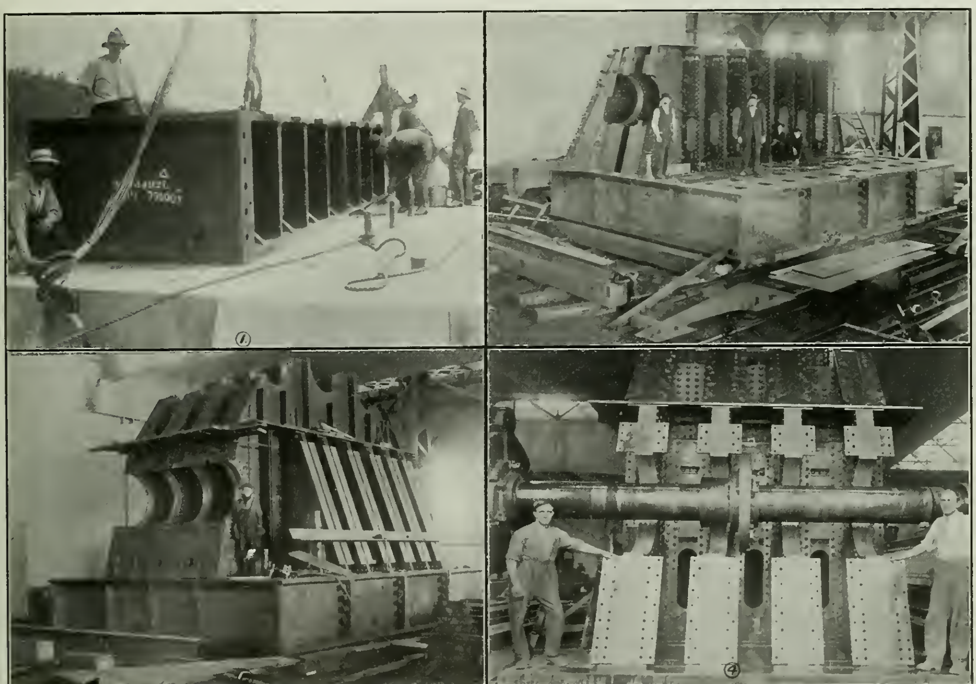

Fig. 1.—One of the 4 Castings Being Placed on the Pier. Fig. 2.—Casting Assembled (shop) and Second Story Under Construction. Fig. 3.—Second and Third Stories Nearing Completion. Fig. 4.—Method of Boring 45-inch Pin-hole.

pier can in every case be taken care of by the 30% coefficient of friction assumed between steel and masonry, but an additional factor of safety is provided by 44 3-in. anchor bolts and dowels. The dowels in the interior of the castings are grouted into the masonry and embedded in concrete with which the casting will be filled. The anchor bolts through the exterior lower flanges of the castings are grouted into the masonry with cement, that portion of bolt passing through the steel flange being grouted with molten zinc.

The middle section of the shoe is of built-up construction and is field-riveted to the lower section. This portion of the member is 10 ft. high and is composed mainly of 4 heavy webs which correspond to the webs of the bottom chords. The chord stresses are transmitted direct to this section of the shoe through 30-in. pins with 45-in. bushings. In addition to the chord stresses, this section of the shoe is required to transmit the stresses from the other web members which is transferred from the upper section and as a consequence the webs of the middle section become very heavy, the maximum thickness at the pin being 9¼ in., requiring a 1⅛-in. rivet 12 in. long. The loads distributed upon these webs are transferred uniformly to the base by means of 7 heavy brackets on each side, field riveted to both webs and castings. It was found when designing the connections between brackets and webs that the largest angles rolled would not provide sufficient rivet area to transmit the vertical shear. As a result, special connection-angles with 12-in. legs were manufactured from 1-in. plates. While it is expected that this design will undoubtedly to a large extent distribute the loads uniformly over the lower section, yet the contingencies of fabrication and erection are such that the actual results might not correspond to the theoretical expectations. To provide against the possibility of the load on the centre webs not distributing as expected, the steel castings on the base have been made sufficiently strong to distribute any such concentrated loading. The connection plates for the main bottom laterals are field riveted to the top and bottom of this section. When it is understood that these laterals have an inclination in both the vertical and horizontal plane and the face of the shoe to which they are connected is sloped at another angle in the vertical plane, it speaks well for the accuracy of the shop work that the connection holes in all these parts matched exactly when the shoe came to be assembled.

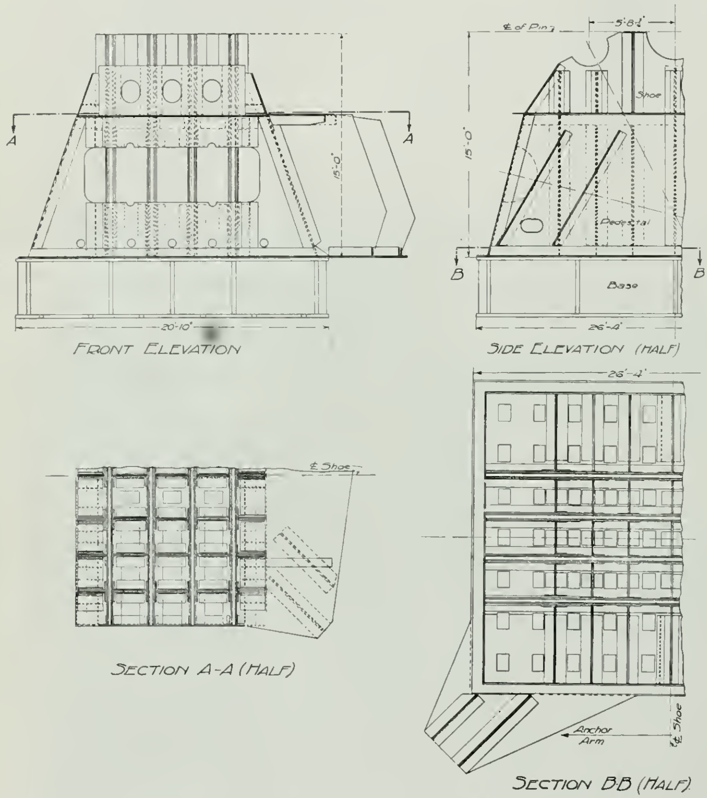

Fig. 5.—Elevations and Sections of Shoe for Main Pier Bearing.

The top or third section contains one 45-in. and two 30-in. half-pin holes which take the bushing for the 30- and 20-in. pins of the main post and diagonal compression members respectively. This section has 4 main webs which correspond to the 4 webs of the web members and post as well as the webs of the second section immediately below. In order to uniformly distribute the reaction, brackets are connected to the sides of the outer webs, spaced to correspond to the lower brackets. This top section is braced by very heavy brackets and diaphragms so that, assuming the whole shoe to act as a girder, transversely, the top and bottom stories will act as the flanges and the middle story as the web.

The maximum vertical loads on the shoe result in a uniform bearing of 660 lbs. per sq. in. on the granite masonry of the pier. This reaction comes from dead load, live load, impact, traction and vertical wind. In addition to the above there are transverse and longitudinal wind loads of 1,300,000 and 6,200,000 lbs. respectively. The transverse force is the horizontal component of the wind forces carried to the shoe by the lateral bracing and chords, and results in an increased toe pressure at the leeward edge. The longitudinal wind force is due to a torque at the main pier, due to normal wind pressure on the longer cantilever arm and half the suspended span resisted by the shorter anchor arm. This action results in equal and opposite reaction on the windward and leeward shoes on the main pier in a direction parallel to the longitudinal axis of the bridge. This longitudinal reaction is resisted by the friction between the steel castings and the masonry. As these castings are narrow in this direction, there is an overturning moment which is assumed to act on each casting individually and not on the entire base as a whole, which results in a very short lever

arm as compared with that used in determining the toe pressure from the transverse wind force acting at right angles. Certain allowances are made for the fact that the castings are riveted to the middle section, but even with this allowance there is a very appreciable increase in the pressure at the edges of the castings. Under such maximum conditions and assumptions, it is found that the maximum toe pressure amounts to 915 lbs. per sq. in. for all loads.

In all these calculations the following wind loads have been assumed: A wind load of 30 lbs. per sq. ft. of exposed surface of two trusses and 1½ times the eleva-

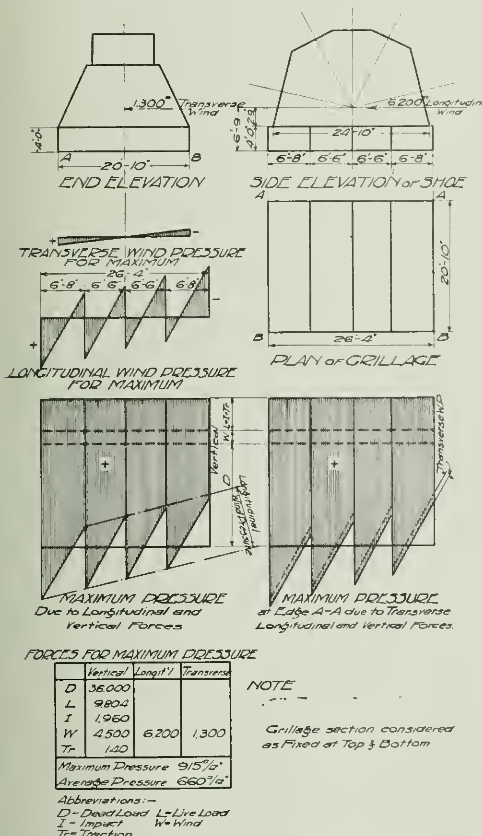

Fig. 6.—Diagram of Pressure Between Shoe and Masonry.

tion of the floor and 300 lbs. per lin. ft. on the exposed surface of a train covering the whole bridge applied 9 ft. above base of rail.

After the various parts of the shoe have been fabricated in the shop it is entirely assembled on concrete and steel skids and all field connections are reamed out in place or to a steel template. All loose parts are matchmarked with stencil and steel dies and all important centre lines chisel-marked on abutting faces. It is then taken down and the main sections re-assembled on the bed of the boring mill, and after having been accurately lined up with field level, transit and other special mechanical appliances, the five holes are bored at one setting. When this operation has been completed the shoe is again taken apart for shipment, the lower base being shipped in four sections, the middle in two main sections, and the top in one. When completed, each shoe weighs about 440 tons. The exterior faces of the middle section are covered with facia plates to give a finished appearance. These plates, as well as all diaphragms and top flange of castings, are provided with manholes, thus providing access to all parts of the shoe for riveting, inspection and painting. In order to prevent rain water settling in the interior, the shoe is partially filled with concrete which is sloped from the centre towards the sides, thus allowing all water to drain out through the holes in the facia plates.

In Fig. 1 is shown one of the four steel castings forming the lower story. It is being placed on the main pier. A thin grout is brushed over the masonry rest before the casting is put in place. The castings are assembled as shown in Fig. 2, which is a shop view showing erection on skids, and a start made on the erection of the middle section of the shoe. In Fig. 3 the second and third

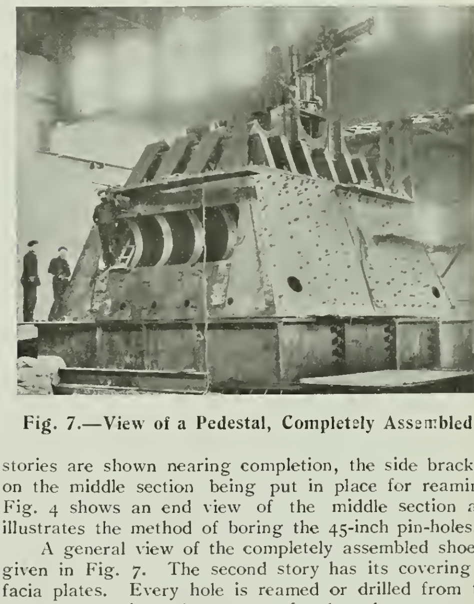

Fig. 7.—View of a Pedestal, Completely Assembled.

stories are shown nearing completion, the side brackets on the middle section being put in place for reaming. Fig. 4 shows an end view of the middle section and illustrates the method of boring the 45-inch pin-holes.

A general view of the completely assembled shoe is given in Fig. 7. The second story has its covering of facia plates. Every hole is reamed or drilled from the solid before being taken apart. It takes about 2 months to assemble, ream and bore this shoe in the shop, not including the time required for fabrication.

TORONTO HARBOR COMMISSIONERS TO CONTINUE WORK.

Although the early formation of ice on the bay will seriously interfere with their work along the waterfront, the Toronto Harbor Commissioners have made a careful survey of the territory under construction and are picking out the portions of the work that can be continued during the winter, in order to give employment to as many men as possible. A considerable portion of this work will consist of grading operations along the waterfront.

POROSITY OF BUILDING STONE.*

By D. G. Campbell, M.E.

THE quality of a building stone depends upon a number of factors, of which the following are more directly influenced by the porosity or water contents: strength, color, mechanical disintegration by climatic agencies, and rate of chemical decay.

Porosity in itself has small effect in determining relative qualities of building stones. That is, stones may vary in percentage of pore space from 0.5 up to 20 or 25%, and yet, other things being equal, these extremes may not show great variation in strength. The important point in connection with porosity, however, is the *size* of the individual pores.

Sandstones are the least compact of the stones used largely for building; and their porosity ranges up to 28% of the total volume, which is near the theoretical maximum. Such rock, when exposed to water, will absorb large quantities, and is equally capable of releasing it by evaporation. Moreover, it is difficult completely to fill the pores of such a stone with water. Stones of which the pores are very fine are slow to give up their contained water; if this be then expanded by frost, such stone is gradually weakened and disintegrated. It is by reason of this fact that sandstones may be quarried and laid in freezing weather without injury, whereas fine-grained stones are likely to be seriously injured by such treatment.

Limestones and marbles have much less pore space than sandstones, ranging from 1 up to as much as 10%; while in granite the pore space is less than 1%. In these stones, the pores are capillary or sub-capillary in size. Hence, such stones absorb but little water, and absorb it slowly; once in, it is equally hard to get out. When such a stone, saturated with water, is exposed to a hard frost, freezing expands the pores, and by breaking the union of the interlocked grains weakens the structure. Stones of such fine-pored character are injured by being quarried in cold weather, for the small percentage of "residual water" cannot then escape readily, and may repeatedly freeze and thaw in the stone, before evaporating, thus increasing the destructive effect.

This distinction applies only to true porosity; for if a stone be laminated, water filling the spaces between the bedding planes may do a great deal of damage. Hence the rapid disintegration of inferior, shaly sandstones under severe climatic conditions.

If limestone and marble be thoroughly seasoned before being used, their small ratio of porosity, and fine pores, are great advantages, contributing much to their durability (*Merrill*). This is because the sub-capillary pores absorb water with extreme slowness and difficulty. Hence, it would seem inadvisable to employ marble or compact limestone where it would be exposed to dampness combined with extremes of temperature. The following table (*Buckley*) gives the ranges in loss of strength suffered by various samples of building stones due to alternations of freezing and thawing for 35 days:

Loss of Strength by Freezing and Thawing.

Rock.	Orig. strength, lb. per sq. in.	Loss of strength, lb. per sq. in.	Loss, %
Granite	24,300	8,210	32
"	34,600	2,800	8
Limestone	30,680	13,675	44
"	8,100	570	7
Sandstone	4,170	1,950	46
"	5,330	930	17

*From the School of Mines Quarterly, Columbia University.

Life of Building Stone. (*Julien*).

Coarse brownstone	5 to 15	years
Fine laminated brownstone	20 to 50	"
Coarse fossiliferous limestone	20 to 40	"
Coarse dolomitic marble	40	"
Fine-grained marble	50 to 100	"
Granite	75 to 200	"
Quartzite	75 to 200	"

The color of a building stone may be due to one or all of three factors: inherent color of the minerals composing the rock; material that acts as a binder to hold the rock particles together; foreign matter and impurities. As examples of the first may be mentioned granites, gneisses, diorites, and the igneous rocks in general. In the second category come sandstones mainly, such as brownstone and red sandstones. In this case the cement that holds the sand particles together is an iron oxide. In the third group comes sandstones containing carbonaceous material, such as bluestone and the like; also igneous and metamorphic rocks, granite, limestone, and marble, containing small but noticeable amounts of iron carbonate or sulphides.

In the majority of the uses to which building stone is put, its color, and especially a small variation of color, is of slight importance. In factories and business blocks, breakwaters and retaining walls, for street paving and similar uses, color is immaterial. In ornamental buildings and residences, however, or for decorative and artistic uses, the permanence of color, and its uniformity, is of considerable importance. These features are largely influenced by the porosity of the stone, and the amount of water which, percolating through it, is able to dissolve mechanically or change chemically the color-producing ingredients. In the first class of rocks named above, change of color is effected only by alteration of the original minerals; this change may be complete after the lapse of long periods of time, but does not take place to any great extent in the ordinary life of a structure or piece of ornamental work.

In rocks of which the coloring is due to, or affected by, foreign matter and impurities, change of color or bleaching is accelerated by dampness and water content. The sedimentaries, sandstone for instance, frequently contain much carbonaceous material, which produces blue, brown, buff, cream, and other tints. These may fade or be washed out by percolating water. This change is, however, fairly uniform, usually, and is not serious enough to depreciate materially the value of the stone.

With such impurities as carbonate and sulphides of iron, the changes that occur are much more marked and objectionable. These impurities are gradually oxidized and deposited on the surface as irregular brown blotches, or as long dripping stains. Such result may be caused by gradual percolation of iron impurities in the cement and mortar used in construction, or in the material of the backwall. This objectionable condition is most frequently met in limestones and some marbles, occasionally in granite; it greatly reduces the value, if it does not completely prohibit a stone so affected from being used for ornamental purposes where it is exposed to moisture.

In such rocks as red sandstones and brownstone, there is much iron present in the form of oxide, serving as a cement to bind the particles of sand together. In this case no appreciable alteration of color is to be feared.

Besides the staining or bleaching produced by the oxidation of carbonate and sulphides of iron, a serious chemical effect is sometimes noted. This is due to the action of sulphurous and sulphuric acids released by this

decomposition, which dissolve calcium carbonate, and deposit an incrustation of calcium sulphate on the surface of the stone. If the quantity of such impurities be large, this may be a source of serious weakening. Artificial stones and concretes have been made from rock and slags carrying a large percentage of iron, and they were either seriously decomposed or completely disintegrated within a few years.

Again, when a stone is subject to the action of running water, or water under pressure, or especially both together, the calcium carbonate contents of the stone must be kept low. Water containing even slight amounts of carbon dioxide is an excellent solvent for that mineral, and not only wears it away on the surface, but, seeping through, is likely to honey-comb it so as to render it useless. An instance is noted where, in an English aqueduct, limestone was used in the construction, and in a few years the leakage through honey-combing had assumed serious proportions. Rocks composed of or bound together by siliceous material are not noticeably affected this way, as silica is insoluble in ordinary surface water.

The minerals composing the igneous rocks, as granite and rhyolite, are also subject to alteration and decay, but this proceeds so slowly that it is seldom apparent in the ordinary lifetime of a structure. Quartz and feldspar are the principal minerals. The former does not change at all, the latter very slowly under the influence of weather-weathering. The accessory minerals, mica, pyroxene, amphibole, and olivine sometimes accur in considerable proportions. These decay by oxidation and hydration much more rapidly and, especially if rich in iron, may cause trouble. If the stone contain many minute fractures, this weakening may be intensified, due to the fact that the products of alteration, serpentine, talc, chlorite, and the like, forming in thin, slippery layers and scales, make an excellent lubricant to aid any severe stress or shock in rupturing the stone. For this reason, stones rich in crystal micas, amphiboles, and pyroxenes, greenstone for instance, are usually viewed with disfavor.

To summarize the foregoing, it may be said that:

(1) The strongest and most enduring rocks have the least porosity; granites and gneisses less than 1%, limestones up to 10%, sandstones up to 20%. (This is ascribed to the comparative value of the binding material, silica, calcium carbonate, and iron oxide, respectively, the relative value of these as binding agents being (*Buckley*) in the order named.)

(2) Of unseasoned stones, those having large pores, as the sandstones, are less likely to be injured by freezing than those having sub-capillary pores.

(3) Water seeping through porous rocks usually bleaches and carries away color-forming impurities, and these may be deposited on the surface in the form of incrustations and stains.

(4) A porous stone possessing calcareous ingredients, on exposure to running water or to water under pressure, is likely soon to become honey-combed and to disintegrate.

(5) The accessory minerals of igneous rocks are also subject to slow alteration by oxidation and hydration, and if present in large quantities, may prove a source of weakness.

The MacArthur Concrete Pile & Foundation Company has sold the patent rights to drive the pedestal pile in Japan to the Oriental Compressol Company, of Tokio, Japan.

THE "FALL INCREASER" FOR LOW WATER FALLS.

By Clemens Herschel,

Civil and Hydraulic Engineer, New York City.

WITH the exhaustion of the available high falls for power purposes, the low falls will necessarily attract more attention than hitherto, from the builders of such plants. These last-named power sites frequently suffer materially from "back-water," in addition to the inroads made upon their annual output of power by low water.

A remedy for both of these power abatements lies, of course, in the use of auxiliary heat engines, but the use of these, means an increase of cost per kilowatt hour during the time of their running, and of the average cost per kilowatt hour during the year. Against low water inroads there is no other remedy; but against back-water power losses the use of the fall increaser offers a remedy that costs less in many cases than burning the fuel needed for generating the same power; that is to say, costs less than to run heat engines installed for the purpose of increasing the output of power during times of low water.

The fall increaser was invented in 1907, in the course of a competition for a power house design for Geneva, Switzerland, in which the competitors were especially invited to provide means for increasing the fall acting on the turbines during the times when, by reason of an overabundant water supply, the fall shall have been diminished. In the case named, the dam was to have consisted merely of "Stoney" gates; with the head water level nigh constant; so that the fall was expected to vary from 43 ft. down to 26 ft. This power house has not yet been commenced, but by the use of fall increasers, and by letting the freshet water pass through them, instead of allowing it to waste away under the Stoney gates, a suction could be exercised at the outlet of the turbine draft-tubes, that would keep the fall at 43 ft., and maintain the full power output some of the time of back-water, and at very nearly full power output, (when there is not enough freshet water to operate all of the fall increasers) the rest of the time.

Since 1907, the fall increaser has been tested at the Holyoke, Mass., Public Testing Flume; so that designs for it, and computations showing just what it will accomplish in any given case, can now be made with precision. A full account of these tests was published in the Harvard Engineering Journal, of June, 1908, and from this record it appears that the "operating water" (freshet water used) was as much as 14 sec.-ft.; the "water lifted" (turbine discharge) 7 sec.ft.; the "operating head" (natural head) was up to 14.35 ft.; the "head gained by the use of the fall increaser," up to 12.52 ft.; the fall increaser penstock, 16 inches in diameter; not mere "laboratory experiments," as anyone can see.

Similar experiments were made thereafter by one Dübi, in Zürich, Switzerland, the results published in book form, and they, naturally, have confirmed the results of the Holyoke tests. It thus only remains now to apply the fall increaser in actual practice.

That this has not already been done, need surprise no one. It is accounted for from the fact that 10 years or more are not infrequently needed to overcome the inertia, business jealousies, misconception of, and lack of appreciation with which new ideas of this sort are generally treated. It was thus with the Venturi water meter,

a first cousin of the fall increaser, 6,000 or 7,000 of which are now in use the world over, though it was 10 years before anyone would use it, except its inventor.

The fact that the fall increaser is only of limited application, and cannot practically be added to a plant already in operation (it must be built into the foundations of the power house) has also much to do with the delay, up to date, of its use in operation.

Its value at any mill site depends on the regime of the river; whether there is back-water, to a material extent, and during enough days in the year.

The situation must also be such as to permit of the conveyance of the freshet water to be utilized to the fall increaser inlets; no long head-race canal.

The writer of this has had cases in which the estimated additional first cost for putting in fall increasers would be returned in value of the *additional* kilowatt hours produced in one average year, or less; and from that the situation ranges up to periods and measurements of back-water so small that it does not pay to build fall increasers; even though first cost is paid but once (operation and maintenance are merely nominal), while the average additional kilowatt hours produced are produced and gained every year.

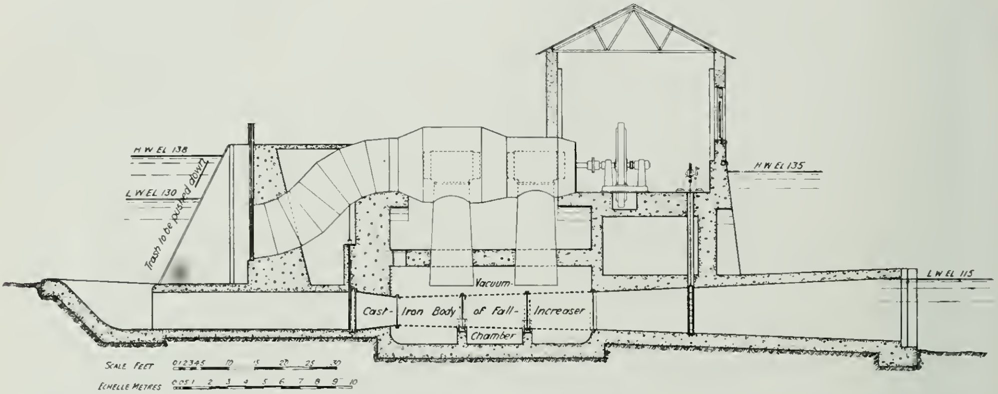
The money considerations involved are well shown by the results of some examinations made. In one case, for an estimated additional cost of $50,000 an additional 8⅓ million kilowatt hours, distributed during times of high water, (that is, when sorely needed), would be secured on the average, annually, forever. The net profit was estimated at not less than $23,000 per annum, forever. This plant has not yet been begun, and may be fitted with fall increasers when built.

In another case, fall increasers would produce, in an average year, 158 million kilowatt hours. They would keep the power practically constant throughout the back-water half of the year, instead of having it fall from some 250,000 h.p. down to about half that amount, during that period; (not considering the low-water half of the year). The additional cost entailed by building them would have been, as per estimate, one million dollars.

It might be thought, at first view, that fall increasers would have offered notable advantages at the Wasdell's Falls, Ont.,* power house, recently put in service, but impending improvements both in the Severn River and at Lake Simcoe outlet will do much to make the fall at this power house nigh constant throughout the year.

Incidentally fall increasers would greatly aid in keeping the racks clear of trash, which, when fall increasers are installed, needs only to be pushed down, and within range of their action, so as to pass through them; instead of having to be raked and lifted up and carried ashore. See the illustration, which is of an extreme case of back-water; only 3 ft. of fall left out of 12 ft. fall at ordinary water, on which account a siphon penstock is shown, to be kept clear of air at the summit by a small (an inch or two) fall increaser acting as an air exhauster.

Roughly and generally speaking, the "operating water" is double the turbine discharge, and the fall acting on the turbine is increased 50%, which increases the power given out by 80%. So long as back-water does not diminish the fall more than 33%, fall increasers will restore (from the fall and power then obtaining) the full, or normal, fall and power, and be of material benefit also, beyond the 33% mark.



Cross-section of a Power House, Showing Application of Fall Increaser. It Shows Also the Use of a Syphon Penstock. Note the Low Fall Remaining at Extreme High Water.

* See *The Canadian Engineer*, October 8, 1914, page 509, for full description of this development.

THE ROGER'S PASS TUNNEL IN B.C.

Since the publication of our last article descriptive of the progress already made in driving the 5-mile tunnel for the Canadian Pacific Railway under Roger's Pass at Glacier, B.C., the work has been advanced by the contractors, Foley, Welch & Stewart, with the greatest possible rapidity. On the east side the pioneer bore has been advanced considerably over a mile while the 8 x 11-ft. centre heading and the full tunnel section had been driven, on October 1st, a distance of 3,100 and 400 ft. respectively. At the western end the approach cut, requiring the excavation of 350,000 cubic yards, has been completed at that time, and the pioneer bore has been advanced over 2,000 ft. In the main tunnel portal a number of small headings have been worked for a considerable distance.

Editorial

THE "GLAGSESTEN" THEORY IN THE STORAGE OF IMPURE WATER.

In investigations which he has long had under way, Dr. A. C. Houston, director of water examination to the Metropolitan Water Board, of London, Eng., has become convinced that storage of impure water is not only demonstratively a process making for safety, but that a most important influence is at work, *viz.*, the devitalization of the undesirable bacteria, owing to their finding water a most unsuitable medium for their sustained activity. In his recent report, a section of which enlarges upon the value of storage in water purification, cognizance is given of such factors as the influence of glass on bacteria, and the effect of agglutination, sedimentation, sticking and enshrouding processes. With due consideration for the opinions of other writers on the theory that these factors really have an influence, he gives to it, for the sake of brevity, the name "glagsesten." The property of glass by which it imparts certain constituents to water, although relatively insoluble, is taken into consideration in conjunction with the storage of water in reservoirs, experiments in the latter confirming laboratory results with the former. It is concluded that the same principle of gradual devitalization is at work in both cases, although, perhaps, with a difference in degree.

The agglutination or clumping together of bacteria is readily explained by the apparent loss of vitality under conditions of storage. "If," Dr. Houston remarks, "we compare stored water with unstored water, we find that the former contains far fewer excremental bacteria than the latter, and the results on the average are not appreciably affected by preliminary violent shaking of the samples with lead shot sand and a mixture of shot and sand. Still it might be maintained that the shaking operations were not sufficiently drastic to break up the clumps, and if this is true the only difference between drinking raw river water and the same water after storage in reservoirs may conceivably be, that in the former case we ingest separated bacilli, and in the latter case clumps or balls of bacilli."

The sedimentation is, of course, a great factor in the importance of storage, and its influence is frequently quite noticeable in even less than twenty-four hours. As for particles in suspension tending to stick to various materials, it was demonstrated that shaking operations with shot and sand failed to explain all the observed facts relating to the storage of the impure water, indicating that sedimentation in itself was not wholly accountable. It was remarked that if the bacteria stick so closely as to be undetachable when subjected to the above process there is good ground to believe that they will stick so long to the sides and bottoms of reservoirs as to lose their vitality and die.

Discussing the enshrouding process, Dr. Houston does not appear to lay much importance upon it in his report. If, however, the enshrouding during the physical and chemical changes which occur under conditions of storage is so complete as to resist all shot and sand shaking operations, and so manifold that when a suitable nutrient medium is introduced no growth takes place, there would appear to be some ground for believing that ingestion of such a water would not be followed by any evil results.

The agglutination, sedimentation, sticking and enshrouding processes, concludes Dr. Houston, all make for the retention of pathogenic bacteria much longer in storage reservoirs than would otherwise be the case; so long, indeed, as perhaps to exceed the most extravagant estimate as to the length of time such microbes can live in water.

ENGINEERING ETHICS.

The Council of the Canadian Society of Civil Engineers has circulated among the members a ballot for the proposed amendment of several by-laws, to be considered at the next annual meeting of the Society. An important one among them is a proposed code of ethics, for adoption in place of the existing code. The regulations are as follows, and relate to every corporate member:—

(1) He shall act in all professional matters strictly in a fiduciary manner with regard to any clients whom he may advise and his charges to such clients shall constitute his only remuneration in connection with such work, except as provided by Clause 4.

(2) He shall not accept any trade commissions, discounts, allowances, or any indirect profit in connection with any work which he is engaged to design or superintend or with any professional business which may be entrusted to him.

(3) He shall not, while acting in a professional capacity, be at the same time, without disclosing the fact in writing to his clients, a director or member, or a shareholder in, or act as agent for, any contracting or manufacturing company or firm or business with which he may have occasion to deal on behalf of his clients or have any financial interest in such a business.

(4) He shall not receive directly or indirectly any royalty, gratuity or commission, on any patented or protected article or process used on work which he is carrying out for his clients, unless and until such royalty, gratuity or commission has been authorized in writing by those clients.

(5) He shall not improperly solicit professional work, either directly or by an agent nor shall he pay, by commission or otherwise, any person who may introduce clients to him.

(6) He shall not be the medium of payments made on his clients' behalf to any contractor or business firm (unless specially so requested by his clients) but shall only issue certificates or recommendations for payment by his clients.

Any alleged breach of these regulations or any alleged professional misconduct by a corporate member which may be brought before the Council, properly vouched for and supported by sufficient evidence, shall be investigated, and if proved, shall be dealt with by the Council, either by the expulsion of the offender from the Society or in such other manner as the Council may think fit.

NEW PUMPING EQUIPMENT AT BRACEBRIDGE, ONTARIO.

BRACEBRIDGE, Ont., has lately installed and put in operation some new electric-driven pumping equipment, to supply water at high pressure for fire service; or, alternatively, to double the quantity of water at half that high pressure. This system, known as the series-parallel arrangement of pumps, is one which is used quite frequently on municipal waterworks systems.

The equipment at Bracebridge consists of 2 single-stage Mather & Platt patent turbine pumps, each capable of pumping 800 Imp. gal. per min. against a total pressure head of 60 lb. The piping, as shown in the accompanying illustrations, is arranged so that these pumps may be run in parallel giving a total of 1,600 Imp. gal. per min. against a head of 60 lbs. They may otherwise be run in series, giving 800 Imp. gal. per min. against a head of 120 lbs. or they may be run singly, each giving 800 gal. against a head of 60 lbs.

Particular attention has been given to the testing of this equipment. Fig. 3 shows the equipment set up complete in the testing plant at Rockfield, Que., of the Canadian Allis-Chalmers, Limited, who manufactured the pumps. Curves giving the characteristics of the pumps at rated speed, as obtained in the test, are shown in Fig. 4.

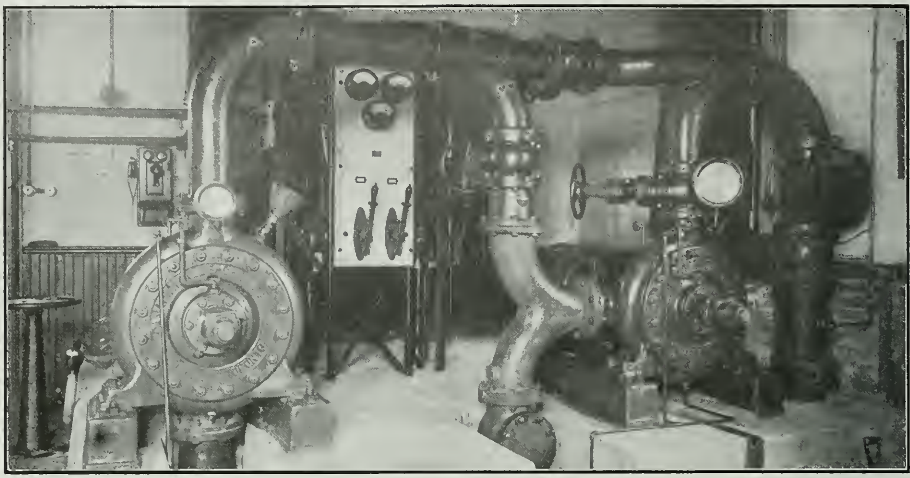


Fig. 1.—View of the New Installation at Bracebridge, Ont.

Fig. 2.—Four Fire Streams (one at a sharp inclination in the background) by Which the Pumps Were Loaded in the 24-hour Duration Test.

After installation, which is illustrated in Fig. 1, the pumps were given a 24-hour run under fire pressure conditions. They were loaded on 4 fire nozzles. (Fig. 2.) To obtain the correct load on these pumps, with rated speed, the pressure was adjusted to that corresponding to the rated quantity of water, as shown in Fig. 4. After this duration test was completed the units were put into service.

Each pump is driven by a direct connected C.G.E. squirrel-cage induction motor rated 60 h.p., 3-phase, 60 cycles, 2,300 volts, 1,800 r.p.m. At the end of the 24-hour run these motors showed a shut-down rise in temperature of 26° C. in the iron and 21° C. in the coils, both being the hottest spots found. From the pump curves it can be seen that 53 h.p. are required to drive each pump at rated capacity, head, and speed, so that not only is ample power provided to drive the pumps but the temperature rise in the motors shows liberal rating. The idea of having ample capacity in the motor is to take advantage of the overload characteristics of the pump. These pumps are equipped with diffusion guides on exit.

Referring to Fig. 5, the advantage of the use of diffusion guides can readily be seen, when the pump is for waterworks systems or similar service. These curves are taken from two other actual pumps, one with

and one without diffusion guides, and both rated 2,500 gal. per min., 880 r.p.m., and 180 ft. head.

The efficiency curves show a higher efficiency in the pump having diffusion guides, due to the better hydraulic conditions prevailing on account of having definite passages for the guidance of the water from the impeller and to the smaller losses in the smaller impeller required. On account of the smaller power required at no load and at full load by the pump with diffusion guides, it is evident that

Fig. 3.—Arrangement of Equipment, Pump-testing Plant.

its efficiency curve must be higher over the full range of the pump since the b.h.p. curves are nearly straight lines.

It will be noted that, with the pump not having diffusion guides, the point of maximum capacity is not very far beyond the point of maximum efficiency which is at rated capacity of the pump. The pump having diffusion guides, however, gives considerably greater capacity than that at which maximum efficiency occurs. So, by taking advantage of the overload guarantee of electric motors (25% for 2 hours) it can be seen that approximately 30% extra capacity can be obtained for two hours. This is valuable for heavy fire service and all the more valuable since the pressure only drops approximately 15 per cent. With a pump not having diffusion guides the pressure falls to zero on small overload demands, which would be serious if firemen coupled on a few extra lines of hose and opened them out too much. Furthermore, with this latter type, no advantage can be taken of the overload capacity of the electric motor.

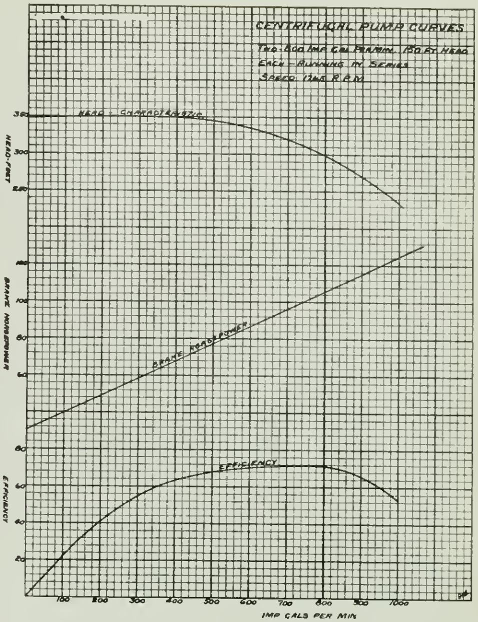

Fig. 4.—Characteristics of Two 800-gal. per min. Pumps Running in Series, 150 ft. Head, 1,765 r.p.m.

The characteristics of the diffusion guide pump were fully demonstrated at Bracebridge. The nozzles were removed and the discharge regulated by a valve. The discharge was increased above the rated capacity and the pressure held up as shown on the curve in Fig. 4. The equipment was intended for 4 fire streams and it was shown that nearly 7 could be obtained without a serious falling off in pressure, or overloading of the motor.

The overload relay on the motor was set for between 35 and 40% overload. On opening up the discharge wide the motors automatically tripped out. These conditions correspond to a break in the water mains and showed how the pressure was automatically removed which would prevent a big washout around the break in the water main. The overload relay can be arranged either to operate an alarm or trip the motor out or both.

Mr. W. C. Simmons, superintendent of the municipal systems at Bracebridge, laid out the equipment and put in the installation. The convenience with which his equipment may be operated is worthy of notice. The operator, standing in front of the switchboard, can start up both motors from that position and is able to watch his instruments while doing so. After the motors are started, by facing about, he has all the valves within reach and the gauges are mounted in front of him, so that he is able to see just exactly what is happening when opening the valves. It is easily possible to start everything from rest and have fire pressure on the mains within 30 seconds from the time the alarm is sent in.

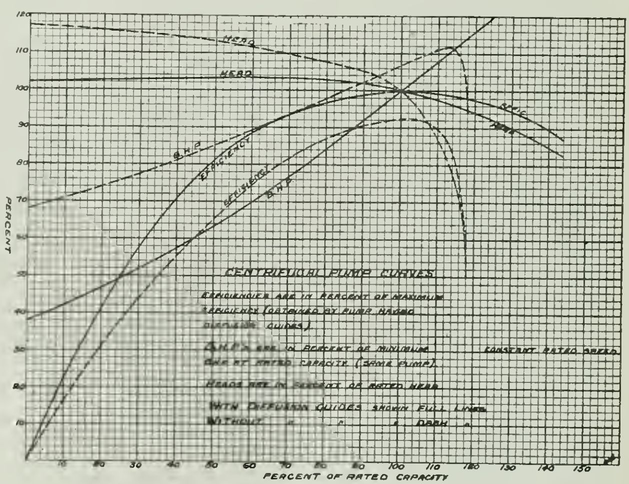

Fig. 5.—Effect of Diffusion Guides on the Characteristics of a Centrifugal Pump, as Shown by Actual Test.

HEAVY TRAFFIC ROADS.

By Henry G. Shirley,
Chief Engineer, State Roads Commission of Maryland.

IN selecting a type of surfacing for any particular road, the engineer not only has to study the amount and kind of traffic that daily passes over the road, but has to make a very comprehensive study of the amount and kind of traffic that will probably pass over the road in the future, by virtue of the development of the surrounding territory on account of the improved road.

The writer has made studies of roads where the traffic, before improvement, consisted of light vehicles and nothing heavier than 2-horse loads, but as soon as the road was reconstructed, the amount of traffic increased from 50 to 300%, and the loads from light 2-ton loads to 10 to 12-ton motor trucks, and 14 to 18-ton tractors. He also recalls constructing a section of road through a very sparsely settled section, and estimating that it would be quite a long time before the adjacent territory would be more thickly populated, and accordingly selected a soft local limestone for the metal surfacing, but which had sufficient strength and hardness to carry the traffic that was passing over the road at that time. Scarcely had the road been completed when several large tracts of woodland, not a great distance from the road, were cut down, and the lumber was transported on wagons, drawn by large traction engines with cleats, over the road to the railroad station. The effect of this heavy traffic on the soft limestone surface can be easily surmised.

Drainage.—Drainage of a road-bed that is required to carry heavy traffic, should be well taken care of by tile or other sub-surface drains, so as to render the subfoundation as dry and firm as possible. The maximum grade should not exceed a 6 per cent., and the alignment should be as straight as possible, with all sharp curves and bends eliminated. The width of the roadway and the width and thickness of the metal surfacing should be designed to meet the requirements of the present as well as the future traffic which it will have to accommodate, but the minimum width should not be less than 30 feet, nor the metal surfacing less than 18 feet. Broken stone or gravel make a fair foundation, but concrete is almost as cheap and is more preferable.

The thickness of macadam and gravel should not be less than 5 inches after rolling, nor more than 10 inches, while concrete should not be less than 4 inches, nor more than 8 inches, depending primarily upon the character of the soil of the sub-base, and the intensity and character of traffic it will have to sustain. In some cases where the loads are very heavy, but the number of loads small, it has been found economical to lay a strip of high-class and durable pavement in the middle of the road for a width of 9 to 14 feet, with a cheaper and less durable material on each side.

Before selecting the type of pavement to be used, a close and accurate census of the different kinds of traffic should be taken, a very thorough study made of the surrounding section, and an estimate made as to the possible increase of the different kinds of traffic, or the decrease of one kind and the large increase of the other. It is the opinion of the writer that in no other line of engineering should there be a larger factor of safety used than in estimating the amount, intensity, and kind of motor and self-propelled traffic that will pass over our improved roads in the near future. The great change in the character of traffic developed in the past five years, is but a small index to what can be expected in the next five years to come.

The types of pavements used on heavy traffic roads should be selected as to their fitness to stand the kind and intensity of the traffic that will travel them. Roads in the outlying districts, where horse-drawn traffic comprises the larger percentage, should be constructed of macadam with a light surface treatment. Concrete will also be found serviceable and desirable. Where motor traffic is in the majority, bituminous macadam or concrete will give good results. Near the centres of population, where the traffic is mixed and heavy, concrete, bituminous concrete, asphalt or vitrified brick will prove the most economical. Where the heavy traffic is concentrated, brick, asphalt or stone block are the most suitable.

There can be given no hard and set rule for selecting the type of construction that should be used on a given section of road to carry a known traffic. For local conditions, the availability of materials, etc., play such an important part in the selection of the type of surfacing in any locality, that each individual case must be worked out on its own merits.

The following method of selecting a type of surfacing to carry an estimated traffic, however, will prove fairly accurate where a study can be made and the maintenance cost can be had of roads constructed and maintained under similar conditions:

Where the annual cost of maintenance of a less durable type of road surfacing will exceed the annual cost of maintenance of a more durable type of surfacing, plus 4 per cent. on the excess cost of the more durable type over the less durable type, the more durable type should be used, and vice versa.

The maintenance on heavy traffic roads should be continuous and thorough—never allowing the surface to remain broken any length of time, but as soon as the slightest defect or indication of failure appears, it should be speedily repaired.

LARGE PROJECTED HYDRO-ELECTRIC STATION IN NORWAY.

The proposed exploitation of the water-power in the Take Falls, with the co-operation of the Norwegian State, is one of the largest undertakings in the country. The first stage is the building of a power-station with a capacity of 125,000 h.p., which can be obtained simply by the regulation of the Totak, by retaining the water of the Totak during the high-water season and using the power of the Vinje waters without any regulation. The plan is based upon an English Company contracting for about 100,000 h.p. for a period of 30 years, with the option of a further 20 years at $7.25 per h.p. per annum, the energy to be supplied as alternate current of some 10,000 volts, the factories in question to be erected within a distance of 100 kilometres from the power-station. The Take waters represent one of Norway's largest and best water-power streams. By regulating the Totak and the Vinje waters a capacity of 250,000 h.p. is confidently reckoned upon, and of this 140,000 h.p. will come from the Totak after regulation. Of this the Hyllands Fall represents 15,000 h.p. The exploitation of either the Totak and the Vinje is not expected to offer any difficulties whatever from a technical point of view, and the cost can, it is confidently asserted, be kept at a comparatively low figure, the existing roads for transport, for one thing, being adequate. The cost of the finished power-station for the first 125,000 h.p. is calculated at $26.80 per electric h.p., and the next 125,000 h.p. will naturally come out somewhat cheaper.

ONTARIO'S MINERAL PRODUCTION IN 1913.

The following table gives a summary of the mineral production of the Province of Ontario for the year 1913, as presented in the statistical review by Thos. W. Gibson, Deputy Minister of Mines, in the 23rd annual report of the Bureau of Mines, 1914.

Table I.—Mineral Production of Ontario, 1913.

Product.	Quantity.	Value.
Metallic:		
Gold .... ozs.	220,837	$ 4,558,518
Silver .... ozs.	29,724,931	16,579,094
Copper .... tons	12,941	1,840,492
Nickel .... tons	24,838	5,237,477
Iron ore .... tons	195,937	424,072
Pig iron .... tons	648,899	8,719,892
Cobalt oxide, etc. ..... lbs.	(a) 1,188,526	420,386
Nickel do ..... lbs.	(b) 232,255	13,326
	....	$37,793,257
Less Ontario iron ore (132,708 tons) smelted into pig iron	....	285,322
Net metallic production.	....	$37,507,935
Non-metallic:		
Arsenic, refined .... lbs.	(c) 2,450,758	64,146
Brick, common .... No.	408,808,000	3,452,352
Tile drain .... No.	16,935,000	292,767
Brick, paving, etc. ..... No.	18,547,000	243,119
Brick, pressed .... No.	81,238,000	919,741
Stone, building and crushed	....	1,137,153
Calcium carbide ...... tons	2,052	123,100
Cement, Portland ..... bbl.	3,802,321	4,105,455
Corundum .... tons	1,177	137,036
Feldspar .... tons	18,615	67,142
Graphite, refined ..... tons	1,788	93,054
Gypsum .... tons	40,581	92,627
Iron pyrites .... tons	71,620	171,687
Lime .... bush.	2,300,991	390,600
Mica .... tons	386	55,264
Natural gas.. million cu. ft.	12,516	2,362,021
Peat .... tons	500	1,750
Petroleum ...... Imp. gal.	7,915,761	398,051
Pottery	....	52,875
Quartz .... tons	54,320	130,860
Salt .... tons	96,799	474,372
Sewer pipe	....	600,297
Sand and gravel ... cu. yd.	425,978	233,567
Talc, ground .... tons	20,738	125,340
Non-metallic production	....	$15,724,376
Add metallic production.	....	37,507,935
Total	....	$53,232,311

(a) The estimated quantity of metallic cobalt contained in the ores raised from the silver-cobalt mines was 377 tons; this includes the quantity converted into oxide.

(b) The estimated quantity of metallic nickel contained in the silver-cobalt ores was 821 tons, which is included in the quantity converted into oxide.

(c) The ores extracted from the Cobalt silver mines are estimated to have contained 3,633 tons of arsenic, which includes the quantity of refined arsenic given in the table.

Coast to Coast

St. John, N.B.—Dredging operations at Salmonier have been completed. A channel, 940 ft. long has been cut into the main basin at Little Harbor to avoid danger from running ice in the winter.

Vancouver, B.C.—Mr. J. G. Bury, vice-president of the C.P.R., while in the city last week, announced that the Kettle Valley Railway from Midway to Merritt, providing an alternative scenic route by way of the Crow's Nest Pass, will be in operation by next June.

Edmonton, Alta.—When the season closes about 345 miles of grading and steel will have been laid upon the Edmonton, Dunvegan and British Columbia, and upon the Alberta and Great Waterways Railways this year. The J. D. McArthur Construction Company are the contractors for the work.

Hamilton, Ont.—The National Gas Company states that it will lay 7½ miles of pipe before January 1st, as required by its franchise. Tenders for trenching and laying pipelines from Black Heath to Hamilton, a distance of 16 miles, and also for the above length of line within the city limits are now being advertised.

Toronto, Ont.—A large steel buoy steamer, 164½ ft. in length, 30 ft. breadth, and 13 ft. depth, built for the department of marine and fisheries, was launched at the Polson Iron Works on November 7th. It is equipped with triple expansion jet-condensing engines of 900 h.p. capacity, and will be provided with all modern electrical equipment, including search light, etc.

Vancouver, B.C.—Oil burning locomotives will be used, according to statements made in an official interview, by the Grand Trunk Pacific on its transcontinental route. The company is preparing contracts for large developments, and oil storage facilities are receiving considerable attention. The terminals at Prince George, Endako, Smithers and Pacific, noted in these columns last week, are among the divisional points where storages will be established.

Toronto, Ont.—To relieve transportation difficulties in Ward 7, the city will proceed immediately with the construction of a car line extending west on Bloor Street from Dundas Street to Quebec Avenue, at an approximate cost of $125,000. Permanent track will not be laid this fall, but a temporary line will be constructed without delay, and will be in operation before the end of the year. It will be a single track provided with turn-out switches. The Street Railway Company has offered to operate the line charging the city 20c. per car mile and allowing single fare rates to passengers using both the proposed line and the company's service.

Montreal, Que.—Grading has been completed on the Canadian Northern Railway from Montreal to the harbor of Vancouver, and it is expected that this length will be completely railed before the beginning of the new year. Two gaps each of about 50 miles in length are waiting for steel in British Columbia, and track-laying is going on at the rate of about two miles per day. There are also three bridges to be completed, viz., at the Back River, at the crossing of the Chat River above Ottawa, and a third in British Columbia. The substructures for the three have been finished, and the superstructures will be completed in about a month. The company's big undertaking at Mount Royal has progressed very favorably since the last announcement in these columns. Over a mile of tunnel has been excavated to full cross section and about 600 ft. of lining has been put in.

CANADIAN SOCIETY OF CIVIL ENGINEERS, REGULAR MEETING, NOV. 5th, 1914.

The President, Mr. M. J. Butler, C.M.G., occupied the chair. The speaker of the evening was Professor H. E. T. Haultain, M. Can. Soc. C.E., of the University of Toronto. The opening paper was a description of an integrating machine for weighing materials in motion. Mr. Haultain described a device which has been in use in the gas works in Toronto since the beginning of this year, whereby coal is weighed without interruption as it passes over the conveyer system. The explanation was illustrated by models and actual working parts.

The automatic weigher consists essentially of a portion of depressible track over which the conveyer runs. The centre of the depressible track is connected to a series of weighing levers which in turn by their motion impart a movement to an integrator. The integrator travels on a plane circular disk which is caused to revolve by the motion of the conveyer itself. The combination of the rotation of the disk and the side movement of the integrator thereon enables a card to be drawn showing the weight passed over the machine. The introduction of batteries renders it possible to record the weights on an ordinary dial.

Following the curtain raiser Professor Haultain read a paper entitled "The Wielder of the Weapon." This unique and masterly address was followed by an interesting discussion taken part in by Messrs. M. J. Butler, R. A. Ross, Professor Porter, Walter J. Francis, Charles E. Fraser, R. F. Uniacke, Julian C. Smith, and J. M. R. Fairbairn.

PERSONAL.

W. K. MOWATT has been appointed hydro-electric inspector for the city of Brampton.

A. W. THORNE, of St. John, N.B., has been appointed provisional secretary of the New Brunswick Union of Municipalities during the illness of Mr. J. W. McCready.

A. E. PICKERING, formerly manager of the Tagona Light and Power Co., Sault Ste. Marie, is manager for the city of the same concern now that it is taken over by the city.

C. M. WATERMAN, Canadian manager of the Eugene Dietzgen Co., Limited, has returned to Toronto after an extended visit to the firm's head office and factory at Chicago, Ill.

C. A. ELLIS, for several years resident engineer at Winnipeg for the Dominion Bridge Co., has been appointed assistant professor of civil engineering at the University of Illinois.

A. S. FARMER, formerly superintendent in Moncton, N.B., of the natural gas department of the Moncton Tramways Electricity and Gas Co., has resigned to accept a similar position in Oklahoma.

JOHN S. BATES has been appointed superintendent of the Dominion Forest Products Laboratories of McGill University to succeed Mr. A. G. McIntyre, who resigned to take charge of a new paper mill at Bathurst, N.B. Mr. Bates is a graduate of Acadia University in arts and science, and of Columbia University in chemical engineering.

The Canadian Northern Railway is developing a 50,000-h.p. plant from the Sumallo and Nicaloon Rivers, which will be employed in operating the Canadian Northern trains from Port Mann to the False Creek terminals at Vancouver, B.C.

OBITUARY.

Last week the death occurred of Mr. Donald McDermid, Toronto. For many years he had been engaged in railroad construction work. On the mountain division of the C.P.R. he constructed a number of bridges and snow sheds. He was also associated with Mackenzie, Mann & Co. on the C.N.R. At one time he was in partnership with Hon. J. S. Hendrie, now Lieutenant-Governor of Ontario, in the firm of McDermid and Hendrie.

The death has been announced of Mr. Keith Ross Cameron, whose connection with railway building in Ontario is well known. Mr. Cameron was engaged in railway work for some time with the Grand Trunk Railway, and later with the Lake Erie and Detroit River Railway.

BACK COPIES WANTED.

The following back copies of *The Canadian Engineer* are required by one of our Canadian libraries to complete sets for binding:—January 1st, 1907; February 1st, 1907; March 1st, 1907; January 29th, 1909; January 8th, 1912; October 31st, 1912, and January 2nd, 1913. If any of our readers can supply one or more of these copies, we will be glad to extend his subscription one month for each copy returned to this office.

COMING MEETINGS.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

WASHINGTON STATE GOOD ROADS ASSOCIATION.—Convention to be held at Spokane, Wash., November 18th, 19th, and 20th. Secretary, M. D. Lechey, Alaska Building, Seattle, Wash.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

AMERICAN ROAD BUILDERS ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

CANADIAN NATIONAL CLAY PRODUCTS ASSOCIATION.—Annual Convention to be held at the King Edward Hotel in Toronto, January 26, 27, and 28, 1915. Secretary, G. C. Keith, 32 Colborne Street, Toronto.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

AMERICAN WATERWORKS ASSOCIATION. — The 35th annual convention, to be held in Cincinnati, Ohio, May 10th to 14th, 1915. Secretary, J. M. Diven, 47 State Street, Troy, N.Y.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.—Annual meeting to be held at the Iowa State College, Ames, Iowa, June 22nd to 25th, 1915. Secretary, F. L. Bishop, University of Pittsburgh, Pittsburgh, Pa.

Volume 27. Toronto, November 19, 1914 Contents of this issue on page 3

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

STREET IMPROVEMENT IN FREDERICTON, N.B.

NOTES ON THE COMBINED CURB AND GUTTER, DESCRIBING THE METHODS OF LAYING AS ADOPTED IN THAT CITY—DATA ON LABOR AND MATERIALS.

MANY styles of curbs are in use to-day, with varied opinions associated with each. The combined curb and gutter type has been adopted by the city of Fredericton, N.B., and the past season has seen some interesting pieces of construction there. The following information has been furnished us by Mr. R. R. Stevenson, B.Sc., who, the office of city engineer being vacant at the time, did the engineering work for the city. The methods, forms and materials used are described below, and some valuable cost data is added.

Laying Out the Combined Curb and Gutter.—Fig. 1 shows a plan of a small section of the city showing Regent St., just laid with concrete curb and gutter, and the cross streets (which can be picked out from the plan as they are named). As in nearly every city, there are instances where old residents have encroached on the streets due to slackness on the part of the city in the past years, in holding them to the proper street lines. This has necessitated building the combined curb and gutter to fit the existing house lines of to-day.

This entails the plotting of a plan and deciding the best location for the combined curb and gutter. As can be seen from the plan, it was impossible to get a straight line the entire length of the street, hence the engineers decided that the next best plan would be two straight lines with the smallest possible deviation in direction. The best place to make the turn, it was decided, was at Charlotte St. A ship's spike was driven at the exact middle of the street at Brunswick and another in the middle of Charlotte and Regent Sts.; another spike was driven at Aberdeen St., exactly in the middle of the roadway. The bend between these two straight lines was hardly noticeable, there being only an angle of 19 ft. between them. At each street crossing the curbs were carried around the corner so that if the curbs of the cross streets were later built the existing ones would be in a position to connect without the necessity of extra work. At the proposed extensions of cross streets the combined curb and gutter was carried only far enough to allow for the turn around the corner and a space left.

Method of Alignment.—The line could not be laid out in the middle of the road due to the interference of the traffic. It was offset 25 ft. on each side, which brought it on the asphalt sidewalk. The line was then laid down

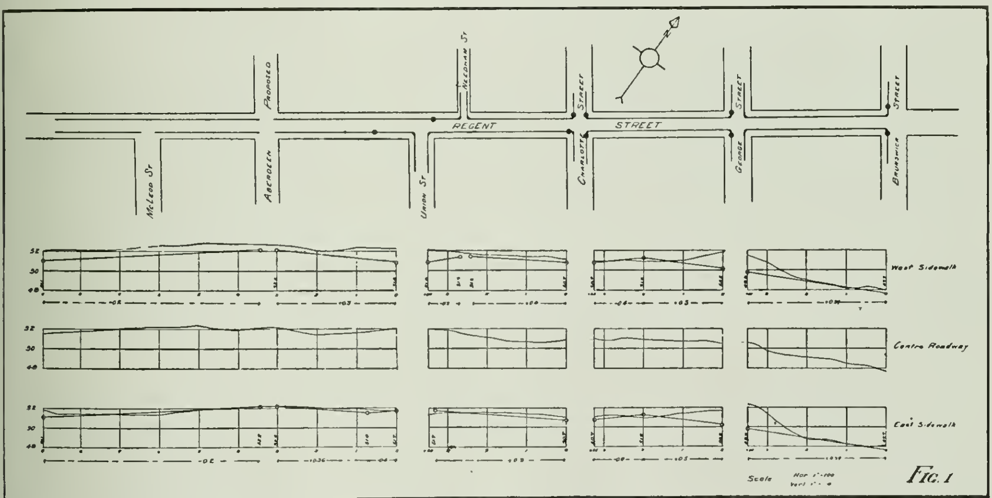

FIG. 1

Regent St., Fredericton, N.B., Showing Alignment Grades, Levels, Profiles, etc., Required.

at 25-ft. intervals by means of tar-paper tins and 8d. nails, the nails being driven through the tins and into the asphalt sidewalk on the exact 25-ft. line. This gave the contractor a good chance to place his forms on the exact line of the back of the curb, there being no possible chance to be out in distances less than 25 ft. Instead of measuring every 25 ft., a batter post was often put in every 200 ft. and a cord stretched between them. The line was hardly necessary every 25 ft., but in putting in the grade plugs, which are necessary every 25 ft., the extra alignment points proved very handy.

After the points were in, the contractor simply had to measure 10 ft. from them, which would give him the location of the front of the curb, it being decided by the city that a 30-ft. roadway would be allowed. This gave 18 ft. of sidewalk from the front of the curb to the house line, the streets being 66 ft. wide.

The alignment of the curb being established, the next thing was to determine the grades and elevations of the combined curb and gutter and to establish them. In Fig. 1 is shown the profiles on the different blocks on Regent St., there being 3 profiles of each block in the determination of the grades and elevations, one on each side of the street and one in the middle of the roadway. The level readings were taken every 25 ft., and after being plotted up, the grades, as shown in Fig. 1, were determined upon. The only parts that needed much judgment were at George St. and the block from Needam out.

At George St., as seen from the profile, there was a sudden rise which looked strange, whereas the rest of the town was level. It was decided that it would be best to cut this hill down, making a gradual slope which would be much easier on traffic than the sudden rise, a gradual 0.6% slope was put in from Brunswick to George St. After the road was completed it was seen that this was by far the best thing that could be done both from general appearance and the ease with which big loads were handled. From Union St. out one side of the road was much higher than the other, so that the combined curb and gutter had to be put in so that it fitted both in the best way possible.

Catch-basins were put in where necessary and are marked in Fig. 1 by small circles. These were built with loose rock with only a sand bottom, and each was therefore more of a cesspool than a catch-basin, the water draining out through the loose rock and the sediment being held in the basin.

Construction of Curb and Gutter.—The combined curb and gutter was constructed by J. M. Chappell, Esq., of the City of Fredericton, N.B., and his method of constructing is well worthy of comment, he having a system of forms which cuts down the cost of construction materially, as will be seen.

Fig. 2 is a drawing of a section taken through the curb and also giving a plan and elevation of one 8-ft. block showing another joining on each end. This shows the expansion joints which, in past years, has been a great trouble to get in correctly and cleanly. First, the trench has to be dug out to a depth of 30 in. below the top of the grade plugs. In this trench is placed about 16 in. of broken stone or field stone and tamped tightly into place, forming the foundation and underdrainage for the curb and gutter. Next, the cinders; these are simply coal clinkers and provide an even bed or "cush" for the concrete. (Gravel or sand would answer the purpose just as well but would make a difference in the cost, the gravel costing $1.25 per yard and the coal clinkers 50 cents.)

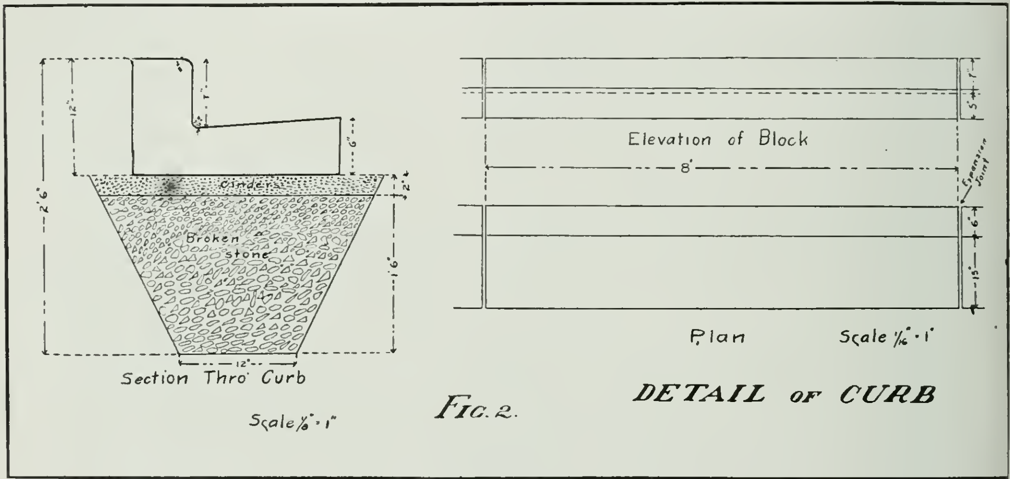

FIG. 2.

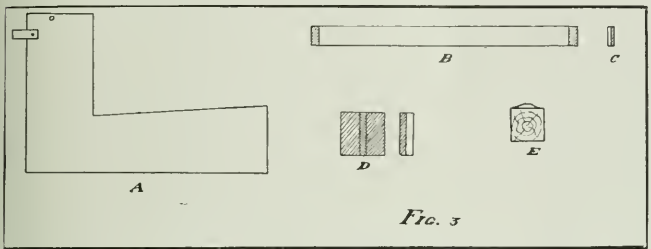
Plan, Elevation and Cross-section of an 8-ft. Length of Curb.

The form for the back of the curb is now put in place. This should be the most carefully done of any of the form-placing as on this all the rest of the form-placing hinges. If it is correctly done, all of the forms must, as a matter of course, come to their place. This form is a 2-in. plank 12 in. wide and of any convenient length. It is placed on the line of the back of the curb and just so that the top of the plank is level with the grade plugs. This brings the cinder "cush" just up to the bottom of the plank. It is then nailed and braced into place.

Next the steel forms that make the expansion joints are put into place. These are made of ⅛-in. steel and are the shape of the section of the curb. They are the same size as the curb and gutter except that they are just a little longer to supply a hold to enable them to be

pulled out easily after the concrete has set. A small piece of steel is riveted on the side 12 in. from the bottom, or at just the height of the curb. In this way the plate stays in place, as shown by *A* of Fig. 3. One of these is placed every 8 ft. in the length of the curb.

The next step must be made with planks which must be made in a special manner and cut to fit. These are 2-in. dressed lumber with one edge bevelled, as shown in *B* and *C* of Fig. 3. These planks are in lengths of 7 ft. 11 in., and the ends of each plank are cut half through 3 in. from the end and this small piece cut out. *D* of Fig. 3 is the connecting piece between the plank. It is cut into 7-in. lengths, as shown. The boards forming the front of the curb are now placed on the steel forms, being held apart by means of blocks 6 in. square, as shown in *E* of Fig. 3. The ends of the plank are kept just an inch apart to allow the part *D* to fit in. This is put in place and makes the front form solid by the joint. Clamps are now put on and the back and front forms are clamped together, the wooden block only allowing them to be clamped to their proper distance—6 in. This is shown in Fig. 4.



Details of Expansion Joint Forms.

The form for the edge of the gutter must be put in place. This is made of plank 6 in. wide and cut to any suitable length. The plank is placed against the gutter part of the steel form with the top of the plank just level with the top of the gutter part of the steel form. Earth is then filled in to keep the plank in place. The forms are now complete and ready for the concrete, as shown in *B* of Fig. 4.

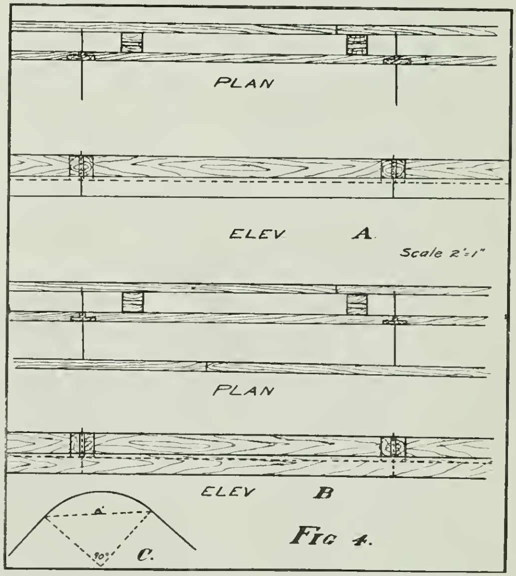
Mixing.—As one crew is mixing the concrete and placing the forms, another can be sprinkling the old work, backfilling, etc.

The mixing is done with a small hand-turned mixer capable of mixing 1/10 yard of concrete in one mix. This answered the purpose very well, mixing quite fast enough to keep a small crew of men busy. The mixer should be on wheels, to be wheeled easily from one part of the work to another, so that, while one man turns the machine, two shovel into the mixer and one man with a wheelbarrow may easily handle all the concrete being mixed.

Corners.—Taking the combined curb and gutter around the corners should be one of the most carefully done parts of the work, as an even, symmetrical corner adds more to the general appearance of the work than the ordinary workman would imagine. The general public is much more liable to notice a small error in the corner turn than a large one in the block length of the curb and gutter. A design of the turn is given in *C* of Fig. 4. The form for the back of the curb is the usual plank used on the block cut to a length of 8 ft. The steel forms are put in at the ends of this plank and the ordinary 7-ft. 11-in. plank put in to make the tangent to the curve. The form for the front of the curb on the turn is made of some pliable lumber, ½-in. thick, and is bent to the required circle. If necessary, it is braced into place until the concrete has taken its initial set. The forms are then taken off and the concrete is patched up at any place that the forms have not left in good shape.

Finishing.—In the finishing up of the work the trowel is used very sparingly on the concrete, the work being floated with wooden floaters and only where it is necessary to round the edges is the former used. It has been found by experience that a steel trowel tends to bring the cement in the mixture to the top, thus making a very rich mix on the surface, which, with age, will make hair cracks and cause checking. After the forms are taken off any rough parts in the concrete may be gone over with a concrete brick mixed in the proportion of 1 : 2, which fills up the small voids, takes off any rough edges and gives a general finished appearance to the work.

Cost Data.—The work in Fredericton was handled by one foreman with a crew of 11 men, arranged as follows: One man turned the mixer and dumped it; two men placed the cement and gravel in the mixer while one man wheeled the concrete from the mixer to the forms, thus making a total of 4 men required to do the mixing. One man placed and tamped the concrete in the forms, putting in the top dressing as the concrete was placed; two men were required to place the forms, leaving them ready for the placing of the concrete, while two more dug the trench and placed the broken rock and cinders. One experienced man was needed to do the finishing and floating while the rest of the workmen were common laborers without much knowledge of concrete.



Details of Forms.

Materials.—*Cement*: The cement used was Portland in bags, the work requiring 20 bags per 100 ft. of combined curb and gutter. The price of the cement, taking out the refund on the bags, was 50 cents per bag.

Gravel.—The fine aggregate and coarse aggregate was combined in the form of river gravel, the work requiring about 5.6 cu. yds. per 100 ft. of combined curb and gutter. The gravel cost on the work $1.25 per yard.

Broken Stone: The stone for the foundation and underdrainage was ordinary building stone broken to the proper size. The work required 8.7 cu. yds. per 100 ft. of combined curb and gutter. This stone cost $1.25 landed on the work.

Cinders, Forms and Labor: The cinders used were ordinary hard coal clinkers, costing 50 cents per yard landed on the work; 100 ft. of curbing requiring 1.4 cu. yd.

The forms used were made of spruce planks and, roughly speaking, 3,000 ft. B.M. was used, the forms being used over and over again. This lumber cost $30 per M.

In this work 11 men were used, there being a foreman at $3 per day and 10 laborers at $2, making a total of $23 per day.

Following is the cost data given in tabulated form. Table I. gives the amounts of the different materials used and the number of feet of curb constructed every 6 days in the 41 days needed to finish the work. Table II. gives the total costs of the different materials and the total wages paid.

The total amount constructed was 4,032 feet, while the total cost was $2,192.30, making the cost per lineal foot 54 cents.

Table I.—Materials.

Days.	Cement used, bbls.	Gravel used, yds.	Cinders used, yds.	Broken stone used, yds.	Curb constructed, ft.	Men per day.
1-6	15.6	17.3	4.8	27.8	320	11
7-12	30.2	31.3	8.7	50.5	580	11
13-18	31.7	32.9	9.6	53.1	610	11
19-24	33.8	35.1	9.7	56.6	650	11
25-30	37.4	38.9	10.8	62.6	720	11

Forms	3,000' B.M.	30.00	90.00
Men	11 per day	23.00 per day	943.00
Total cost			$2,192.30

The first railway in Shantung was commenced in 1899. It extends from the port of Tsingtau to Tsinanfu, the capital of the province (a distance of 395 kilometers), and has been built by the Shantung Railway Company, which was founded in 1898 for the purpose of taking over the railway concession granted to Germany by the treaty of 1898. The capital of this German-Chinese company is 54 million marks, in 54,000 fully paid-up shares. The company is registered at Berlin, where is also its head office. It is a single line throughout, of a 1.535-metre, or normal gauge; but sufficient land to build a double line is provided for.

THE IRON AND STEEL SITUATION.

Regarding the iron and steel market in the United States as it stood at the beginning of the month, the "Steel and Metal Digest" observes that it was not in a state of stagnation but of complete prostration. The closing fortnight of October witnessed an absence of buying, of specifying on contracts, and of general interest in the market on the part not only of buyers but even of sellers, that certainly has never before been witnessed in the history of the steel trade, now some quarter century old. In earlier years, when wrought iron was the controlling factor, instead of steel, some parallel to present conditions may have existed for periods in 1878, long remembered as a phenomenally bad year although, naturally enough perhaps, followed the next year by one of the greatest booms, if not the greatest, in all iron and steel market history. Taking up the great industrial depression of the eighteen nineties, picking out the worst of those years, 1896, and the worst period in that year, one does not find a parallel to what has occurred, or rather has failed to occur, in the past fortnight. The reference to 1878 having been a phenomenally bad year, immediately followed by a boom year, furnishes no basis in itself for predicting much better things next year, though the reference contains a suggestion. There was a similar boom in 1899, but while 1879 was preceded by a year in which pig iron production was less than in three much earlier years, 1872, 1873 and 1874, the boom year 1899 was immediately preceded by two years which while dull each broke all previous records for pig iron production. It was a sudden change from 1878 to 1879, but the change from 1896 to 1899 was slow.

The rate of steel production at the beginning of November is approximately 40% of the capacity. Only in very exceptional instances, as when many mills have been closed over Christmas holidays, or when there has been a sudden but largely temporarily closing by reason of a panic, has the percentage rate fallen so low. The steel mills have never run for more than three consecutive months at a lower rate than 50% of capacity.

There is no definitely established price situation. Prices are not a consideration. Usually in dull periods they are an issue, and a very important one, but at present the buyers have nothing like a definite position. They are waiting for a chance to act, not a chance to buy at certain prices. Indeed, with many products it is a question where the market price really stands. There is actually not enough business offered, in some instances, to disclose at what prices mills would be willing to sell. The great majority of producers have nominal asking prices, which they would be only too glad to be tempted to cut in an effort to start business moving.

COST OF SUPERVISION OF HIGHWAY CONSTRUCTION.

The following statement shows the annual cost of supervision of construction of highways by the State highway department of Ohio in percentage of the amounts expended by the State in such construction:—

	Per cent.
1914	4.03
1912 and 1913	5.71
1911 and 1912	6.18
1910 and 1911	6.40
1909 and 1910	5.39
1908 and 1909	5.43
1907 and 1908	5.28
1906 and 1907	7.55

THE MAXIMUM POWER CAPACITY OF A PIPE LINE.

By T. H. Hogg, C.E., Toronto.

In hydro-electric power plant design it is sometimes interesting to know the maximum possible power output of a prospective development which is to have a long feeder conduit. This information is desirable in fixing the diameter of the pipe to be used. To do this accurately entails a study of the economics of the design with reference to the value of the power consumed in friction, the cost of the pipe, transportation conditions, speed-regulation, etc.

The electrical horse-power to be obtained from a given installation is obtained from the formula:

$$P = \frac{62.5\, Q\, h\, E_t\, E_g}{550}$$

where P = electrical horse-power; Q = quantity of water in cu. ft. per sec.; h = net head; E_t = efficiency of turbine; and E_g = efficiency of generator.

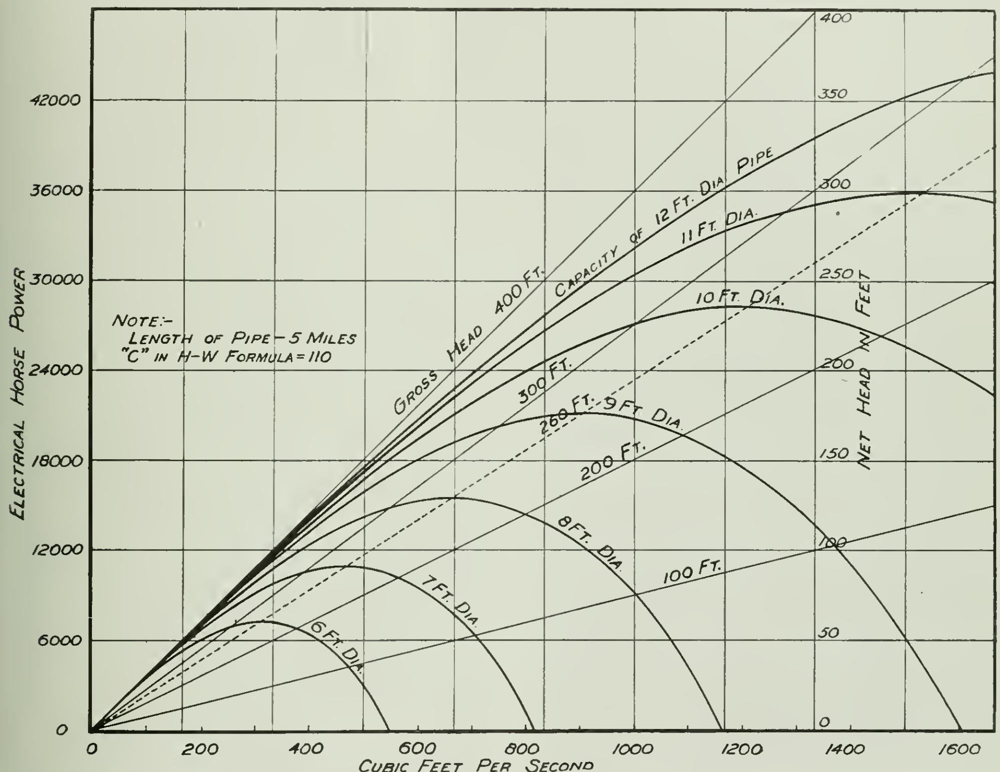
This may be written in the form $P = n\,Q\,h$, where n is a constant, and equal to $\frac{62.5\, E_t\, E_g}{550}$; or $P = n\,A\,v\,h$, where A = area of conduit, and v = velocity in ft. per sec.

Now, $h = H - c\,v^m$, where H = gross head and $c\,v^m = h_f$, or the friction loss in feet. Therefore, $P = n\,A\,v\,h = n\,A\,v\,(H - c\,v^m) = n\,A\,v\,h - n\,A\,c\,v^{m+1}$. In order to get the maximum value of this expression, differentiate with respect to v and equate to zero.

$$\frac{dP}{dv} = n\,A\,H - (m+1)\,n\,A\,c\,v^m = o$$

Therefore $H = (m+1)\,c\,v^m$.

The value of m is a constant usually taken, as a result of experiment, at some value between 1.8 and 2.



Maximum Power Capacities of Conduits of Various Diameters.

Hazen and Williams, in their tables for the losses in pipes, use the value of m equal to 1.85.

Substituting, $H = 2.85\,c\,v^{1.85}$. Now $c\,v^{1.85} = h_f$.

Therefore $c\,v^{1.85} = h_f = \frac{H}{2.85} = \frac{\text{gross head}}{2.85}$. Or, for maximum power in a conduit, the friction loss is equal to the gross head divided by 2.85. If we assume that the losses vary as the square of the velocity this expression will become the gross head divided by 3.

If we use velocities higher than those sufficient to give these losses, the power will decrease as the velocity is increased, until, at the limit, all the available energy in the water is being used up by friction; or when $c\,v^{1.85} = h_f = H$.

The accompanying chart illustrates this very well, as a short study will show. It will be noted that the

maximum power for each diameter of pipe falls on the head line for 260 feet, or when the loss of head is $\frac{400}{2.85}$ equal to 140 feet.

It will be appreciated, of course, that no conduit would ever be designed for this maximum condition, as the losses of head are too large for economical operation unless water economy is of no object. In any case, conditions at this point are far too unstable to permit of any speed regulation. Probably, in an actual case, the maximum velocity to be used will give losses about one-third of that for maximum power.

REINFORCING PAVEMENT FOUNDATIONS.

The determination of the use of reinforcement in concrete pavement will depend upon the type of foundation and width of pavement. A paper by C. D. France, before the Indiana Engineering Society, gives some useful information respecting it. The writer states that reinforcement may be used in either single or two-course work, and is particularly designed to care for slight settlement of fills, and to guard against contraction cracks developing where the pavement is wide. In any road where a new fill of over 2 feet is made, and the material used is other than sand or gravel, the pavement should be reinforced, no matter what the width of the road. No amount of compacting by roller or puddling can effectively settle such a fill, so that no further movement of the foundation is probable after the placing of the pavement.

The type of reinforcement which is most economical in price and handling is wire fabric. The weight of material to use in this fabric has been the subject of much discussion and, although it may be well sometimes to consider each specific case, in general it may be said that reinforcing metal running parallel to the centre line of the pavement should have a cross-sectional area of 0.038 inches per foot of pavement width, and a cross-sectional area perpendicular to the centre line of the pavement of at least 0.049 inches per foot of pavement length. Reinforcing has been advocated in two-course work where it is spread upon the still plastic base, which, being slightly undulating, insures that no line of cleavage can possibly develop between the two courses, and, in addition, imparts greater strength and security to the pavement. In single-course work, reinforcing is placed about 3 inches from the surface.

PROGRESS ON SOOKE LAKE AQUEDUCT.

In *The Canadian Engineer* for July 23rd, 1914, the essential features were published relative to the project under way at Victoria to supply 16,000,000 gallons per day through 27.3 miles of reinforced concrete gravity pipe line and 10 miles of 36-inch steel pressure pipe, the supply to come from the Sooke Lake watershed. The work has progressed very favorably since that time. On October 8th the steel pressure main was successfully tested under a maximum pressure of 200 lbs. per square inch. Construction on the 42-inch concrete pipe line is well under way. It is to be noted that little success was achieved in the steam treatment used to hasten the setting of the pipe in the molds at first, and many of the sections had to be culled. Later on, however, the improvement of the steaming process gave much better results, and has proved a decided advantage in the construction of the pipe, and well worthy of note.

GRADES AND EXCAVATIONS.*

By A. D. Williams,
Chief Road Engineer, State of West Virginia.

IN the past two or three years stress has been laid upon the subject of permanent roads. Many articles have been written bearing upon the various kinds of surfaces, but the ever-important subject of grade and excavation has received only passing notice. Yet the only permanent thing about a road is its grade and location. The various kinds of surface will yield to the actions of the elements and pass the march of time, but the road once established will become more fixed as the years go by, adding improvements and new property lines to bind it firmly in place. This makes more important the engineering subject of our roads. The establishment of grades and location should be given the greatest consideration.

Minimum Grade.—The principal factor entering into the determination of a minimum grade is the question of sufficient drainage. Except on fills over 2 feet the minimum grade should not be less than 3/10 of 1% and preferably not less than 5/10 of 1%.

Maximum Grade.—There are a number of factors that enter into the maximum grade, but, before attempting to locate any road or to establish any grade the engineer should make a thorough study of the territory to be developed by the proposed road, giving due consideration to the following points:

(1) What will be the present and future demands of the territory adjacent to the proposed improvement;

(2) What are the possible developments in the territory from an industrial, agricultural, educational and social standpoint;

(3) What part will the proposed road be of a general system of roads reaching to other communities and what will be the effect of the improvement on other sections;

(4) The nature of traffic that the road will be called upon to take care of, making due allowance for development, considering the present and future tonnage;

(5) The general direction in which the greatest amount of tonnage will be transported, the class of tonnage and the time necessary to move it in order to make it the most marketable;

(6) The direction in which the ascending grade will be in comparison with the possible traffic demands;

(7) The maximum load that a horse can pull based upon the length of grade and the time required to make the trip, from the standpoint of the horse and the time necessary to get the best results for the kind of material the country will produce;

(8) Consideration should always be given to climatic conditions and to the season that the roads will be required to take care of the heaviest traffic, as well as a study of the foothold for horse-drawn vehicles. The possible amount of frozen or icy weather should be noted in determining a maximum grade;

(9) The class of material over which the road is to be made and the cost of construction on the longer distance compared with the steeper grade and shorter distance have a certain bearing upon the subject, because the most important subject in connection with the cost of roads on grades is that of maintenance which increases very rapidly with the increase of grade. Roughly speaking, the destructive effect of violent and periodical storms

*From a paper read at Fourth American Road Congress, Atlanta, Ga., November 9 to 14, 1914.

is four times as great on a 5% as on a level ground, and nine times as severe on a 10% as on level grade. Thus if no other factors were to be considered on earth roads alone the cost of upkeep in a very few years would justify the elimination of bad grades;

(10) The condition of the right-of-way and the possible chances for disposition of water and drainage are factors of much importance when considering the maximum grade, because on steeper grades the increasing velocity demands more drainage and greater skill in handling the water, which, if kept on or near the road, will soon destroy it;

(11) The consideration of a grade from the ascension is not the only angle of approach in the location of highway grades because important items enter into the descending grade that should be given as much, if not more, consideration than the ascending direction;

(12) A grade should not be steeper than a horse can descend safely in a trot;

(13) A grade should not be steeper than a team can safely descend with a load that it can handle for ten hours under normal conditions, exerting its normal tractive force;

(14) The amount of time necessary to descend a grade should be considered, making due allowance for the maximum speed that can safely be used on that grade;

(15) The highway engineer of to-day must remember that as time passes the motor traffic requirements of the public highway will be more and more exacting. Experiments as to gasoline consumption and its efficiency on difficult grades and materials are now being conducted near Uniontown, Pennsylvania, by Mr. R. O. Gill, Experimental Engineer for the Chalmers Motor Company of Detroit, Mich. In this connection we have but little data. Some recent experiments made by Mr. H. Kerr Thomas and Mr. D. Ferguson, of Buffalo, N.Y., for the Pierce-Arrow Motor Company, show that the class and kind of surface exert more influence upon the motor-driven truck than the percentage of grade and that it requires practically the same tractive force on a 1% grade in sand and loose stone to handle the same load as it does on a 27% grade on concrete, asphalt, new brick and first-class macadam. But observations lead to the conclusion that grades of any length exceeding 5 or 6% are not as satisfactory and as economical as lighter grades for motor traffic owing to the increased hazard, increased consumption of gasoline, and loss of power due to the resistance to gravity. Observation further concludes that in frozen or icy weather motor traffic is extremely hazardous on grades exceeding 10%, and entirely unsafe on grades exceeding 16%;

(16) Grades crossing a summit should merge into each other by some form of vertical curve. The writer has been accustomed to using the following formula which proves satisfactory and practicable. Take the summit grade at e and a grade point 100 feet on each side or any other desirable distance and by use of either one of the following formulas find the elevation at f, which will be half-way between e and g, then by use of the formula find the offset from the tangent at each of the ordinates. This subtracted from the elevation of the ordinate will give the true elevation of the grade.

By reference to Gillespie, whose work contains about all we have upon tractive power of a horse, which embraces the experiments of Sir John McNeil, Sir Henry Parnell, and Mr. Cayffier, some of whose works are quoted by nearly every writer, we find that a horse traveling at the rate of 2½ miles per hour can exert 10% of his weight, and traveling at the rate of 4 miles per hour, can exert 6% of his weight. These observations prior to 1850 and just before the advent of the steam road into our field of engineering embrace about all the experiments we have, excepting the work of Mr. E. B. McCormick, of Kansas State Agricultural College, and the works of Prof. J. H. Waters, of the University of Missouri, and other work by Mr. McCormick is now being done for the Office of Public Roads, at Washington. The writer's personal observations have shown that a horse for a limited period can exert ¼, and sometimes even greater percentage of his weight, this depending in a measure upon the kind of shoes on the horse and the foothold on the grade. A horse on a road material that offers safe footing can be safely trotted down a 5% grade, but cannot be trotted down this heavy a grade for any great length of time without injury by "jamming" or "stoving" him up. Therefore, the ruling grade should not exceed 5%, if for a horse-drawn vehicle over which speed must be made on the descending grade, because the average horse in walking down a grade will not make over 4 miles per hour, while he will trot 12 miles per hour; thus, from this standpoint, we can double the distance of the road and increase the time 33⅓%. The speed of 12 miles

per hour should not be undertaken down a grade of more than 3% with a vehicle bearing any kind of a load. In ascending a 5% grade the capacity of the team is about 4/10 of its capacity on level ground and about ¼ of its capacity on 10% grade, on a loading for the same tractive exertion, but a point here that should not be forgotten is that for a short duration a horse can exert from 25 to 40% of his weight, thus doubling and quadrupling its normal tractive force and in this connection it is often better economy, considering the financial condition of the community, to put in a short piece of 6 and even 7% grade, than to expend a large amount of money in making an exhaustive and expensive cut, especially so if the cut must be made at the expense of development in some other part of the community. One thing that should be borne in mind is that each year's development of our country makes the chances for changing of grades and their elimination less possible, and that while the improvement of the surface of a road increases its tractive efficiency about 200% on level ground it only increases about ¼ for a horse-drawn vehicle on a 10% grade, thus money expended in decreasing the grade within a reasonable amount of distance is the best possible investment.

Then, with these conclusions drawn and a decision as to the kind of surface that will possibly be placed upon the road at some future time, we are in position to determine what should be the maximum grade.

Methods and Costs of Grading and Excavating.—This is a machine age and wherever grading can be done by machinery it is usually more economical. The following table, based upon figures taken from different pieces of work, is approximately correct to a wage scale of 15 cents per hour and capable supervision.

By a glance at the figures it will be seen that at 22 cents per yd., or at the same cost for any given ratio, the ratio cost distances are: for wheelbarrow, 200 ft.; drag scraper, 400 ft.; wheel scrapers, 500 and 600 ft.; 1-horse cart, 1,500 ft.; wagon, 1,800 ft., while tractor and truck on track do not reach the amount within one mile. The cost of grading depends materially upon the class of material, the location and the management of the operation.

As to methods, the writer would suggest the use of machinery wherever possible under competent supervision and under proper direction. On work that is light and on which machinery can be employed the work should be done by day labor. On heavier work and large quantities the writer would recommend contracting, and to the contractor a systematic organization of his work so as to get the most efficient service from his men and equipment. There are volumes written covering the subject of cost data in heavier work, but my experience in highway work leads to the conclusion that there are many elements entering into the cost of highway construction that are often overlooked when comparing this class of work with heavier work. One point of deficiency that has been noticeable and should be emphasized here is the lack of organization in highway construction in the various sections of the country. In many instances 50% of the cost could be saved by an adequate organization.

Economical Considerations.—The economical phases of highways and highway construction are many, and call for more than the available space. The history of highways and highway economics can be divided into three periods: The Roman or Ancient Road; the Telford and Macadam period, extending from 1750 to about 1840, and our modern or twentieth century awakening. The Roman road, with its 3 feet of stone, was reduced about one-half in the days of Telford and Macadam, and now, with modern machinery, we are constructing macadamized roads at costs ranging from $1,000 to $4,000 per mile, concrete from $7,500 to $12,000 per mile, and brick from $9,000 to $20,000 per mile. It should be borne in mind that the cross-section of a road should be so as to permit the greater portion of the work to be done by machinery on ground where machinery can be operated, and that an extra width of the road on hillsides increases the cost. A road on hillsides should not be wider than is needed to care for the traffic. In country districts a 9-ft. concrete bituminous or brick or a 10-ft. macadam with 5 ft. of earth on each berm will meet all the requirements at much less cost.

On ground free from roots and stone, where a road machine can be used the material can be moved at a cost of less than 5 cents per yard, and on hillside grading, where the work is casting, a small steam shovel is an economical machine to use. With this should go a drilling outfit and attachments so it can be operated with the same power.

In conclusion, the most economical thing a community can do is to improve its roads so as to serve all its demands, and to do this it should employ a competent highway engineer to make a careful study of the needs of the territory, its financial ability to construct and maintain a road and to locate and superintend the construction of their road for them. When the road is constructed a competent patrolman should be placed on it to continually keep up the maintenance and repairs.

DOMINION GOVERNMENT ELEVATOR FOR VANCOUVER.

The Department of Public Works, Ottawa, purposes constructing a grain elevator with a capacity of 1,500,000 bushels on the government dock on Burrard Inlet, Vancouver. A site 578 x 352 feet with an additional wharfage 800 x 300 feet is being prepared.

The foundations of the plant are to be concrete piers carried down to concrete footings which shall rest on natural bedrock.

The buildings will be of reinforced concrete and will consist of a working house, track shed, storage house, sacking plant, transformer building, and conveyer galleries to handle bulk grain and grain in sacks from the elevator to the dock.

The whole of the work is to be furnished complete and ready for operation to receive, clean, and ship bulk and sacked grain on or before November 1, 1915.

The elevator will complete the chain of terminal and interior elevators erected by the government throughout the west from Port Arthur to the Pacific. The Vancouver elevator is intended to take care of the grain which will move westward from the prairie provinces for shipment via the Panama Canal.

Tenders close on November 30th.

In view of the fact that the war had cut off the supply of blocks formerly secured by England from Northern Europe, British Columbia millmen have forwarded to London samples of blocks made from British Columbia fir.

Division engineers of the New York State Highway Department have been directed in submitting estimates for construction to include hereafter an approximation of the number of working days required to complete each contract. This, it is expected, will enable the Highway Department to specify time limits on contracts more accurately, as the local engineers who work up the field notes are unquestionably in a better position to weigh carefully the elements which enter into the building of a piece of road than the office force are.

MUNICIPAL IMPROVEMENTS IN ALBERTA TOWNS AND CITIES.

SOME very interesting figures relating to the installation in 1913 of waterworks, sewerage and sewage disposal works in the Province of Alberta are presented in the report of R. B. Owens, B.A., B.E., Provincial Sanitary Engineer, in the recently issued report for last year of the Alberta Department of Agriculture. The following is a detailed list of new works or extensions, with estimated costs:

Waterworks.

Gleichen: Completion ....$	4,851.00
Blairmore: System	15,000.00
Tofield: System	14,000.00
Redcliff: Extension	120,000.00
Bassano: System	17,800.00
Athabasca Landing: System	127,440.00
Edmonton: Extension	311,600.00
Lethbridge: Extension	34,636.00
Medicine Hat: Waterworks plant	75,000.00
Extension	225,000.00
Extension	193,410.00
Calgary: Extension	378,000.00
Extension	643,200.00
Edson: System	90,000.00
Coronation: System	40,000.00
Total estimated cost for water....	$2,289,937.00

Sewerage and Sewage Disposal Works.

Bassano: Sewage disposal system ....$	12,000.00
Extensions, sewerage system	1,500.00
Athabasca Landing: Sewerage system	70,000.00
Edmonton: Extension to sewerage system..	569,500.00
Lethbridge: Extension to sewerage system.	92,500.00
Extension to sewerage system	72,000.00
Extension to storm sewerage system..	13,595.00
Extension to sanitary sewerage system	18,627.00
Medicine Hat: Extension to sewerage system	144,484.00
Main trunk sewer outlet and pumping station	105,000.00
System of storm sewer	50,000.00
Calgary: Extensions to sewerage system...	348,750.00
Extension to sewerage system	43,731.00
Extension to sewerage system........	30,628.00
Edson: Sewerage and sewage disposal system	55,000.00
Total estimated cost of sewerage and sewage disposal works	$1,627,315.00
Total estimated cost of waterworks, sewerage and sewage disposal works	$3,917,252.00

The present standing of the various cities and towns in Alberta, with respect to municipal improvements, with the exception of roads, streets, etc., is as follows:

Edmonton.—Population, 73,000; water supply, m.o. (municipally owned), pumped from Saskatchewan River; 2 intakes consisting of steel pipes with screens and cribbing protection. Water mains, 128.6 miles; 9,275 house services; 5,738 houses without services; 1,477 stopvalves; 648 hydrants, and 14 fountains. Daily consumption, 5,000,000 gal. Mechanical filtration plant (Roberts). Samples tested every other day in provincial laboratory.

Sewerage system, partly combined and partly separate; 117 miles of sewers, ventilated at man holes and vertical soil stacks; 9,275 house services; 8 gravity outfalls to be reduced to 3. Part of the sewage treated by sedimentation.

There are two refuse destructors, a Heenan and Froud on the south side and a Decarie on the north.

The first town down stream is Fort Saskatchewan, 20 miles distant by river.

Calgary.—Pop., 80,000; water supply, m.o. Source, by gravity from Elbow River and by pumping from Bow River, both chlorinated. Bow River intake is a compound flume of reinforced concrete leading to pumps 600 ft. distant. Elbow River intake is a timber crib at the river bank. Water mains, 184 miles; 12,000 house services, and 400 houses supplied from 50 standpipes; 1,002 hydrants. Daily consumption, 11,750,000 gal. Samples tested regularly in municipal laboratory.

Sewerage system partly combined and partly separate; 188 miles of sewers, ventilated at every house service; 7,940 house services; 1,010 catch basin connections; 7 gravity outfalls into Bow and Elbow Rivers east of city, to be reduced by intercepting sewers built or under construction, to one main outfall. No part of sewerage treated. Plans under way for treatment system; packing plants and other trades deliver waste into sewers without preliminary treatment.

There are two refuse destructors, both Heenan and Froud.

Municipal gas supply, natural; obtained from Bow Island.

Medicine Hat.—Pop., 14,000; water supply, m.o.; source, South Saskatchewan River, by low-lift pumps to filters and high-lift pumps to reservoir and standpipe, with capacities 2,750,000 and 500,000 gal. respectively. Intake is a 36-inch cast iron pipe with concrete pier and a 20-ft. diameter well on the river bank. Water mains, 31 miles; 2,350 house services; 240 stop valves; 170 hydrants, and 6 fountains. Daily consumption, 3,000,000 gal. Mechanical filtration plant (New York Continental Jewell). Samples tested regularly in Medical Health Officer's laboratory.

Sewerage system, separate plan; 20.3 miles sanitary sewers ventilated through man-holes 94 yards apart, and vertical soil stacks; 3.2 miles storm sewers; 1,000 house services; 96 catch basin connections; three outfalls into South Saskatchewan River, each with a pumping station for discharge during high water. Daily discharge, over 1,000,000 gal. Sewage is not treated.

The first town down stream is Saskatoon, about 600 miles distant by river.

Municipal gas supply, natural, 1,050 B.t.u.; 38 miles of high and low pressure gas mains; 2,265 house services.

Lethbridge.—Pop., 11,000; water supply, m.o. Source, by pumping from Belly River; 38 miles of water mains; 2,000 house services and 120 houses without services. Daily consumption, 1,500,000 gal.; not filtered.

The first town up stream is Macleod, 30 miles distant by river; down stream, Diamond City, 6 miles distant.

Sewerage system, separate plan. One storm sewer with 100 catch basin connections. Two gravity outfalls; sewage treated in sedimentation tanks and filters.

Gas supply, natural; supplied by private company from Bow Island.

Macleod.—Pop., 2,500; water supply, m.o. Source, Old Man River; pumped by steam; 2 intakes, 16-inch wood pipe 700 ft. long and 20-inch wood pipe 2,300 ft. long, respectively. Water mains, 8.5 miles; 425 house services; 152 stop valves and 55 hydrants. Daily consumption, 450,000 gal.; mechanical filtration plant (Roberts).

Sewerage system, combined plan; 6 miles sewers with man holes 100 yards apart; 225 house services, catch

basins trapped; 1 gravity outfall into Old Man River; disposal works to be constructed.

Wetaskiwin.—Pop., 3,500; water supply, m.o. Source, 3 wells each 250 ft. deep; pumped by compressed air to underground concrete reservoir, thence to elevated water tower with 227,000 gal. capacity. Supply ample. Water mains, 6.25 miles; 268 house services; 300 houses without services; 65 stop valves and 51 hydrants. Daily consumption, 100,000 gal.

Sewerage system, combined plan; 6.4 miles of city sewers and 3.5 of outfall sewers; ventilated at man holes and tops of house service stacks; 267 house services and 17 catch basin connections; 1 gravity outfall 3½ miles from city. Daily discharge, 120,000 gal.; treated in sedimentation tanks and effluent disinfected.

Municipal gas supply, natural, 975 B.t.u.

Red Deer.—Pop., 2,500; water supply, m.o. Source, Red Deer River by pumping; 1 intake, an 18-inch gravity flow pipe to two wells 18 ft. diam. and 20 ft. deep. Water mains, 7.25 miles; 305 house services; 102 stop valves; 34 hydrants, and 2 fountains. Daily capacity, 400,000 gal., filtered through 2 ft. of sand cylinders in each well.

Sewerage system, combined plan; 4.76 miles of sewers, ventilated at man holes 130 yards apart. 215 house services; 45 catch basin connections, untrapped; 1 gravity outfall into Red Deer River.

Redcliff.—Pop., 3,200; water supply, m.o. Source, South Saskatchewan River by pumping. Water mains, 15.5 miles; 308 house services, 108 houses without services; 106 stop valves, 33 hydrants. Daily consumption, 100,000 gal.; natural filtration.

Gas supply, natural, supplied by private company; 16 miles of mains and 430 house services.

Camrose.—Pop., 3,100; water supply, m.o. Source, 3 wells 130 ft. deep; pumped by compressed air to reservoir, thence by centrifugal pumps to water tower. Water mains, 2.5 miles; 90 house services; 23 stop valves, and 28 hydrants. Daily consumption, 37,500 gal.

Sewerage system, separate plan; 3 miles sewers and 90 house services; 1 gravity outfall discharging 33,000 gal. per day; treated on earth beds and effluent, disinfected by bleaching powder.

Athabasca.—Pop., 2,000; water supply, m.o. Source, Athabasca River by pumping; 1 intake, two 8-inch lines steel pipe to suction well; 4 miles water mains. No house services, system used entirely for fire protection. 22 stop valves and 24 hydrants.

Bassano.—Pop., 2,200; water supply, m.o. Source, Bow River, by pumping to a stand pipe; 1 tunnel intake, water gravatating to deep well. Water mains, 5½ miles; 40 house services and 250 houses without services. Daily consumption, 180,000 gal. to town and 150,000 to C.P.R.

The first town up stream is Calgary, 85 miles distant; down stream, Medicine Hat, 97 miles distant.

Sewerage system, combined plan; 3½ miles of sewers; 40 house services and 16 catch basin connections; 1 gravity outfall discharging into disposal works 2.5 miles from town.

Town has a Reid incinerator.

Claresholm.—Pop., 1,000; water supply, m.o. Source, Willow Creek; filters into gallery, gravitated to town and is pumped to increased pressure; 4 miles water mains. Daily consumption, 50,000 gal.

The town is supplied with natural gas by a private company.

High River.—Pop., 1,500; water supply, m.o. Source, Highwood River by pumping; infiltrates into concrete well at 600 gal. per min.; 1½ miles water mains; 43 house services; 34 hydrants.

Sewerage system commenced in 1913. Sewage to be discharged by pumping.

The first town down stream is Carmangay, 40 miles distant.

Blairmore.—Pop., 2,200; water supply, m.o. Source, York Creek by gravity; 4½ miles water mains; 200 house services; 8 stop valves and 38 hydrants.

Gleichen.—Pop., 80,000; water supply, m.o. Source, deep well by pumping; 1½ miles water mains; 22 stop valves; 6 hydrants. Daily consumption, 6,200 gal.

Sewerage system, combined plan; 1½ miles sewers, ventilated at man holes; 1 gravity outfall discharging 5,000 gal. per day. Sewage treated in sedimentation basin.

All these cities and towns have municipal engineers and staffs, with the exception of Red Deer and Comrose, where the municipal engineering is looked after by local firms of civil engineers.

THE GREATEST PRACTICAL TEST FOR THE MOTOR TRUCK.

IN *The Canadian Engineer* for October 8, editorial reference was made to the extensive use of the motor vehicle in the European war and to the policies of the belligerent powers toward the subsidization of manufacturers and users. Motorized military equipment extends beyond the main services of transportation of troops and commissariat to a host of auxiliary needs. The various services in which motor vehicles are employed receives a concise but comprehensive study by R. W. Hutchinson, Jr., in The Engineering Magazine for November. The following extracts will be found interesting:

Both light artillery and machine guns are being hauled on motor trucks. In the advance on Liège over a hundred motor trucks were used in carrying machine guns alone. In transporting field guns the cannon are generally placed on a trailer wagon, the carriage on another trailer, while the truck carries entrenching equipment, repair parts, tools, tanks of fuel and oil for itself, etc. Heavy siege guns and mortars are being moved, where road conditions permit, by two large tractor trucks in side-by-side fashion; but the 30-horse team is still being largely used for the heaviest siege guns. Trucks may serve as towing units, but they are too valuable for other services—provisioning the army, for instance. A close comparison of the speed and distances moved by the Germans and French in the war of 1870-1 will disclose the fact that to-day with motor transport the armies are operating at twice the distance from their base compared with the work 44 years ago.

Also without motor trucks, the immense armies now measured in millions instead of thousands would be difficult indeed to provision, as the battle lines have extended from 100 to 250 miles front, and have shifted so rapidly in position that if dependence were just on army mules supplying them with food, movements would be slow, the fighting efficiency of the men greatly impaired, and the slaughtering of the huge herds of cattle now necessary to victual the vast hosts would make sanitation impossible, leading to malignant disease and pestilence. Again, space where such prodigious numbers are now employed is valuable. A motor-transport train occupies only one-third of the space of the animal-drawn wagon, and being positioned much farther behind the army, causes less congestion between the main army and its auxiliaries and be-

tween the army and its base. Moreover, half of the load carried by animal-drawn army transports is a "non-paying" load, as it is food for the motive power—the mules; the efficiency is very low and the speed but a third that of motor transports.

The number of wounded in the present war is reported to be unexpectedly great, due to small-calibred, high-penetrating-power steel bullets; hence the carrying of wounded to hospitals in motor ambulances to save time and lives and to pick up the wounded rapidly is as important as motor supply trains. The usual form of motor ambulance in the service of both the French and German armies is in general appearance similar to the now more or less familiar automobile ambulances of city civilian service. Inasmuch as they are expected to do cross-country work, they are usually modified or standard passenger-car chassis of larger wheel base, arranged with stretchers in decks along the sides, and collapsible, removable seats for the less severely wounded. A number of army motor ambulances are, however, mounted on truck chassis and are veritable modern travelling hospitals, as for example, the Boulant type (named for its originator) field hospital of the French army. The body of this moving hospital (which, though of restricted capacity, adequately meets the surgeons' requirements) consists of three compartments—the forward one containing electrical apparatus, the middle one an operating room, and the rear division radium and X-ray equipment. The wide compartment bodies mounted on long-wheel-base chassis are lighted by roof windows and dome lights, with space enough in the operating room for tables, stands, and other absolute essentials. Electrical sterilizers in the front compartment sterilize 15,000 liters of water in 24 hours by the use of ultra-violet rays. Fitted alongside of the body are folding tents for hospital service, the interior of course, being too small to keep the patient permanently there. These Boulant field motor-hospitals are accompanying the troops in service, or are stationed at temporary convenient points. When mobile they can travel at a speed of 18 miles per hour. The number of these Boulant hospitals is small, however, and even the large number of standard motor ambulances are inadequate, so passenger cars and motor omnibuses of large carrying capacity are being requisitioned. When the veil of censorship is lifted and we get a detailed report of the frightful conflicts, the motor-vehicles' service in saving the lives of thousands of wounded will be a bright and comforting commentary.

In the aviation corps of the armies a two-wheeled trailer on which is mounted a canvas-covered frame constituting a portable hangar for aeroplanes is being pulled by a light truck at a speed of 18-25 miles per hour. These trucks carry, in addition to the renewal parts for themselves, extra parts for the aeroplanes, motor fuel, etc., and when a number are concentrated in one zone or section they are maintained in fit operating condition by a motor aeroplane-repair shop, consisting of a large, wide-bodied motor truck fitted up with an assortment of machine tools, small lathes, drills, a small forge and anvil, with tools power-driven by the truck's own engines through small electric motors. Skilled mechanics qualified to do repairs and adjustments on aeroplanes and motor vehicles accompany these ingenious portable machine shops. The French and German infantry are also equipped with a number of aeroplane destroyers, which are light, swift, armored motor trucks with superposed rapid-firing guns of 7-mile range, shooting a projectile of special type of 4.1 kilogrammes weight with a muzzle velocity of 670 meters and 93.8 meter-tons energy equivalent. Mounted in roofless steel towers and with a 45 degree inclination of muzzle of these aeroplane-destroying guns, the projectile has an ascent of 3,700 meters; with 75 degrees angle, 7,910 meters. The turret walls are such as to give a sweep of the gun a considerable distance above. Sighting of the gun is effected by means of a hand wheel working free of the pointing angle and the angle of the earth, final aiming being made by telescope with rigid eye-glass. Twisting reaction is arrested automatically. Armor plate protects gun and operator from light projectiles, as well as the vital mechanism of chassis and projectile receptacles along the sides of the truck.

Armored motor trucks operating both on railways by means of special flanged wheels and in regular manner, equipped with mitrailleuse, machine, and other forms of light guns or loopholes for sharpshooters, are being used to harass advance forces or cavalry. In addition, many hundreds of motorcycles carrying small quick-firing guns are being used to disperse advance scouts.

Quick and efficient communication between the tremendous forces of combatants with battle fronts of 50 to 250 miles is no longer possible by scouts, couriers, and heliographic devices. The long-range combat with terrible engines of destruction means radio or wireless communication, and every one of the Powers now at war is employing portable wireless telegraph plants carried on motor-truck chassis geared for speeds of 25 to 35 miles per hour. The truck motor drives an electrical dynamo which generates the primary current of the high-tension transformer necessary in radio transmission, and the complete paraphernalia of condensers, interrupters, collapsible antennæ, etc., are carried on the truck which is generally fitted with a protecting shield for the driver, and a special convertible body with sliding panelled sides which can be tightly closed in stormy weather. These motor-truck wireless outfits having an effective land range of 200 to 300 miles have enabled the armies of the "Dual Alliance" and the Triple Entente to keep in communication with their base, wings, and reinforcements—a task impossible in modern warfare without the radio telegraph and—most important—the motor truck on which to move swiftly the instruments and their relatively large space-requiring auxiliaries from position to position.

Numerous motor-searchlight outfits are being used by the armies of both sides. Like the wireless field outfits, the engine of the motor truck on which they are carried generates the electrical current for their operation. The searchlight is mounted on a four-wheel platform truck with rubber-tired wheels, which enable the auxiliary searchlight truck to be quickly and easily demounted and remounted and drawn independently by men or horses if required, and enable the motor truck to be utilized for other purposes. These portable searchlights, being thus self-contained, independent power plants, have permitted the dreadful night battles of which censors have undeleted enough to let our imagination portray in part the horror. These portable searchlights and their allied motorized aerial observation ladders have indirectly served as terrible allies of death and destruction. The aerial observation ladders are carried on long-wheel-base fast motor trucks and in general appearance are like the motorized hook and ladder outfits of modernized city fire departments.

The supplying of ammunition to the armies of 15,000,000 men now, or that probably will be, participating, will be a gigantic task—a task in feeding thousands of machine guns that use cartridges at 400 per minute, second to feeding the prodigious troops. only bigger-capacity motor trucks moving 3 to 4 times faster than horse-drawn ammunition wagons can be equal to the task.

Fig. A.—Main buildings of a typical modern creosoting plant.

THE BATTLE AGAINST ROT

WHY CANADIAN RAILROADS AND MUNICIPALITIES ARE PREFERRING TREATED TO UNTREATED TIMBER — DESCRIPTION OF METHODS USED AND RESULTS OBTAINED — SOME NOTES ON THE WOOD PRESERVING INDUSTRY IN CANADA.

CANADA'S rapid railway growth—thirty thousand miles now, compared with half that amount twenty years ago—and the increasing cost and decreasing supply of good ties, has attracted the attention of the wood preserving industry to the Dominion. Forestry experts claim it takes sixty years to grow a tie, and that we place it in the track to rot out in from five to seven years, whereas it would give from eighteen to twenty-five years' service if preserved, or treated, before being used.

On this continent in 1885 only 120,000 ties were treated out of a total of 50,000,000 used, while in 1912 about 30,000,000 were treated out of about 150,000,000 used. In other words, only about 1/400th part of the ties were preserved in 1885, while in 1912 1/5th of all the ties used were treated. In Canada alone in 1910 practically no treated ties were used. In 1911, 200,000 ties were preserved before being placed in the roadbed. This was 1.4 per cent. of the total number used. Last year about 2,500,000 ties were treated, or 10 per cent. of the total number used. This shows that the Canadian railways have commenced the battle against rot.

Rot is the chief cause of failure of timbers such as ties, paving blocks, piles, etc. It is the breaking down of wood fibre that is caused by the growth of small plants organisms known as fungi. The spores or seeds of the fungi, which are usually carried by the wind, alight on timber and grow, sending microscopic threads or rootlets into the timber. These organisms live on the timber as food, causing the eating away or breaking down of the wood fibre.

Certain amounts of each of four things are absolutely essential to the existence of these fungi; namely, air, moisture, heat and food. Take away entirely any one of these four, and the fungi cannot live. The timber cannot be protected from air except in occasional instances, such as piles that are entirely submerged, in which case the timber needs no other protection from fungi, but may be exposed to teredo attacks.

It is also difficult, as a general rule, to protect the timber from moisture, but where it can be so protected the growth of the fungi is stopped. This is shown, for instance, by the excellent condition in which one often finds very old timber in interior construction.

If one could keep timber at or below the freezing point—say, in a cold storage plant—fungi could not live; but from the practical standpoint it is impossible to protect timber from heat.

Therefore, the only thing that can be affected to destroy the growth of the fungi—the only one of the four essential conditions that can be removed—is food. The fungi have only the wood fibre for food, and if that food can be rendered poisonous, the wood will be preserved against their attacks. This is done by treating the wood with a highly antiseptic fluid.

To properly treat a tie in order to preserve it against decay requires a modern treating plant of considerable cost and complexity. In 1885 there were only three of these plants in operation on the continent, while there are now over one hundred such plants in existence, with an aggregate capacity of over 100,000,000 ties a year. In Canada we have but five of these plants, all built within the last four years, with an aggregate capacity of approximately 4,500,000 ties per annum. These plants are located at Sydney, N.S.; Fort Francis, Ont.; Trenton, Ont.; Transcona, Man., and Vancouver, B.C.

Such plants consist of retorts, pressure pumps, vacuum pumps, proper gauges, storage tanks, measuring tanks, etc. Fig. B is an interior view of the retort house at the Trenton plant. The retort (1) is shown at the right of the photograph. It is 134 feet long, 7 feet in diameter, and has a net capacity of about 2,500 cubic feet of wood.

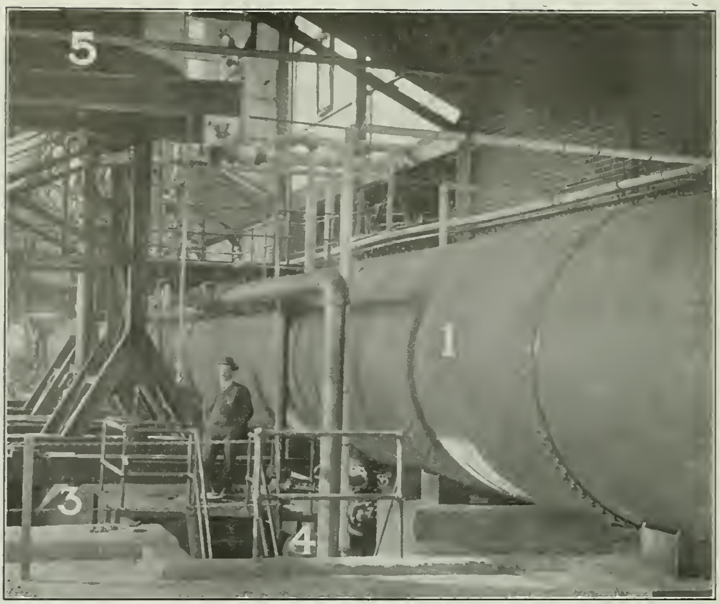

Fig. B.—Interior of retort house. 1, Retort. 2, Retort door. 3, Receiving tank. 4, Pump. 5, Overhead tank.

The retort is built of riveted boiler plate to withstand 225 pounds pressure per square inch. There is a door (2) at each end which is securely bolted and sealed after the retort has been charged. A receiving tank (3) holds the creosote oil that is drained from the retort after the finish of the pressure treatment, and also after the finish of the vacuum treatment. A centrifugal pump (4) forces this oil from the receiving tank to the overhead tank (5), from which the supply is drawn when the treatment is begun.

Steam coils run along the bottom of the retort for its entire length in order to regulate the temperature of the preservative during treatment. The end of these coils can be seen in Fig. E. At the operator's station is a board on which is mounted a number of gauges, both indicating and recording. One gauge indicates the pressure in the retort and one records it on a timed sheet. The amount of vacuum is indicated by another gauge and recorded, with the time, by still another. The temperature is indicated and recorded according to time.

Among the plant's equipment are several trains of tram cars, such as are shown in the centre of Fig. C. These are used to convey the ties and lumber into the retort for treatment. Sixteen tie lengths are used to make up a train; a tie length to each tram car; each tram car holding about 60 ties. The train is pushed by an electric locomotive right into the retort. Fig. E is a view of the end of the retort after a train has been pushed in and just before the door is closed. The stretch of track shown in the foreground of Fig. E is removable, the two rails simply forming a connecting link between the end of the track which runs from the yard and the track in the retort. These links, of course, must be taken up before the door is closed. The cars are not coupled, but are so constructed that they can push against each other without disturbing the load, a cast steel bumper being attached to each end of every car. A wire cable is fastened to the car farthest from the locomotive, so the train is easily drawn out.

A different type of tram is used for treating paving blocks. A train of them is shown at the left of Fig. D. After these trams are filled with blocks, a perforated slide closes across the top of each tram, holding the blocks in place but allowing the creosote oil to flow through the perforations and fill the car.

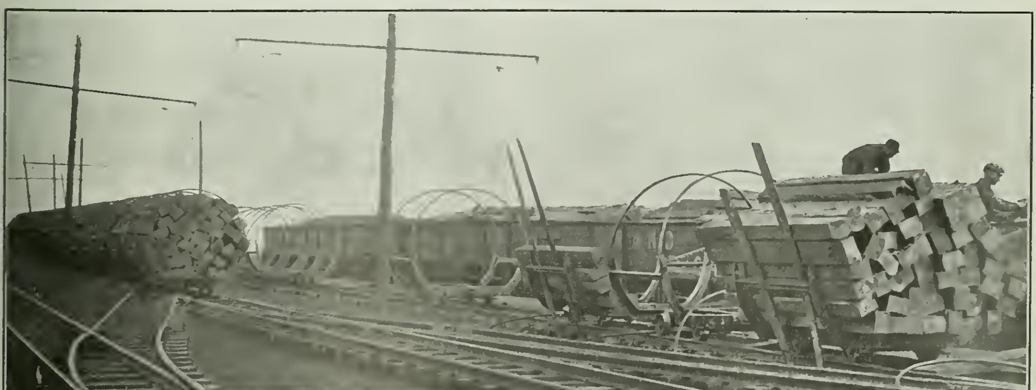

Fig. C.—Train of ties just drawn from retort, and one type of the trams used.

The paving block mill which operates in connection with the treating plant and manufactures the lumber into paving blocks, consists of a conveyer, a planing mill, saw tables with saws, etc. Seasoned lumber is loaded onto the conveyer, shown in the foreground of Fig. A, which carries it into the block mill. It passes on live rolls in a straight line through the planer and onto the saw table, on which it is fed into a mill of from sixteen to twenty saws which cut fifteen to nineteen blocks at a time. The sawn blocks drop onto another conveyer which carries them from the mill. As they pass out they are inspected and, from the conveyer shown in Fig. D, they are loaded into the cages, as the paving block trams are called. Sixteen of these cages are used to make up a train for each charge. Each cage contains about forty square yards of blocks.

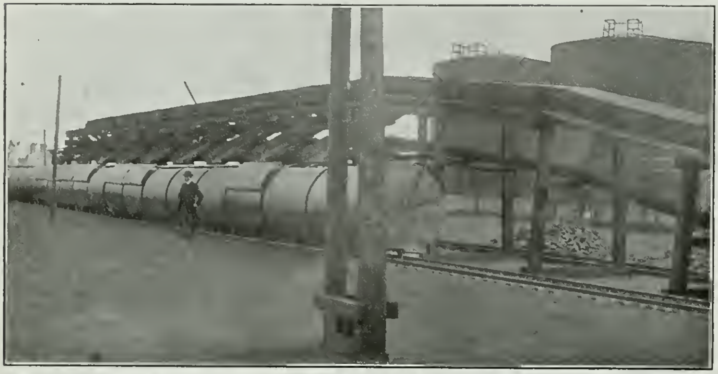

Fig. D.—Conveyer filling trams with paving blocks. Storage tanks in background.

Ties and timbers from the seasoning yard are loaded onto tram cars such as are shown in the centre of Fig. C and a number of trams placed together to make a train such as is shown at the left of Fig. C, ready to be pushed by the electric locomotive into the retort. The trains of block cages are made up at the conveyer at the end of the block mill, as shown in Fig. D, where they have been filled with blocks.

When the treatment is started after a train of paving blocks, ties or lumber has been placed in the retort, and the end doors closed and hermetically sealed, oil is allowed to flow into the retort from the overhead tank, filling the voids around the timber. Then by means of steam pumps additional oil is forced into the retort to obtain the amount of pressure required to thoroughly saturate the wood, 100 to 180 pounds pressure being used, according to the kind of wood. Upon completion of the pressure treatment the pressure is released and the oil is rapidly drawn into the receiving tank. A vacuum of from 23 to 27 inches is then quickly created in the retort by means of a special arrangement of vacuum pump and condenser. This vacuum is sustained from an hour to an hour and a half, and draws from the wood the surplus oil. After this surplus oil is drawn off, the doors of the retort can be opened and the train withdrawn.

During the treatment heat plays an important part as well as pressure and vacuum. The temperature during the pressure treatment is never allowed to drop below 150 degrees F., nor to rise above 190 degrees F. The degree of penetration depends largely upon the temperature of the oil; the higher the temperature, within certain limits, the freer the liquid will flow and the more easily it will enter the pores of the timber after the timber has become warm and the pores expanded by the heat. Some kinds of wood offer little resistance to the oil, while other kinds offer great resistance, depending on the size of the pores, the smoothness of the cell walls and the extent to which material obstructions are contained in the cells. The temperature, pressure, vacuum, etc., are readily regulated by the operator, all valves and the controlling apparatus being near the station from which he watches the process.

A complete record is kept so that any official of the creosoting company, or the customer's representatives, can check the operator's discretion and skill. These records are kept, and should it be desired to refer to them at any time for any reason, even after a lapse of many years, one can easily do so.

A clocklike device shows the amount of oil in the overhead tank, both before and after treatment. The difference, of course, is the net amount left in the charge. This method is remarkably accurate. It is checked up monthly by actual and precise measurements, and is also verified by weighing the timber before and after treatment. The whole process of treatment takes from three to five hours for ties and from four to eight hours for paving blocks. If the ties are well barked, in good condition and well seasoned, the treatment does not take so long as it does otherwise.

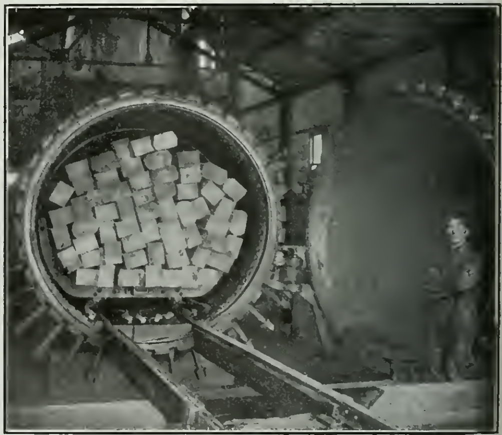

Fig. E.—End of retort after insertion of charge but before door is closed.

Various preservative fluids are employed, but that which is in most general use is creosote oil. Of the five plants in Canada equipped for preserving wood on a large scale, all except one use creosote oil. The plant at Fort Francis, Ont., uses chloride of zinc. Unless the timber is penetrated so deeply with the preservative that checks

or openings cannot reach beyond the treated zone, the spores will find their way in through the checks to the untreated portion and cause interior rot, which is frequently misnamed "dry rot." The depth of penetration of the creosote oil depends on the amount of oil that is forced into the wood, yet it is not necessary for the preservation of the timber to leave so much oil in the timber as must be put into it in order to obtain the required penetration. Therefore, many plants use the process whereby a large quantity of oil is forced into the timber, thus insuring thorough penetration, but whereby a considerable portion of this oil is afterwards drawn from the timber by the creation of a high vacuum. This leaves in the timber only the amount of oil that is needed, and the oil is evenly distributed throughout the timber (except impenetrable heart wood), instead of simply being distributed densely at the surface. By this method proper penetration can be secured without adding so greatly to the cost as would be done if all the oil were left in the timber that had been put in to obtain the penetration.

Following is the record of a treatment recently given an order of Norway pine paving blocks, three inches wide by four inches deep, for the City of Toronto:

Creosote oil in each cubic foot of timber at end of pressure.	Net gallons remaining in each cubic foot at end of vacuum.
34.35	22.41
25.20	19.61
26.60	19.57
26.50	20.61
27.03	21.53
25.74	20.64
24.80	19.01

The objective was a twenty-pound treatment. It will be seen that the net average was 20.48 pounds. These blocks were treated at the plant of the Canada Creosoting Company, Limited, at Trenton, Ont.

After the blocks, ties or timbers have been treated, the penetration is inspected by the representatives of any inspection company who may be present on behalf of the purchasers of the materials, by cutting the blocks in two by means of a hatchet, or extracting small borings from the ties and timbers. These borings are made with a Swedish instrument which resembles a miniature core drill in its action. A perfect core several inches long and about 3/16ths of an inch in diameter is taken out of each timber that is bored. Examination of these cores shows the depth and uniformity of penetration.

The method of loading ties onto the railroad cars after treatment is shown at the right of Fig. C. The handling of large timbers, both before and after treatment, is all done mechanically.

Before ties and timbers are treated, or before lumber is cut into paving blocks, it is stacked on the seasoning yard for months, to become properly seasoned. The lumber is stacked in open piles, so as to permit the free circulation of air, for three to five months. The ties are piled in such a manner as will permit of good air circulation and at the same time not allow sufficient exposure to cause checking. It requires from 6 to 10 months to properly season ties. Fig. F shows the manner of piling ties.

Fig. A is a general view of the Trenton plant. The buildings, reading from the left to right, are the block mill, machine shop, boiler house, office and retort house. The company also owns its own tie camp, north of Trenton, which it organized in order to get hard wood ties.

The trestlelike structure in Fig. D is the conveyer running out from the block mill. The sawn blocks are carried out on this conveyer. Chutes will be noticed running from the conveyer to the cars; and when the cars are pulled into place under these chutes, trap doors are opened in the conveyer just over the chutes and the cars are filled. In the background of Fig. D can be seen large tanks for storing oil, holding 150,000 gallons each.

Creosote oil, the preservative used at the Trenton plant, is defined scientifically as any and all distillate oils boiling between 200° and 400° C. which are obtained by straight distillation from tars consisting principally of compounds belonging to the aromatic series and containing well-defined amounts of phenoloids. Or, to be less

Fig. F.—Tie stacking yard.

technical, creosote oil might be defined as a distillate from the tar which is produced as a by-product in the manufacture of coal gas from bituminous coal by the retort method; or a distillate from the tar which is produced as a by-product in the manufacture of coke from bituminous coal in by-product ovens; or a distillate obtained from a mixture of these two kinds of tar.

Creosote oil is highly antiseptic and thoroughly protects the timber against fungus growths. For ties, eight to twelve pounds per cubic foot (about 2½ gallons per tie) is left in the timber, while for paving blocks from sixteen to twenty pounds per cubic foot is left in. Creosote oil may have a preservative value from physical properties as well as from its antiseptic or poisonous nature. This is especially true when applied to paving blocks. It may be capable of adhering to the cell walls and fibre of the wood with such permanency as to prevent conditions favorable for the development of elements destructive to timber. With the idea of obtaining the greatest prevention, both chemically and physically, pure coal-tar of low carbon content is frequently mixed with the creosote oil.

During the past few months there threatened to be a serious shortage of creosote oil on this continent owing to the war in Europe, but the release by the British government of a number of cargoes of creosote oil has helped the situation for the time being at least. England and Germany are the leading producers of creosote oil distilled from coke-oven coal-tar. When coke is manufactured in bee-hive ovens the coal-tar is burned in the process. On this continent most coke ovens are of the beehive type, while in Europe they are of the by-product type. Therefore we are largely dependent on Europe for our supply of coal-tar and creosote. The only by-product ovens in Canada are at Sydney, N.S., and Sault Ste. Marie, Ont. A bee-hive oven costs only about one-third

or one-fourth as much as a by-product oven, which explains the popularity of the bee-hive ovens. The quality of coal for coking in Europe is not so good as on this continent, and requires the by-product oven in order to make the greatest quantity and best grade of coke. Therefore the use of the more expensive by-product oven is not altogether a matter of choice in Europe.

Creosote oil is one of the fractions of crude coal-tar obtained by its distillation. It is the fraction coming off between the benzol and carbolic acid compounds, which come off at low temperatures, and the pitch, which remains in the still at the highest temperatures. Coal-gas tar usually has a high percentage of free carbon which should be filtered out, or otherwise removed, before such tar is ever mixed with creosote oil. Refined coal-tar is often added to the creosote oil in preparing it for use in wood preservation, as the treatment is more permanent when the mixture is used than when only creosote oils of low specific gravity are used, as there is a marked evaporation of the low-boiling fraction of the creosote oil. The coal-tar and the creosote oil, when mixed, combine thoroughly, and cannot be separated again, either physically or chemically.

Up to the present only wood block and ties have been treated at Trenton, but it is expected to treat timber for station and outdoor platforms; switch ties; dimension timbers; decking; flooring for docks, bridges, fire halls, warehouses and heavy manufacturing plants; crossing planks; fence posts; signal poles; snow fences; piling; mine props; telegraph and telephone poles; cross arms; mine timbers; tie plugs; wooden pipe; and all material for breakwater and marine work.

The first ties ever treated in eastern Canada from Canadian timber were creosoted at the Trenton plant last month for the Toronto, Hamilton and Buffalo Railway. The only woods used so far have been beech, birch and maple for ties, and southern yellow pine and Norway pine for wood block, but spruce, tamarack, fir, hemlock and other woods will probably be treated later on.

Special attention will be given to the treatment of mine props, as timbers for use in mines decay very readily, owing to ideal conditions of moisture and temperature for fungus growth. Much of the failure of mine props now attributed to breaking and splitting is due primarily to rot. This can be prevented, and the original strength of the timber maintained, by creosoting or otherwise preserving it. The creosoting of mine timbers is not so expensive as come other forms of creosoting, because it is not necessary to obtain such great penetration. The uniformity of temperature and moisture in mines, and the lack of exposure to the direct rays of the sun, result in no checking taking place, so that it is not necessary to get such deep penetration. A much lighter treatment than is given other timbers will therefore prove satisfactory. But this does not necessarily mean that any merely superficial treatment is sufficient.

The difference in strength between untreated and treated ties and timbers, except in the case of those treated with heavy oils which protect the timber from excessive moisture and add to its strength, is so slight as to be of no importance. This assumes that ties and timbers are properly treated and not injured by steaming or excessive heat during treatment. The drier that wood is kept, in ties and timbers, the stronger and better service they render.

The very great value derived from the treatment of wood is not only the prevention of the rot which makes the wood useless. The treatment maintains the original strength of the timber, especially in the case of ties treated with oil, and causes it to resist mechanical abrasion and wear longer. Furthermore, when ties are properly seasoned before treatment and preserved with creosote oil, the oil resists moisture and prevents the ties from becoming soft and spongy.

The added life due to creosoting depends upon the quality of treatment, and upon the kind of timber and the manner in which it is used. It is only fair to say, however, that creosoted ties will last from three to five times as long as untreated ties, while the cost of treatment does not double the cost of the tie. Therefore the great saving in the use of treated instead of untreated ties is apparent. This saving is even more pronounced in the case of other timbers.

NEW SAFETY AND DETONATING FUSE.

In a paper presented at the Pittsburg meeting in October of the American Institute of Mining Engineers, Mr. Harrison Souder, of Cornwall, Pa., directs attention to a safety detonating fuse by the use of which he claims misfires in blasting may be eliminated and safety in blasting operations provided. The detonator, which is known as the Cordeau detonant, is sold under the name of Cordeau-Bickford, and consists of a lead tube 5 to 6 mm. in diameter, filled with trinitrotoluene. It is applicable to all classes of mining, but is of especial value in connection with deep-hole blasting in open-cut mine or quarries, or any operations where a large number of holes are to be shot at one time. After detailing the superior results obtained with the use of this fuse in actual practice, the author summarizes its peculiar advantages as follows:

(1) There is no danger in handling or storage of the fuse. It cannot be exploded by friction, fire, or ordinary shock. It requires the use of a strong blasting cap properly attached to explode it. In blasting charged holes, the cap or exploder can be applied outside the hole, thus avoiding the danger of burned powder caused by side spit from ordinary fuse; also any risk of accident while tamping and the risk from a portion of an unexploded charge accompanied by a cap remaining in the debris from a blast is entirely obviated.

(2) The average rate of speed of this fuse is estimated to be close to 17,000 feet per second, so that when it is used, the explosion charge is detonated instantly throughout its entire length, instead of at one point as is the case with the blasting cap or electric exploder.

(3) It is known that the speed of an explosive decreases as the explosion wave travels away from the detonator. That the powder in a hole has the strongest explosive effect around the exploder is evident from an examination of the face of the bank after a shot. This can be demonstrated also by placing sticks of dynamite on the ground end for end, about 6 inches apart, with the cap in the first stick. The explosive force gradually lessens until it finally ceases to progress, leaving the farthest stick unexploded.

By using this fuse, the charge is detonated instantaneously throughout its entire length. This results in a saving of about 10 per cent. of explosives as determined by results obtained at Cornwall and elsewhere. It is not affected by heat, cold, or moisture, and lasts indefinitely without deterioration.

It is wound in continuous lengths on spools containing 100, 200, or 300 feet each, and weighs about 7 pounds per 100 feet. It is accepted by transportation companies without restrictions except that it shall not be packed with other high explosives.

THE COST OF POWER AS A FACTOR IN LOCATING INDUSTRIES.

By H. E. M. Kensit, M.Can.Soc.C.E.

THE above title implies a subject that is of interest to every progressive city in Canada. There is a very general impression that the cost of power is a largely determining factor in inducing most industries to select a location, and constant repetition of this claim has caused its general acceptance. Little investigation appears to be made, however, as to the basis of this belief, in which industries the cost of power is an important item and as to what proportion the cost of power bears to the total cost of production or total expenses.

This impression leads cities, which means the councillors in power in any particular year, to embark on expensive and in many cases doubtful projects for providing cheap power, without having any definite knowledge as to what industries the general local conditions will make it possible to locate, or of the relative importance of cheap power to such industries.

The questions of distribution facilities, proximity of raw materials, extent of labor market, etc., are awkward matters that cannot be controlled by that year's council, and they are, therefore, left in the background, while it is decided to enter on some extensive project to provide cheap power in the hope that this will make everything all right and produce a rush of industries anxious to take advantage of it.

The fallacy of this view has been impressed upon the writer by various personal experiences and has led him to collect a large amount of data on the cost of power in different industries. A large amount of manufacturing data has also recently become available in the statistics issued by the United States and Canadian census bureaus, the Ontario Bureau of Labor and other sources, and it is, therefore, possible to tabulate the average proportionate costs of many different industries in a manner to give an approximate idea of their relative importance.

A comparison of these statistics by such factors as the per cent. of wages to gross value of product and the ratio of the value of the product to the capital employed shows that, while the figures vary appreciably in the two countries in some individual industries, if the average is taken over a considerable number of miscellaneous industries they are in very close agreement and that, therefore, the conditions are not widely different. On the whole, the United States statistics are the most satisfactory to work to, because the explanation given of the meanings of the terms, the precautions taken and exactly what the headings include, is much more complete and specific than in the others. It involves some little labor to dig out the figures and give them in the form shown, but the tables that follow are deduced direct from the census figures, the only assumptions being the rate for interest and depreciation on the stated capital and an assumed price per h.p.-year for the stated horse-power employed.

A certain number and class of industries will attach themselves to every town in proportion to its population and other local conditions, entirely irrespective of the cost of power.

Such industries in a town of 5,000 population would be, say, a brick-yard, steam laundry, machine shop, flour and grist mill, planing mill, mineral water factory, elevators, etc. When it reaches 12,000 or 15,000 there may be added, still without regard to cost of power, further factories of the same class and in addition a foundry, brewery, sash and door factory, tent and mattress factory, etc. At 50,000 population, and still without regard to cost of power, there would probably be, in addition to the foregoing, some or all of the following: box-works; abattoir and cold storage, harness factory, soap works, creamery, show-case factory, etc.

The results are so general that a little investigation will satisfy anyone that they are obtained under normal conditions irrespective of the cost of power.

The reason can be clearly seen from Table I. on consideration of the percentage cost of power, compared to other items of expense incurred by miscellaneous medium sized industries. It will be seen that at the assumed figure of $50 per h.p. year the highest figure for the cost of power in per cent. of total costs is under 6% and the average is 3%.

The intention in this and the following tables is to give a fairly approximate idea of the proportion that the cost of power bears to the other items of expense, not to attempt to give an exact figure of the cost of the power itself, which must vary in each case in each industry.

Before proceeding further it will be well to explain the basis on which this table is constructed, so that those interested can make any allowances they see fit.

The total capital employed is given in the census reports for each group of industries and it is specified that the expenses given do not include interest and depreciation.

"Materials" include all raw materials, mill supplies and containers. It also includes (as given in the census reports) fuel, rent of power and heat; and fuel includes all fuel used whether for heat, light or power or for process of manufacture.

Salaries and wages include labor for power and this latter cannot be given separately.

Power. The census returns show the primary power employed in each industry, but do not give the cost of power separately, this being included in "materials" and in wages, as above stated. The cost assumed for power has, therefore, been deducted from the amount given in the census reports for materials and the amount so deducted represents only fuel, oil, stores and water and rented power, or the equivalents. The writer finds that the average proportion of costs of producing power in factories, from a large number of individual cases where the costs were accurately kept, is as follows:

Fuel	50.00%
Oil, stores and water	4.25%
Wages	17.00%
Repairs	4.25%
Interest and depreciation on power plant at 10% on investment	25.00%
	100.00%

To correctly show the percentage cost of power it would therefore be necessary to correct the interest and depreciation column and the salaries and wages column shown in the tables. This can be easily done for any particular case but to do it to the whole of the table on an assumed cost of power would diminish the value of the original figures. Furthermore, it is not necessary to do so to support the contention as to the low percentage cost of power in miscellaneous industries.

If, for instance, taking the averages of the columns, power at $50 represents 3% of the total costs and we assume that power costs 25% more or less than $50, this will only be 25% of 3% or 0.75% on the total cost taken

as 100%, but 25% on wages or materials would be 5.7% and 13.5% respectively on the total costs.

The method by which Table I. is figured is shown by the following sample calculation:

Census Figures for Totals per Establishment.

Primary horse-power	69.5
Capital invested	$68,500
Expenses—	
Salaries and wages	16,250
Materials (including power)	45,200
Miscellaneous	7,240

From which the following is deduced:

Interest and depreciation, say 12%	$ 8,220	10.7%
Salaries and wages	16,250	21.2%
Power: 69.5 h.p. @ $50 per h.p.-year	3,475	4.6%
Raw material and general supplies	41,378	54.0%
Miscellaneous	7,240	9.5%
	$76,563	100.0%

The relative position of industries as power users can be obtained in a different manner and is shown in Table II. Columns 1, 2 and 3 are calculated direct from the census figures. The last or fourth column is an arbitrary attempt to establish a numerical rating, and while objections may be made to the method, it does establish clearly which industries may be classed as using a relatively large amount of power on the three principal bases. For instance, it is obvious that the cost of power must be a more serious consideration to numbers 27 and 28 than to numbers 3 and 4.

Some of these industries using relatively large amounts of power are shown in Table III. in a similar manner to those in Table I. It would not do to assume a figure of $50 per h.p. year for all these because in some cases this would be prohibitively expensive power.

Steam power for blast furnaces costs about $70, with gas engines using blast furnace gas from $30 to $40. In cement mills the power required is relatively very large but their large plants and good load factor give them low costs and several concerns buy hydro-electric power at cheap rates. Pulp mills are usually in districts where water power is available at $18 to $30 per h.p.-year. The figures for cost of power have therefore been chosen accordingly to give an approximate idea of the relative cost of power in each case.

Looking at these large power-using industries from the location point of view, it will readily be seen that while the cost of power is a serious consideration, matters of raw material, labor market and distribution facilities are still more serious and that it would require a good deal in addition to cheap power to determine their location.

Table I.—Percentage Cost of Power in Miscellaneous Industries. Power Assumed at $50 per h.p.-year.

	Interest and depreciation at 12% on capital.	Salaries and wages.	Power at $50 per h.p.-year.	Raw materials, etc.	Miscellaneous.
	%	%	%	%	%
Boots and shoes	9.8	43.3	1.8	41.4	3.7
Breweries	21.7	16.7	4.5	20.7	36.4
Canning and preserving	9.2	17.3	2.6	62.7	8.2
Carriages, wagons	13.0	28.2	2.5	49.1	7.2
Clothing	5.4	24.8	0.4	56.5	12.9

Foundry and machine shops	14.4	33.0	3.4	39.4	9.8
Furniture	9.5	43.8	3.9	34.6	8.2
Lumber, saw and planing mills	5.9	34.5	5.9	42.3	11.4
Meat packing	3.4	5.3	0.3	87.8	3.2
Paints and varnish	10.0	15.1	2.2	61.6	11.0
Woollen goods	11.8	18.8	4.1	60.2	5.1
	10.2	22.6	3.0	54.5	9.7

Table II.—Relative Position of Industries as Power Users.

Industry.	Horse Power. 1. Per Capita.	2. Per $1000 Capital.	3. Per $1000 Value of Product.	Relative Use of Power. Average of 1, 2 & 3.
1. Clothing	0.14	0.16	0.07	0.12
2. Boots and shoes	0.45	0.43	0.19	0.36
3. Canning and preserving	1.13	0.68	0.52	0.78
4. Meat packing	1.92	0.55	0.02	0.82
5. Foundries and machine shops	1.40	0.57	0.71	0.89
6. Farm implements	1.66	0.39	0.68	0.91
7. Car-shops, railroad	0.98	1.23	0.72	0.98
8. Carriages & wagons	1.52	0.72	0.79	1.01
9. Paints & varnishes	2.55	0.56	0.45	1.13
10. Furniture	1.54	0.98	0.93	1.15
11. Electrical machinery and apparatus	1.51	0.60	1.41	1.17
12. Woollen mills	2.07	0.84	0.83	1.25
13. Smelting, lead	3.45	0.20	0.16	1.33
14. Creameries	3.22	1.42	0.37	1.67
15. Petroleum refining	5.45	0.50	0.38	2.11
16. Breweries	5.20	0.56	0.93	2.23
17. Cotton mills	3.35	1.58	2.06	2.33
18. Grindstones	3.72	1.16	3.38	2.75
19. Lumber, sawing and planing mills	3.62	2.51	2.46	2.86
20. Bricks and tiles	3.99	1.95	3.68	3.21
21. Chemicals	7.50	1.34	1.77	3.54
22. Smelting, copper	9.40	1.42	0.42	3.75
23. Iron and steel rolling mills	8.1	2.09	2.13	4.11
24. Sugar and molasses	10.70	1.05	0.58	4.11
25. Oil and cotton seed	9.00	2.11	1.30	4.14
26. Flour & grist mills	12.90	2.44	0.97	5.68
27. Portland cement	12.6	1.98	5.9	6.83
28. Paper & wood pulp	16.0	3.19	4.86	8.02
29. Blast furnaces	27.2	2.41	3.00	10.87
30. Carbide of calcium	37.4	12.1	14.5	21.3

In this connection it is of interest to consider the proportion of power owned by and the proportion purchased by industries. The census summaries of the total power used in all industries show that the percentage owned by the establishments using it is 97% in Canada and 90% in the United States, so that the proportion of purchased power is still quite small in relation to the whole and there must still be a very wide field for central station power.

It is also of interest to observe the large proportion of power, other than water power, used in both Canada and the United States, by industries that are essentially large users of power. This is shown in Table IV., which

gives the total primary power owned by the establishments and excludes electric motors driven by that primary power.

The above particulars appear to indicate clearly that in ordinary miscellaneous industries the cost of power is a comparatively small consideration, that even in industries where the cost of power is a large proportion of the total costs, other considerations of raw material, distribution facilities and labor market are of even greater importance.

Table III.—Percentage Costs in Industries Using Large Amounts of Power.

	Interest and Depreciation at 12% on Capital.	Salaries and Wages	Power. Per H.P. Year.	Power. Per Cent.	Raw Materials, etc.	Miscellaneous.
	%	%	$	%	%	%
Blast furnaces.	13.9	7.4	35	9.8	66.3	2.6
Chemicals	16.5	18.0	50	9.3	47.6	8.6
Cotton mills ...	13.8	20.5	50	9.0	51.7	5.0
Portland cement	30.2	25.4	35	17.4	21.9	5.1
Rolling mills ..	11.9	18.7	50	10.3	54.7	4.4
Wood pulp and paper	17.1	17.6	25	11.4	46.4	7.5

Table IV.—Class of Power Used in Large Industries.

Industry.	Canada, Census 1911. Water Power.	Canada, Census 1911. Other Power.	U. S. Census 1909. Water Power.	U. S. Census 1909. Other Power.
	%	%	%	%
Wood pulp and paper..	94.0	6.0	60.0	40.0
Portland cement	2.3	97.7	....	....
Carbide of calcium	3.2	96.8	....	....
Smelting	2.0	98.0	6.9	93.1
Iron and steel products	0.8	99.2	0.05	100
Cotton	48.5	51.5	24.4	75.6
Flour and grist mills...	52.0	48.0	31.0	69.0
Lumber products	19.3	80.7	5.0	95.0

There is no question that very cheap power has located industries at certain points *where the other conditions were also favorable*, but it is extremely doubtful whether the large sums spent by municipalities in competitive efforts to attract industries by the offer of cheap power produce any tangible results, except where the other essentials predominate and really form the deciding factors in locating the industry.

BRITISH LOCOMOTIVE EXPORTS.

Notwithstanding the war, the British locomotive shipments exhibit, upon the whole, satisfactory results for the nine months ended September 30th, the value of the engines exported to that date having been £2,929,502, as compared with £2,067,316 in the corresponding period of 1913, and £1,430,977 in the corresponding period of 1912. Argentina took British locomotives in the first nine months of this year to the value of £603,766, as compared with £499,254 and £313,432. This result must be regarded as favorable in view of the current disorganization of the Argentina railway interest. It is, however, in British India that the greatest progress in the demand is observable, the value of the Colonial imports having been as follows to September 30th, this year, as compared with the corresponding periods of 1913 and 1912:—

Colonial Group.	1914.	1913.	1912.
British South Africa	£ 64,099	£ 96,831	£148,442
British India	1,322,082	711,910	298,996
Australia	430,950	338,861	237,919

It will be seen that purchases of locomotives upon Australian account have been good this year. The war may exert an unfavorable influence upon Australian development, but thus far it has not had much effect.—Engineering, London.

THE ROYAL ENGINEERS OF THE BRITISH ARMY.

By Geo. Laidler.

FROM the earliest times, engineers have been employed in the field of war on the construction of fortifications, earthworks and batteries for besieging defences. In modern times, however, the application of scientific devices to warfare has given rise to many minor branches of military engineering in addition to the primary duties of fortification and siegecraft, such as the field telegraph service, the flying corps, the construction of temporary roads and bridges for the transport of an army; also works which more properly belong to the realm of civil engineering, such as surveying, the construction of permanent military buildings, railways, piers, etc. All these branches require special knowledge, and consequently the "field companies" and "fortress companies" represent the application of their arm to works of offence and defence in field and siege warfare.

It is difficult to distinguish between military and civil engineers in early modern history, for all engineers acted as builders of defensible strongholds, as well as makers and manipulators of engines of war for attacking and defending them. The annals of the science of glorification record artists, architects and soldiers as being responsible for the design and construction of the various systems. Artillery naturally became just one branch of military engineering; in fact, the word "engine" which, at the time of Chaucer meant "natural talent," or "invention," (corresponding to the latin "engenium" from which it is derived) was formerly used especially to denote a weapon of war, such as the catapult or battering-ram.

By the middle of the thirteenth century there was in England an organized military body of skilled workmen controlled by a "chief engineer." At the siege of Calais in 1347 this corps consisted of masons, carpenters, smiths, tentmakers, miners, armourers, gunners and artillerymen. When Harfleur was besieged in 1415 the chief engineer was designated "master of the King's works, guns and ordnance," and his men numbered 500, including 21 foot archers. About 1450 the engineer branch had developed into the Office of Ordnance, whose duty was to administer all matters connected with fortifications, artillery and ordnance stores.

Henry VIII. employed many engineers to construct coast defences around England, and also added to the organization a body of pioneers under trenchmasters, to clear and repair roads and to remove obstacles to the march of troops. Up to 1715 the commander of an ordnance train was nearly always an engineer, but after that date it was decided to separate the artillery from the engineers. It afterwards became common for the officers of engineers to hold commissions in foot regiments in addition to their rank in the corps of engineers.

In 1757 all engineer officers were gazetted to army as well as engineer rank—chief engineer as colonel of foot and so down the scale to practitioners as ensigns (second lieutenants). In 1782 the engineer grades except that of chief engineer were abolished. Ten years later a small corps was formed, and in 1787 the designation "Royal" was conferred upon it.

In 1802 the title of Chief Engineer was changed to Inspector-General of Fortifications, and from this time up to the conclusion of the Crimean War many augmentations took place on account of the widely increasing duties which devolved upon the officers.

In 1772 the formation at Gibraltar of the "Company of Soldier Artificers," officered by Royal Engineers, was authorized, and in 1787 the "Corps of Royal Military Artificers" was established at home. In 1813 its title was changed to the "Royal Sappers and Miners," doubtless on account of the intrenching and subterranean nature of much of its work. In 1856, after the Crimean War, it was incorporated with the "Corps of Royal Engineers," by whom it had always been officered. There is a School of Military Engineering at Chatham, England, (the headquarters of the corps) where officers are trained, and where the official textbooks on military engineering are compiled.

The ordinary strength of the regular Royal Engineers of the British Army is about 10,000 officers and men, with mounted and dismounted sections. The territorial and overseas forces also include a proportional complement of Engineers. The privates (called "sappers") in the regular Royal Engineers are generally skilled artisans. They are trained in tactics and the use of the rifle and are paid at a higher rate than infantrymen. The utility of this important branch of the service has frequently been shown in the course of the present war, especially on demolitions, entanglements and bridges.

DRAINAGE STRUCTURES.*

By W. E. Atkinson,
State Highway Engineer of Louisiana.

In determining the length of bridges and spans between bents and piers and the size of culverts, consideration is given to the maximum rainfall, amount of run-off, average slope of ground of drainage area, seepage, etc., as included in the same factors governing similar structures under railroad construction. After determining the required opening for waterway, the factor governing the required strength or carrying power of the structure is determined, so far as it is possible, upon the maximum load the structure is likely to be subjected during its bonded life. As to the bonded life of structures of this character, it is figured that they should last until bonds or taxes voted for the construction of same are retired, all structures being computed, however, to safely carry a minimum live load of not less than ten tons, plus 50 per cent. impact and a factor of safety of four.

Standard Plans.—It has been the policy of the highway commission of Louisiana to construct, wherever funds and conditions will permit, permanent structures and adopt uniform and standard plans for bridges and culverts for any particular highway project. However, oftentimes different designs are necessary to meet existing conditions. The type and design of bridges, whether they be of wood, concrete, or masonry, etc., are determined largely by the amount of funds available, and the character and nature of soil for foundation.

Due to the alluvial character of the soil, with the exception of some sections in the northern part of the State, there are instances where it is not safe nor economical to construct the arch type of concrete bridges; even with some of our girder and slab bridges, it oftentimes becomes necessary to provide pile foundations for the piers, abutments and wing walls. In some places it is necessary for these piles to be of concrete instead of wood on account of many reclamation projects, now under way, lowering the ground water which would become detrimental to the latter type of construction.

* From a paper read at the Fourth American Road Congress, Atlanta, Ga., Nov. 9 to 14, 1914.

Uniform Design.—We have found it advantageous and economical to provide, where conditions will permit, a uniform design for all drainage structures, especially for those of concrete construction, that the contractor may use the same drainage forms over and over, permitting thereby much lower bids per cubic yard on such work than otherwise under a system of non-uniform standard designs for such structures, and in addition, many times permitting, without greater cost, greater waterway opening than theoretically computed, resulting in a larger factor of safety, and often providing for some unprecedented rainfall or cloudburst not anticipated. In addition to concrete bridges, the department is building many wooden bridges, both of creosoted and uncreosoted materials; this character of construction predominating in some parishes due to lack of funds for more permanent construction.

Types of Culverts.—The department has installed several types of culverts, that of vitrified clay, cement, concrete, cast iron, wood, corrugated galvanized iron, etc., the type of construction being governed by the available funds and topographical features together with character of soil encountered in foundation. However, where practicable, concrete has always been recommended.

At many places, however, we have found it impracticable and not economical to use concrete culverts and others of a monolithic character, especially in some of the bayous and coulees. In one place in particular, it is recalled, where the foundation in one bayou was so poor that a strip 2 in. x 2 in. x 16 ft. was pushed down its full length in the bottom of the bayou, and could have been pushed farther if the strip had been longer. This bayou was 250 ft. wide across the top and 25 ft. deep, and the only opening necessary was that of an equalizer with an area of some 28 sq. ft. to be filled over with earth, thereby making a bridge of earth and of an equalizer. The equalizer installed at this particular location was a 10-gauge 6-ft. diam. corrugated galvanized iron pipe culvert. The entire cost of this combination bridge, if it may be so termed, amounted to $2,059.27, including an item of $215.73 for riprap, whereas to have bridged the bayou with concrete, or to have attempted to build a concrete culvert, would have made the cost very much in excess of this amount.

Due to debris, drift wood, and other extraneous matter, our highway department has adopted a policy not to install any culverts of less than 18 in. in diam. where possible, it preferring that they should be not less than 24 in. in diam. Experience has shown that culverts of these sizes have proven more satisfactory and given better service, requiring less maintenance both for road and culvert at such places than when culverts of smaller diameter are used, even though the smaller culverts are ample to carry the water, due to the ineffectiveness of the latter from drift choking and filling them up.

PACIFIC GREAT EASTERN RAILWAY CONSTRUCTION.

The British Columbia Government has decided to guarantee bonds to enable the Pacific Great Eastern Railway Company to float a loan of $5,000,000, to provide for further construction.

The American Society for Testing Material has added to its specifications for reinforcing steel rolled from billets, an intermediate grade between the structural and hard grades. The new grade has a yield-point of 40,000 lbs., and an ultimate tensile strength of from 70,000 to 85,000 lbs.

Editorial

THE ROYAL CANADIAN INSTITUTE AND SCIENTIFIC RESEARCH.

Mr. Frank Arnoldi, K.C., President of the Royal Canadian Institute, has announced that the Institute, with a mature and comprehensive knowledge of the fact that the necessities and welfare of every member of the community and the attainment of efficiency are bound up with the advancement of the scheme of co-operation of science with industry, is about to undertake to promote the establishment within itself of a Bureau of Scientific and Industrial Research. As Professor Haultain observes, in his open letter commending the procedure, it marks the return of the Institute to the channel molded for it in the minds of its founders over half a century ago.

Science and Industry must co-operate if Canada is to make any material advance in the readjustment of industrial greatness, of which this war is the curtain-raiser. The universities have long realized this, and have not hesitated to extend offers to co-operate with the Institute in its move. But, in Canada, as previously in England, there has been some disinclination on the part of the industrial and business man to embrace the advantages which Science has proffered. On the other hand, it has not been the enemy's militarism but the co-operation of Science with German industry that has placed that country where it is industrially. Enemy though it is, the German nation has given the world a great lesson.

Down in the University of Pittsburg, there is nearing completion a home for the Mellen Institute of Industrial Research and School of Specific Industries. It will provide ample accommodation for seventy researchers besides accommodation for graduate courses. Industrial fellowships constitute the basis of the system, and these are constantly increasing in amounts subscribed for their maintenance by industrialists. We have not the space here to describe the system as fully as we would like; for although in its infancy the Institute has gained world-wide fame through its investigation of the Smoke Problem. Suffice it to state at this juncture that there is every indication of a successful start on the road to the ideal for which it is striving. This ideal may be read from the inscription on the door:

> "This building is dedicated to the service of American Industry and to young men who destine their life-work to the Industries; the goal being Ideal Industry, which will give to all broader opportunities for purposeful lives."

In a quiet way the graduates of the Faculty of Applied Science and Engineering of the University of Toronto raised a fund among themselves and have financed a considerable amount of engineering research. The movement has had the closest co-operation of the the University of Toronto, and the results obtained in a recently completed fellowship will, when published, be found very valuable.

The Royal Canadian Institute, in its revival of scientific investigation in relation to Industry, will receive warm support from the scientific world, and there is little doubt that the organization will make a creditable showing in making Canadian industry more efficient in its manufacturing practices.

LAYING CONCRETE ON THE LEVEL.

Mr. Geo. H. Gooderham, chairman of the Toronto-Hamilton Highway Commission, is quoted in the daily press as having answered in the following way some criticisms directed against his action in appointing as chief engineer of the proposed highway, an engineer who is not a Canadian:

> "I received no less than three hundred applications for the position, some from engineers from Toronto and Hamilton; but there was not one among them who had the necessary qualifications for the work. Some were capable of building a 20-story building, but none were capable of laying concrete on the level."

The layman's intelligence and knowledge of present conditions is no doubt responsible for his belief that of those 300 applications the majority at least were from Canadian engineers; that the applicants felt qualified in technical ability and practical experience to undertake the responsibility of laying a concrete road, and that, considering the present prostration of engineering work, the proposed piece of construction must have attracted the attention of many of our engineers, of broad engineering experience and careful training.

It is painful, in view of the wide publicity and endorsation that has been given the whole project in the technical, trade and daily press, since its inception, that engineers of this country should be the objects of such a remark from an individual who, by virtue of his position, should know better. It points once more to the questionable silence on the part of the engineer respecting his profession and his achievements therein. His ability to lay concrete on the level should not be so conscientiously shielded from the gentle gaze of the interested public.

As for the appointee, who is also a capable engineer, it is no doubt of some little concern to him if the chairman of the commission knows as little about engineering and engineers in their relation to concrete road building as the above quotation implies.

REINFORCED-CONCRETE FACTORY BUILDINGS.

A paper to be read by F. W. Dean at the coming convention of the American Society of Mechanical Engineers (Dec. 1 to 4) presents the advantages of the use of reinforced concrete for the use of factory buildings, such as fire-resisting qualities, great window area, and good lighting, and also some of the disadvantages. It also points out that regular mill construction buildings have shown their fire-resisting qualities when properly designed. The best methods of finishing the floors are discussed and also the application of wood as a wearing floor above the concrete. The difficulties of fastening shafting hangers and machinery are brought out and the extra cost of drafting in consequence of this, as well as the great care required in making provision for everything to be installed. The different methods of constructing floors and the different forms of ceilings are taken up and also the relative costs of concrete and regular mill construction buildings.

"CO-OPERATION BETWEEN SCIENCE AND INDUSTRY."

An Open Letter to Frank Arnoldi, Esq., K.C., President of the Royal Canadian Institute.

Congratulations, sir, not so much on the addition of the word "Royal" to the title of the Institute, which in itself is no small thing, but on the goal towards which, as we now recognize, that was but a step.

"Co-operation Between Science and Industry in Canada," recently issued over your signature, will be read with interest by engineers everywhere and they will recognize and appreciate the partial return of the Institute to its old love.

The study of nature to woo from her the knowledge of her secrets is one thing and this knowledge may be called Science, or Pure Science, or Exact Science. To convert this knowledge to the use and convenience of man is another thing. It is sometimes called Applied Science, but it is really Engineering. It is the new form of the old struggle with nature to make her work for man. This struggle has been aided, has been entirely changed by the knowledge supplied by the sciences, but the knowledge is but a weapon and much lies in the wielding of it before nature is compelled to yield in usefulness. This wielding for the community is Engineering. The methods of the Engineer are scientific methods, but they are very different from the scientific methods that produced the weapons. It is Engineering that makes the weapons useful.

You are seeking methods of developing this Engineering aid. You are pleased to consider yourself neither a scientist nor an Engineer, but you belong to that profession which has a broader and at the same time a more intimate view of the real needs of the community than any other other, and you have chosen to lead back the Institute to the lines favored by its founders. The Royal Charter of 1851 stated the objects of its incorporation to be "more particularly for promoting the acquisition of those branches of knowledge which are connected with the professions of surveying, engineering and architecture." The aims of the Institute show the conventionalized symbols of Engineering and its founder was an Engineer, but for more than a generation the Institute has departed from the lines laid down for it, and the tangible results have been meagre compared with the promise of the future. Our congratulations on the return to the original trail.

Yours faithfully,

H. E. T. HAULTAIN.

C.N.R. SHOPS AT PORT MANN, B.C.

The buildings for the proposed machine shops and repair plant of the Canadian Northern Railway at Port Mann, about 16 miles from Vancouver, were completed some months ago and equipment is now being installed. The buildings are practically all of reinforced concrete construction with wood and steel roof trusses. The main erection and repair shop is 276 x 143 ft. and is laid out with two main bays. The other buildings include a 15-stall round house, a large storehouse, an 80-ft. turntable, an 80,000-gallon steel water tank mounted on a steel tower, and housing and boarding accommodation for about 150 men. The bay of the main structure devoted to repair shop has a 30-ft. elevated platform running the full length of the building to be used for purposes of light repair. Both bays are served by 10-ton travelling cranes. An electrically operated pair of jacks with spacing capacity of 25 to 45 ft. is being installed for the manipulation of locomotives. The drill, lathe and other equipment are of the most modern types.

SANITATION AND THE WAR.

At a recent meeting of the Canadian Club of Toronto, Dr. John A. Amyot, director of the Provincial Board of Health, pronounced sanitation as the most vital factor in a modern military campaign and corroborated his statement by reference to war fatalities in the past. Where efficient precautionary measures against disease had not existed, fatalities had been overwhelmingly more numerous as the result of epidemics of sickness than from the destructive forces of the enemy.

It was stated that in the South African war 12,669 men and non-commissioned officers had died from disease, while only 7,000 had died from wounds. In the American Civil War the northern army lost 102,000 men, and 20,000 of that number died from disease. Going back to the Crimean War, during 6 months, from October, 1854, to March, 1855, there were 52,000 men in the hospitals and only 3,800 of that number had been disabled by wounds.

The Russo-Japanese War very stoutly emphasized what sanitation in war meant. By rigid measures, conditions as outlined above were reversed and less than 25% of those who met death, died from disease.

The speaker pointed out the work of the Army Medical Service Corps—to keep men fit and to return as many sick and disabled persons as possible to the firing line. It was stated that before the time of antiseptic surgery the mortality in cases of amputation and injuries to lower extremities on the field of battle was as high as 90%, and that it has now been reduced to as low as 5%.

He expressed the great difficulty in the present war to be that the armies were of such a mixed nature that the difficulties attending complete sanitation on such a gigantic scale are enormous.

Dr. Amyot paid due attention to the problem of water supply and remarked that in war the army always assumed water in a new district to be impure, until it had been proved to be otherwise.

GOVERNMENT DRY DOCK AT SELKIRK, MANITOBA.

Late in October the Department of Public Works, Ottawa, completed at Selkirk, Man., the construction of a $100,000 dry dock. The capacity of the dock is 1,500 tons, and it is of sufficient size to handle a vessel 250 ft. in length. The cradle is 192 ft. long in itself, and 208 ft. over all. Its width is 52 ft. It has been constructed in two parts in order to provide for repairing two small vessels simultaneously.

The dry dock is operated by a 150 h.p. motor. By it the dock cradle is raised or lowered on a track extending 525 ft., or to any depth necessary for hoisting the craft to be repaired. The hoisting is accomplished by chains. The cradle is chiefly of steel construction, while the dock walls are both of concrete. The Crandle Engineering Co., of Boston, were the contractors. Inspection work was carried out by the Canadian Inspection Co.

Coast to Coast

Lethbridge, Alta.—The Lethbridge-Weyburn line of the C.P.R. has about 67 miles of steel still to be laid.

Woodstock, N.B.—Mr. F. T. Gutelius, general manager of the Intercolonial Railway, states that the finished portion of the Valley Railway will likely be taken over by the Intercolonial before the end of the month.

West Vancouver, B.C.—Work is progressing rapidly on the new Capilano bridge. Naylor Bros. are the contractors, and expect to have it completed early in December. This firm is also rushing to completion a new wharf at Dundarave.

Vancouver, B.C.—A large suction dredge of the Pacific Coast Dredging Co. is doing a large amount of reclamation work at Pitsilano beach. The fill, which varies from 3 to 10 ft. in depth, will aggregate about 100,000 cubic yards, and is being placed at the rate of about 3,500 cubic yards per day.

Toronto, Ont.—During the season Mr. Frank Barber, engineer for the county of York, has constructed two bridges south of Brownhill, one at Newmarket, one at Schomberg, one at Willowdale, and another on the Dawes Road, while there is one still under construction between Scarboro and Markham.

London, Ont.—Complete estimates have been prepared by engineers of the Hydro-Electric Power Commission for five different schemes of radials to connect the municipalities of Tillsonburg, Brownsville, Springfield, Port Burwell, Aylmer and Belmont with St. Thomas and London. They include buildings, equipment, and all data as to probable revenue and cost of operation.

Revelstoke, B.C.—The double track of the C.P.R. between Revelstoke and Taft, and also between Kamloops and Hapgood, each about 25 miles in length, will soon be in operation. The double-track system over the new bridges crossing the Harrison and Pitt Rivers is now in operation, giving continuous double trackage from Vancouver to Ruby Creek, a distance of 83 miles.

Edmonton, Alta.—It is stated that before the war the Alberta government acquired over $12,000,000 for use in railway construction. This sum had been received from guaranteed railway securities and had not been paid up. It is to be applied to the Canadian Northern, Canadian Northwestern, Edmonton, Dunvegan and British Columbia, Alberta and Great Waterways, and the Lacombe and Blindman Valley Railways.

Vancouver, B.C.—As announced in August 27th issue of *The Canadian Engineer* in connection with an article descriptive of the proposed Second Narrows Bridge at Vancouver, Mr. Ralph Modjeski, consulting engineer, Chicago, has been retained by the Burrard Inlet Tunnel and Bridge Co. to report on the three designs and tenders for its construction. It is expected that this report will be in the hands of the company in the course of a few days.

Winnipeg, Man.—Grading for the construction railway in connection with the Shoal Lake aqueduct was completed on November 4th to mile 9, and the remainder of the line is 75 per cent completed. Track-laying is completed for over 70 miles and ballasting for over 60 miles. In the Brokenhead River ditch 4,400 lineal feet has been constructed, resulting in considerably lowering the water level at the railway crossing. The telephone line over the entire system has been completed.

Montreal, Que.—The newly-opened Montreal branch of the Ford Motor Co. of Canada, Limited, will give employment to about 200 men. The factory has been erected at a cost of about $300,000, and covers an area of 150 x 160 ft. It is four stories in height, but has been designed to add six more stories, should the business demand it. A novel feature of the plant is the flat concrete roof, surrounded by a parapet, and to be used for testing cars after they have been assembled. The building has been designed with the view of obtaining a maximum of light for the workers.

Winnipeg, Man.—In connection with the Shoal Lake aqueduct scheme of the Greater Winnipeg Water District, a dyke 5,070 ft. in length has been constructed to divert a considerable quantity of water from the Falcon River, because of its dark color owing to muskeg effluent (see *The Canadian Engineer*, October 23rd, 1913, page 606). Since its construction the color density of the water in this section has been very noticeably reduced. On October 9th tests gave the water a color density of 186. Recently similar tests gave it a color density of 9, quite unnoticeable in a glass of water.

Vancouver, B.C.—The Pacific Great Eastern Railroad, under construction from Vancouver to Prince George, 480 miles, is in operation from North Vancouver to Whitecliffe, 12.7 miles. The line is under construction from this point to Squamish, at the head of Howe Sound, and is in operaion north of Squamish, via Cheakamus, on about 20 miles. The grading work is finished to Lillooet, 100 miles from Vancouver, and track-laying is now under way. It is expected that track-laying and ballasting on this section will be finished this year. The remaining section from Lillooet north to Prince George on the Grand Trunk Pacific is all under contract.

Pitt River, B.C.—A large reclamation scheme is now nearing completion at Pitt Meadows, in the Fraser Valley, at an expenditure of approximately $200,000. The scheme, inaugurated for agricultural and market-garden purposes, has entailed a large amount of dyking and drainage, the former necessitated by the tides which flowed over the land, and the latter by its extremely level surface. A dyke 12 miles in length, 10 ft. in height and 6 ft. wide at the top, equipped with flood-gates, key-ditch and pumping equipment, was constructed at a cost of about $100,000. The drainage work has included about 40 miles of ditching. The era of systematic dyking and drainage is beginning in British Columbia. Another scheme is under way in the municipality of Richmond, as noted in last week's issue. The lands already dyked in the Fraser River Valley are the most productive in British Columbia.

North Vancouver, B.C.—North Vancouver gets its main supply from Lynn Creek, to the north-east of the city. This supply is abundant at present, but is not absolutely reliable, fears being occasionally expressed that an exceptionally dry year or a devasting forest fire might produce a shortage in the watershed. To overcome this, the city decided upon a scheme three years ago to increase the supply by the construction of a storage reservoir at Rice Lake, the work entailing the deepening of the lake and the clearing of its banks. When finished it will have a storage capacity of about 150,000 million gallons of water. The cost is estimated at about $175,000.

At the present time the water supply from Lynn Creek comes through an intake pipe 16 in. diam., with a fall of 180 ft. to Rice Lake below it. This pipe delivers some 6¼ millions of gallons of water daily. From the lake a shaft is driven through the mountain 1,000 ft. long to connect the lake with the city system. This shaft is 6 ft. wide by 7 ft. high and has cost approximately $25,000, and through this the necessary pipes are laid, while a flume has also been constructed therein to carry away the debris from the bottom of the lake, which is being sluiced out. When a survey was taken of the lake some four years ago it was found that the bottom was covered with silt, logs and other debris to a depth of from 5 to 10 ft.

PERSONAL.

W. S. DINGMAN has been appointed water commissioner of Stratford, Ont., to succeed J. D. Barnett, resigned.

J. L. McKEE has been appointed superintendent of the St. Thomas (Ontario) division of the Michigan Central Railway.

G. C. BATEMAN, Toronto, has been appointed consulting mining engineer to the Long Lake Gold Mines, near Sudbury, Ont.

W. A. McLEAN, Engineer of Highways for Ontario, will be a speaker at the coming convention of the Union of Manitoba Municipalities, to be held at St. Boniface, November 24th, 25th and 26th.

FRANK E. LATHE, B.A., B.Sc., has been appointed lecturer in metallurgy at the University of Toronto. Mr. Lathe, who is a graduate of McGill University, Montreal, resigned a position on the technical staff of the Granby Smelter (B.C.) to accept the appointment.

J. H. BILLINGS, B.A.Sc., a graduate in mechanical engineering of the University of Toronto, was, at the outbreak of the war, on his way to Germany to take a course of study at the University of Berlin. He is now at the Massachusetts Institute of Technology taking a course for a master's degree in mechanical engineering.

A. G. CHRISTIE, B.A. Sc., has resigned his position as assistant professor of steam engineering in the University of Wisconsin to accept a similar professorship in the engineering department of Johns Hopkins University. Prof. Christie is a graduate in engineering of the University of Toronto, and is the author of a valuable series of articles on the design of central heating systems, appearing in *The Canadian Engineer* in July, 1913.

T. C. KEEFER, C.E., C.M.G., LL.D., twice president of the Canadian Society of Civil Engineers, an honorary member of the Canadian Society and the American Society of Civil Engineers and of the Institution of Civil Engineers of Great Britain, celebrated his ninety-fourth birthday on November 4th. Mr. Keefer was born in Thorold, Ontario, educated at Upper Canada College, and has had a notable and distinguished engineering career.

J. VIPOND DAVIES, Vice-President of Jacobs and Davies, Inc., Consulting Engineers of Montreal and New York, was awarded on November 3rd, by the Institution of Civil Engineers, London, England, the Telford gold medal of that Institution for his paper on the "Extensions of the Hudson River Tunnels of the Hudson and Manhattan Railroad." The Telford medal dates back to the year 1835, funds for it having been bequeathed to the Institution by the celebrated engineer, Thomas Telford, its first president (1820-1935).

AMERICAN CONCRETE INSTITUTE.

The 11th annual convention of the Institute will be held in Chicago, Ill., February 9th to 12th, 1915. This convention will mark the completion of the tenth year of the existence of the Institute, and an especially interesting and profitable program is being arranged. The sessions will be at 10 a.m., 3 p.m. and 8 p.m. The following is a summary of the program:—

Concrete Roads, Sidewalks and Bridges.—Important papers and discussions relating to the status of concrete road construction will be presented, and special attention given to costs, repairs and maintenance. (Tuesday, Feb. 9th.)

Concrete and Reinforced Concrete Tests and Design.—Discussion of the very important column tests made by the Institute at Pittsburgh, tests of buildings, and other matters of current special interest. (Wednesday, Feb. 10th.)

Concrete in Art and Architecture.—Discussion of architectural design in concrete, dimension and art concrete stone, treatment of surfaces, etc. (Thursday, Feb. 11th.)

Plant Management and Costs.—This day will be devoted to concreting plants, covering plant management and costs, the design and cost of wood and metal forms, and the methods of placing, proportioning and selection of concrete materials. (Friday, Feb. 12th.)

CHANGE IN A PROMINENT CONSULTING ENGINEERING FIRM.

Dr. J. A. L. Waddell and Mr. John Lyle Harrington announce the dissolution of the firm of Waddell and Harrington. The firm's business will be conducted as usual till the conclusion of its affairs in July, 1915, except that it is accepting no new commissions. Dr. Waddell will give his attention to special engineering and financial matters and to important advisory work. Mr. Harrington will be joined by the firm's Associate Engineers, Mr. E. E. Howard and Mr. Louis R. Ash, in the establishment of the firm of Harrington, Howard and Ash, Kansas City, Mo.

INTERNATIONAL IRRIGATION CONGRESS.

The new officers of the International Irrigation Congress are: J. B. Case, Abilene, Kan., president; Arthur Hooker, Spokane, Wash., secretary; J. S. Dennis, of Calgary, first vice-president; Richard Burges, of El Paso, Tex., second vice-president; J. F. Hinkle, of Permiston, Cal., third vice-president; Kert Grunwald, of Denver, fourth vice-president; and George A. Smith, of Salt Lake City, fifth vice-president.

COMING MEETINGS.

WASHINGTON STATE GOOD ROADS ASSOCIATION.—Convention to be held at Spokane, Wash., November 18th, 19th, and 20th. Secretary, M. D. Lechey, Alaska Building, Seattle, Wash.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

AMERICAN ROAD BUILDERS ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

CANADIAN NATIONAL CLAY PRODUCTS ASSOCIATION.—Annual Convention to be held at the King Edward Hotel in Toronto, January 26, 27, and 28, 1915. Secretary, G. C. Keith, 32 Colborne Street, Toronto.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

AMERICAN WATERWORKS ASSOCIATION. — The 35th annual convention, to be held in Cincinnati, Ohio, May 10th to 14th, 1915. Secretary, J. M. Diven, 47 State Street, Troy, N.Y.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.—Annual meeting to be held at the Iowa State College, Ames, Iowa, June 22nd to 25th, 1915. Secretary, F. L. Bishop, University of Pittsburgh, Pittsburgh, Pa.

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

ST. PAUL STREET BRIDGE, ST. CATHARINES

NOTES ON THE DESIGN OF FOUNDATIONS AND SUPERSTRUCTURE OF THE PROPOSED STEEL HIGH LEVEL VIADUCT FOR WHICH CONTRACTS ARE NOW BEING LET.

By H. C. TAYLOR,
City Engineer's Office, St. Catharines.

THE substructure is under way and tenders have been called for the superstructure of a steel viaduct 1,236 ft. 3½ inches in length to provide a better means of communication between the business centre of the city of St. Catharines and the section known as the Western Hill. The only steam railway entering the city is the Grand Trunk, and its station and freight sheds are also situated on Western Hill. A deep valley intervenes, through which extends the old Welland Canal.

The need of a high level bridge has been a subject of controversy for a quarter of a century, and several campaigns were started at different times by private enterprise to provide funds for its construction. No definite action was taken by the city itself, however, until shortly after the outbreak of European hostilities, when, in the face of an indefinite period of monetary stringency, a by-law was passed by the ratepayers authorizing its immediate construction.

Of the several possible routes the St. Paul St. extension was finally chosen as being in the best interests of the city. A very slight deviation of the street alignment was necessary, and the structure at the same street level, as proposed, is made to provide for the elimination of 80 ft. of heavy grades with which the present roundabout road to the station is handicapped.

Several designs for the contemplated structure were submitted by Messrs. Sprague and Reppert, consulting civil engineers, Pittsburgh, Pa. Fig. 1 shows the type selected. In the test borings on the site no rock was found nearer the surface than 85 ft. There was also a matter of $40,000 difference between this design and an alternative one of concrete construction. Both factors figured materially in the selection of a steel structure. The cost of the bridge is estimated at $165,000, while the right-of-way has been purchased by the city for $55,000. Against this there are two grants, one from the Dominion Government amounting to $50,000 and one from the Grand Trunk Railway to the amount of $20,000; making a net cost to the city of $150,000. Preliminary work has included, in addition to the above, the cost of removing four stores and three large houses from the site of the north approach to the bridge. A new street will be made, and, when the structure is completed, there will be two

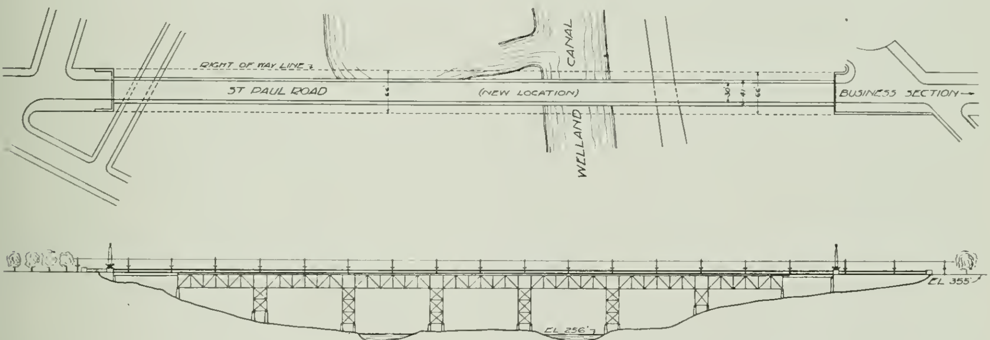

Fig. 1.—General Plan and Elevation of the Proposed Bridge.

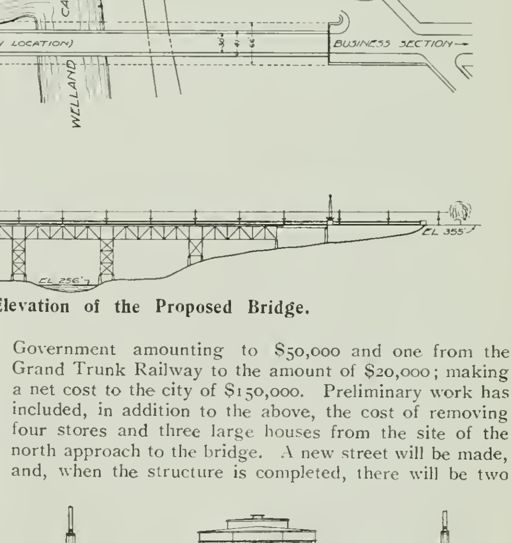

Fig. 2.—Section of Roadway.

streets leading directly to the bridge at the north end, thus allowing for future extension of traffic.

Contracts are being let in three sections. The substructure has already been let by contract to Campbell &

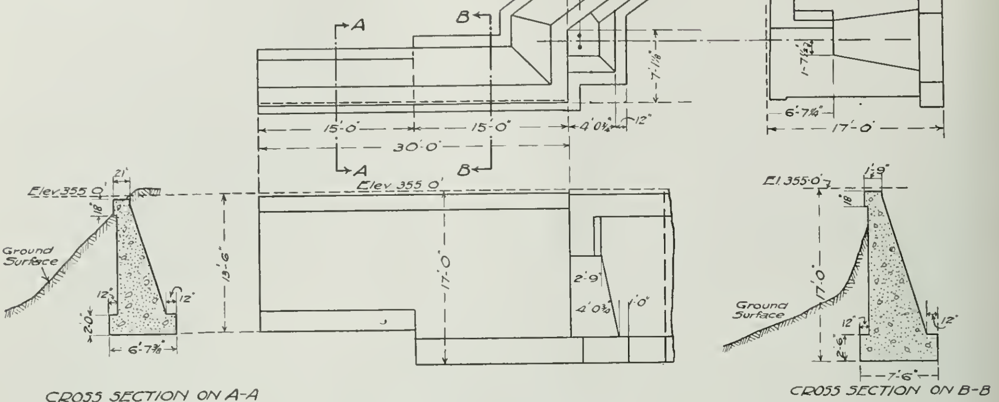

Fig. 3.—Details of Wall Section No. 1.

Lattimore, Toronto. Tenders for the steel superstructure close on December 8th. The contract for paving, which will probably be of creosoted wood block, will be let at a later date.

The work in connection with the substructure consists of about 3,000 cubic yards of excavation, and 1,850 cubic yards of concrete in piers and abutments. There will also be considerable concreting in copings and parapet wall. About 10,240 lineal ft. of timber is being used in piling. Other quantities of interest include 7,250 pounds of anchor bolts and 3,000 pounds of reinforcing steel for the piers and abutments. The contract for this work has

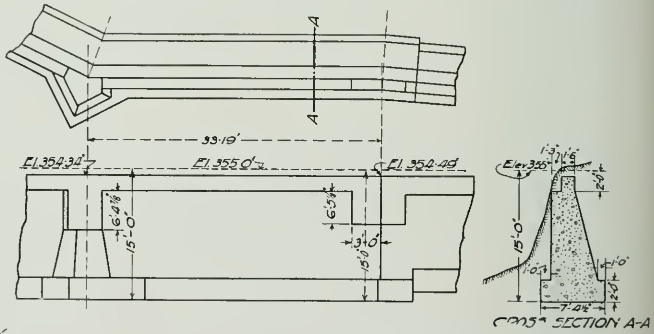

Fig. 4.—Detail of Wall Section No. 3.

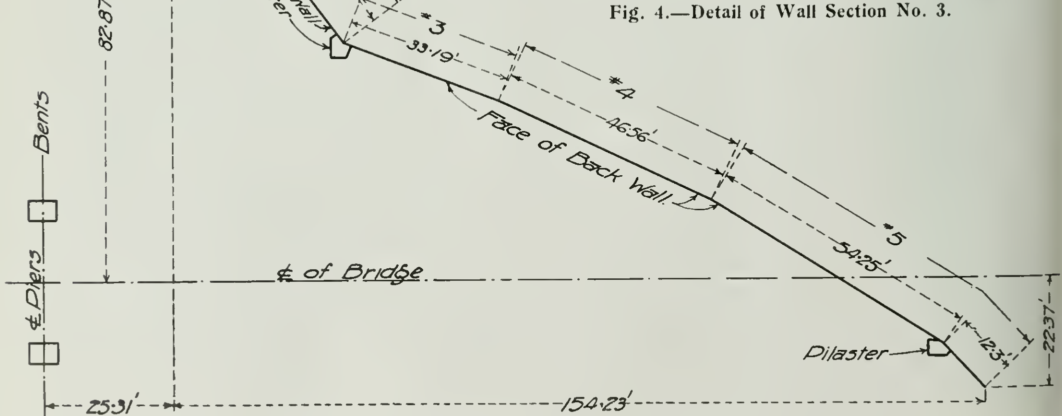

Fig. 5.—Location Diagram of Wall at North Approach.

been let at an amount about $10,000 under the engineer's estimate, the latter being based on normal conditions.

The design of the north abutment possesses some points of considerable interest. As shown in Fig. 5, the wall has been divided into sections with alignments at angles to the centre line of the bridge. Section 1, 30 ft. in length, marking the extreme end of the abutment along Yates St., is shown in detail in Fig. 3. It varies in height from 13½ ft. to 17 ft., and includes a pilaster at the intersection with wall section No. 2. Section No. 3, the details of which are shown in Fig. 4, which is 33.19 ft. in length, is uniform in depth, 15 ft., and its section corresponds to section BB′ in dimensions. In section 4, 46.56 ft. long, the height decreases owing to an elevation of 2 ft. of the base, while the thickness of the base of the retaining wall decreases with the height to 6 ft. 10½ in. Wall section No. 5, which is illustrated in Fig. 6, is 54.25 ft. long with a depression of the base to 15 ft. and a corresponding enlargement of the base to 7 ft. 4½ in. in width, as shown in Fig. 5. The centre line of the bridge is crossed by this wall section, and a pilaster, shown in Fig. 6, connects a sub-section 12 ft. 3 in. in length, which forms the extremity of the abutment wall.

The south abutment, 24½ ft. in length, is shown in Fig. 7, which illustrates clearly the general features of its design and the proportioning of the supporting walls.

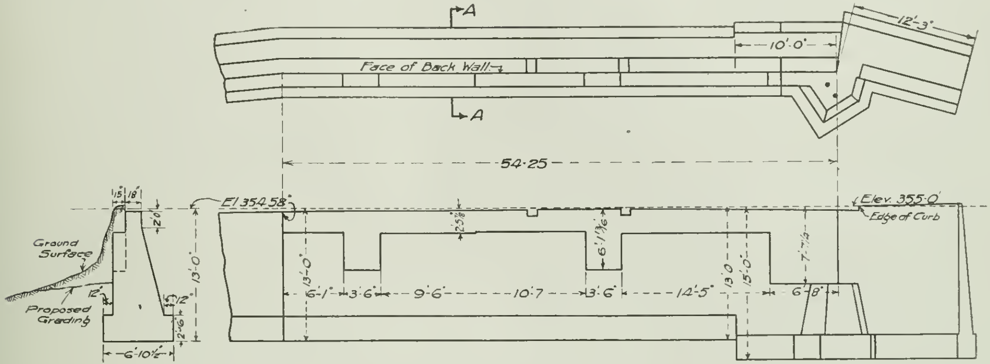

Fig. 6.—Details of Wall Section No. 5.

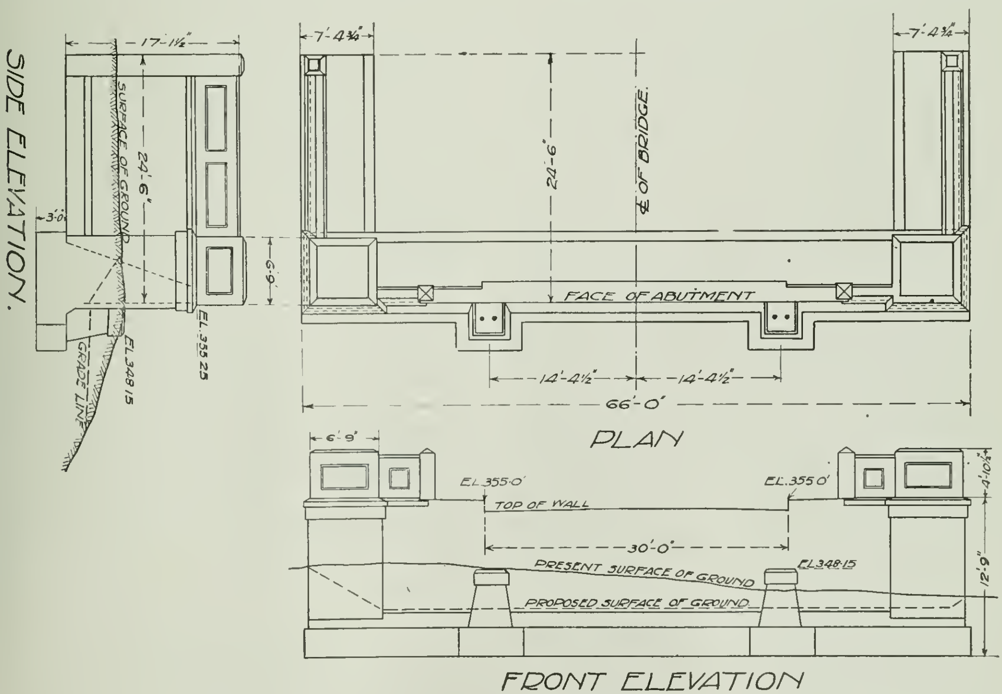

Fig. 7.—General Design of South Abutment.

There will be seven Warren truss spans, with plate girders at the ends extending to the concrete approaches. The steel is supported on 35 concrete piers, two for each of 17 bents, and a single pier at the south end. Five of these piers are reinforced. The 8 bents on the level portion of the valley rest on timber piles driven to a depth of about 40 ft., or to a point where each pile will sustain a load of at least 30,000 pounds. There are 16 piles to each pier, the piers being 12 ft. square at the base, with the piles spaced 3 ft. c. to c. both ways, and 18 inches in from the edge, the point of cut-off being 6 inches above the bottom of the pier. The bents adjacent to the canal banks are to be sheeted with 3-inch tongued and grooved material, driven to a depth of at least 6 ft. below the bed of the canal, the sheeting to remain in place and to be cut off 1 ft. below water level. The 4 anchor bolts for each pier are to be placed by means of a templet. This is a part of the work that requires accuracy and carefulness, as the steel will be ordered some time before the completion of the substructure.

As illustrated in Fig. 2, the bridge has been designed for a single-track electric railway, a 30-ft. roadway, and two 5-ft. sidewalks. The members are designed to carry a 36-ton car.

It is expected that the completed structure will be open to traffic in the fall of 1915. Mr. W. P. Near is the city engineer.

FIELDS FOR THE INDUSTRIAL APPLICATION OF CANADIAN WATER POWERS.

SOME very potent arguments bearing upon Canadian water powers and the rate at which they are being made of service to the country were presented at a meeting of the electrical section of the Canadian Society of Civil Engineers in Montreal, November 16th, 1914. A paper entitled "Making Our Water Powers Valuable" was read by Mr. Arthur Surveyer, consulting engineer, Montreal. It dealt chiefly with the position Canada holds in respect to other countries and presented in their true light the possibilities which exist and the national asset which we have in our water falls as a guarantee of future industrial superiority.

The paper presents a concise history of the harnessing of the larger and higher water falls by the modern turbine, in various countries, the first development of this sort in America being a 15,000 h.p. plant constructed at Niagara Falls in 1893. It alludes to the wonderful progress made in the technics of hydro-electric work since that time, to the recent improvements in installation which have made possible the economical transmission of energy for distances of 200 miles and over, and to the improvement of the modern turbine whereby low head developments are now commercially feasible. It compares the water powers of different countries and shows that Canada is not the wealthiest in water powers, especially if provinces are compared with countries of similar area, for example France, Austria, Sweden and Norway. The truth is brought out that although the available horsepower per square mile is greater in some cases, we are woefully behind other nations in the percentage of utilization. The following table indicates the uses made of hydro-electric energy generated in Ontario, Quebec, France, Sweden and Norway, and shows that up to the present we have only progressed in the simpler applications of electricity. It shows also that we have somewhat neglected its utilization as an electrolytic agent and as a heat-generating agent in electro-chemistry and electrometallurgy.

Countries.	Developed hydro-electric power.	Subdivision of developed power. Electro-chemistry and electro-metallurgy.		Motive power, traction and lighting.	
	h.p.	h.p.	%	h.p.	%
France . . .	592,000	291,000	49.1	301,000	50.9
Norway . .	543,000	275,000	50.6	268,000	49.4
Sweden. . .	370,000	120,000	32.4	250,000	67.6
Ontario. . .	320,000	25,000	7.8	295,000	92.2
Quebec . . .	198,000	28,000	14.1	170,000	85.9

In discussing ways and means for the advantageous alteration of these conditions, the author refers to the consumption of electricity for lighting and for traction as dependent on population, and notes that the consumption of electricity per capita for either lighting or traction is too small to be considered as an inducement for the extensive development of our water falls. The pulp and paper industries are referred to as large users of power and in this instance Canada is not so very far behind, although Sweden utilizes over 120,000 h.p. in this manner.

The author emphasizes the value of closer attention to electro-chemical and electro-metallurgical industries which would require a notable increase in the development of our water powers. He briefly reviews some of these industries that either on account of the abundance of necessary raw materials or because of large neighboring markets, might be likely to prosper in this country.

Electro-chemical Industries.—The manufacture of calcium carbide is the oldest of these industries in Canada. Three plants are in operation at present, absorbing about 14,000 h.p. and producing about 12,000 tons annually, half of which is exported. (The world's production in 1913 amounted to 339,000 tons.) The Canadian Carbide Co., with a capital of $2,000,000, control these three plants, one at Thorold, Ont., of 1,000 tons capacity, one at Ottawa, producing over 4,000 tons, and one at Shawinigan Falls, Que., supplying about 7,000 tons, annually.

There are also the nitrogenized fertilizers all except one process of which utilize electrical energy to combine directly the atmospheric oxygen and nitrogen. This combination gives nitric acid which in presence of water and air in excess is transformed immediately to nitrous and nitric acid and finally into nitric acid only; this azotic is either sold as such or is led over limestone, giving as final product the nitrate of lime which is utilized in place of the Chili saltpetre or nitrate of soda for all agricultural uses.

"The story of the fixation of atmospheric nitrogen can be summed up as follows: In 1902, the Atmospheric Product Company erected in Niagara Falls a trial plant for the manufacture of nitric acid by the Bradley and Lovejoy process. During the same year, de Kowalsky began in Fribourg a series of researches which were continued by Moscicki and led to the erection of a trial station at Vevey, in Switzerland; in 1903, Professor Birkeland, of Christiania, discovered a new process which was afterwards perfected by Birkeland and Eyde, and is now applied on a very large scale at Notodden in Norway. In 1903, also, Frank and Caro made public a new method of fixation based on a different principle and giving calcium cyanamide as the final product. More recently, Pauling and Schonnherr have taken out patents for other processes."

Nitrate of lime has developed in production since 1909 to 110,000 tons last year. For this industry alone the Norwegian Nitrogen Co. have undertaken the construction of plants with the total capacity of 540,000 h.p Nitric acid is produced in quantities ranging from 200,000

to 250,000 tons per year, United States producing about 70,000 tons. The margin between the selling price of ordinary nitric acid and the cost of synthetic azotic acid is large, according to Mr. Surveyer, and indicates that this industry can afford to pay even more than the nitrate plants for its electrical energy.

Calcium cyanamide requires electrical energy in its production. The world's output in 1913 was 226,000 tons. The Canadian plant of the American Cyanamide Co. at Niagara Falls began operation in 1910 with an output of 10,000 tons. The capacity has since been increased to 24,000 tons per year.

Electro-metallurgy.—In dealing with the industries to which hydro-electric power is applicable under this heading, the writer refers to aluminum, the first metal manufactured in a hydro-electric plant, as belonging to electrochemistry on account of the electrolytic method employed and to electric metallurgy on account of the nature of the product. He traces the growth of its manufacture and the enormous reduction in price per pound which it has experienced. In 1912 the United States produced 18,000 tons of aluminum, France 13,000 tons and Canada 9,000 tons. The actual capacity at present of the plants of the Aluminum Company of America is 90,000 h.p. This company has recently signed a contract with the Cedars Rapids Power Manufacturing Co. for the purchase of 60,000 h.p. to be used at their Massena plant on the St. Lawrence. The Shawinigan plant is the property of the Northern Aluminum Company, and has a capacity of 20,000 h.p.

Nickel, zinc and copper are also referred to as minerals extracted from their ores by smelting in the electric furnace. There is a great field for development of the Canadian industry with respect to them.

The production in the electric furnace of pig iron, ferro-silicon, ferro-titanium, and of steel is lengthily considered. The world's production of pig iron by this method was approximately 25,000 tons in 1912. Extensive experiments have extended over the past several years in Sweden. In Scandinavia there are 20 furnaces absorbing over 36,000 h.p. The world's production of ferro-silicon is over 60,000 tons per year. Two Canadian companies are manufacturing it, the Lake Superior Power Co., at Sault Ste. Marie, with an electric furnace of 250 h.p., and the Electric Metals Co., at Welland, with 4 furnaces totalling 5,000 h.p. Ferro-titanium is worthy of interesting study on account of the large deposits of titanium ore in the province of Quebec.

In the production of electric furnace steel 120 furnaces turned out 175,000 tons in 1912. The electric furnace is also extensively used for melting steel for castings. (Although not mentioned in the paper, it is worthy of note that the Moffat-Irving Steel Works, Limited, Toronto, have a furnace now in operation for the direct production of steel castings or ingots. The furnace is of the 3-phase type, and of 300 kw. This furnace was described in *The Canadian Engineer* for October 23rd, 1913.)

The different industries enumerated by Mr. Surveyer absorb approximately 1,500,000 h.p. Canada's contribution to this enormous utilization of power is just about 3.5% of the total.

Some Foreign Opinions.—After giving a brief survey of the large field which is open and worthy of utmost diligence in study, the paper reverts to some opinions of foreign engineers respecting the future for these industries in Canada. The existing obstacles have been well sifted out, and are, in particular, (1) The severity of winter, causing a low-water period; (2) Absence of adequate means of transportation; (3) Unlikelihood of enlarging Canadian Works around Niagara Falls, owing to movements on foot for conserving the beauty of the water power. While these criticisms are partly correct and while we are in a measure handicapped with economical, educational and physical obstacles to a rapid development of our water powers, it is inspiring to note the extensive studies that are being made by the Department of the Interior, Department of Public Works, Hydro-Electric Power Commission of Ontario, and the Quebec Streams Commission.

With respect to the attracting of foreign capital we quote the following from Mr. Surveyer's paper:—

"It is safe to say to-day, that through the lack of surveys, of discharge measurements and of gauge readings there are very few of our water falls which could be offered to oversea bankers. To convince these men we must be able to lay before their technical advisers, complete plans to enable them to make in their office a rough estimate of the first development costs; we must, moreover, show them discharge measurements and gauge readings covering a sufficient number of years to allow them to calculate with accuracy not only the minimum power available, but also the average power on which they could depend. The electro-chemical and electrometallurgical industries require energy at such moderate rates that it would be impossible in most cases to bank on the lowest available power only. These industries must have the help of the periodical power to lower the average cost of the energy utilized during the year."

In concluding, the writer refers to the serious handicap which the development of our water powers has experienced owing to the difficulty of obtaining a clear title of ownership, and to the lack of commerciality of some of the clauses contained in government leases. He urges a separate water power policy for each province.

DUSTLESS STREET CLEANING.

Canada's climatic conditions, to a certain extent peculiar to herself, impose handicaps in the care of pavements which are hard to overcome.

The dust on business streets is the admitted cause of immense damage to stocks of merchandise and also is very disagreeable to the individual. This is especially so in early spring and late autumn, when the water sprinkled on the pavements freezes, resulting in accidents to horses and pedestrians.

Water used on pavements at such times is also the cause of serious damage to them, as it soaks into the crevices in the pavement, and freezing, causes the upheaval and disintegration of the pavement. This is especially noticeable along the curbs and street car lines.

Dustless street cleaners, operated on the combined vacuum and sweeper principle, are in use in a number of North American cities. It is claimed that their work is entirely satisfactory, that after cleaning, no sprinkling is necessary, as the dust has been thoroughly removed. The advantages of this system are numerous, including the absence of the dust nuisance, resulting in conservation of both health and property; the saving of water and a large percentage of the cost of sprinkling; the saving of labor in street cleaning, and the avoidance of damage done by water to pavements in frosty weather.

PRINCIPLES COVERING DESIGN OF INBOUND AND OUTBOUND FREIGHT HOUSES.

THE economical handling of less-than-carload freight at terminals is a problem that is giving a great deal of concern. The cost of handling a ton of freight a mile by train is approximately known, but it is almost impossible to figure the cost per ton mile for trucking and handling of unclassified freight at the freight house. The cost of terminal handling in all cities is so great compared with the cost of moving a train or a vessel when started on its journey that the latter can be ignored. Freight house design should receive serious consideration. In this connection much of interest and value will be found in the following principles adopted this year by the American Railway Engineering Association and appearing in the recently issued supplement to the 1914 manual.

In outlying districts, where fire hazard is not great and business is not large, and the building laws will permit, frame freight houses having wood floors on joists, studding covered with wood sheathing or metal siding, and wood rafters and sheathing covered with appropriate roofing, are fairly satisfactory and cost less than any other type. Floor for this type should ordinarily be designed to carry 250 lbs. per sq. ft.

With such construction there should be ventilation beneath the floor, but access to the space under the house should be prevented to avoid the accumulation of rubbish and increased fire hazard.

But even where a frame house is to be used, it is better practice to use a fill between concrete foundation walls, eliminating some fire hazard and decreasing maintenance charges.

Where the laws prohibit frame structures and the value of freight stored is considerable and it is necessary to build freight houses of so-called fireproof material, floors should be placed on a fill between foundation walls, and the exterior walls should be of masonry or steel frame covered with metal siding. Roof trusses, framing, etc., can be of wood, covered with appropriate roofing, but to provide better fire protection fireproof construction should be used.

Fire walls of brick or other non-combustible material should be located so as to conform to the requirements of the underwriters. The strictest practice limits the area between fire walls to 5,000 sq. ft. This especially applies to houses with no outside platform. In wide houses, this locates the walls rather close together for economical operation. Fire walls should in no case be more than 200 ft. apart.

Doors in fire walls should be as limited in number as possible, no one door opening should exceed in area 80 sq. ft., and all should be equipped with automatic fire doors.

Where non-fireproof construction is used in inflammable parts, the structure should be covered with fireproof material for a distance of at least 5 ft. on either side of the fire wall. This refers especially to overhanging roofs.

Where but a single house is needed, a width of from 30 to 40 ft. is good practice.

When the amount of freight handled is sufficient to justify it, separate houses for inbound and outbound freight are desirable. When these are provided, the outbound house should be narrow, not more than 30 ft. wide, and the inbound 40 to 70 ft. wide, it being considered expensive operation where a house is in excess of 70 ft. in width.

A platform 8 to 10 ft. wide, along the track side of the house, avoids the necessity of considering the location of doors in spotting cars on the track next to the house, and also eliminates the necessity of keeping an aisle-way inside the house on the track side. It should be at least 8 ft. wide, to give sufficient room for two trucks to pass.

The distance from the centre of the nearest track to the face of the platform or freight house should be not less than 5 ft. 9 in. where tracks are on tangents.

The top of rail should be 4 ft. below the floor or platform level at the track edge, where refrigerator cars are not to be handled in any quantity. With occasional refrigerator cars, the doors can be opened before the cars are set.

Where refrigerator cars are to be handled regularly, the height should not be more than 3 ft. 8 in., this conforming to the recommendations of the M. C. B. Association. The alternative of spacing tracks at least 7 ft. from platforms is usually expensive at important terminals. Many roads are building cars that are lower than the maximum figures given above, and each road in deciding the height of platform above the top of rail should take into consideration the sizes of cars that predominate on its line.

The platform should be protected by an overhanging roof, not greater than the width of the platform, and at least 10 ft. above the platform level.

Where state laws permit, protection over the cars is often used. This should be at least 17 ft. above the top of rail and should preferably extend to within 18 in. of the middle of the car. This will allow walking on the top of cars.

There should also be an overhanging roof or other protection on the team side to protect goods while being unloaded, the overhang to be at least 4 ft. and preferably more, 12 ft. being needed to give protection from a driving rain.

Freight houses without outside platforms would seem desirable in some localities, especially in northern climates, where there is considerable snow and sleet, as these houses can be entirely closed, except for that part of the house where the freight is being received or loaded. At some points where ample track room is not available, the elimination of the outside platform gives better results.

With this type it is necessary to leave more trucking space inside the house longitudinally the full length of the building. With the house congested with freight, it is difficult to keep the aisle-ways from being crowded up so that it is almost impossible to get through with a truck that is loaded with large packages. This causes delay and confusion.

On the street side, the floor of the inbound house should be from 3 to 4 ft. above the street grade, depending on the type of trucks in use. At the outbound house the height should not exceed 3 ft.

To assist trucks, the floor of the inbound house should be sloped toward the street, approximately 1 in in 8 ft., this being for the house proper. An outside platform on the track side should slope approximately 1 in. toward the tracks for draining.

For the outbound house, the floor should slope from the street to the edge of the platform alongside of the car not more than 1 in. in 8 ft.

Several kinds of doors are satisfactory, counterbalance lift (either folding or not), rolling shutters and parallel sliding.

It is advantageous to have as much door opening on the team side as possible. And with all types of doors

except the last, all of the house can be opened except for the space occupied by posts.

With the parallel sliding doors, not more than half of the space can be opened up. They are satisfactory on the track side.

Without the outside platform continuous doors should be used, so that an opening can be obtained at any point opposite a car door.

Where an outside platform is provided, a door in each panel is sufficient. Considering the average length of cars and economy in framing, 22 ft. is a good panel length.

It is advantageous to have the floor entirely free from posts; but in houses approaching 50 ft. in width the saving made by using posts becomes considerable and great enough to offset the advantages due to their omission.

On account of light weight merchandise being piled high on trucks, it is desirable to have the edge of the eaves at least 14 ft. above the level of the driveway, where local conditions will permit.

As all freight trucked into the house and cars must pass through the car door, the height of the freight-house door need be little greater than the car door. All doors should be at least 8 ft. high. On the team side a greater height might at times be convenient.

Natural light should preferably be provided in the side walls above the doors. Skylights in the roof are expensive to maintain and ineffective, as is also glass in canopies, or on any plane approaching the horizontal.

Artificial light is needed for operation at night and during the late afternoon in the winter, and, wherever possible, electricity should be used, with wires run according to the specifications of the National Board of Underwriters. One or more lines of lights should be run the full length, inside the house, and one line over outside platforms.

Another circuit should be run along the face of the platform wall, parallel to the track, with outlet boxes not over 40 ft. on centres, with socket arrangement for push plug for use in attaching an extension cord to hang inside the car to provide light for loading on dark days and evenings during the winter season. The need of other outside lights on the train side is questionable.

The type of lights will depend somewhat on the height of the ceiling. All lights should be stationary and operated in circuits from conveniently located panelboards. The circuits should be carefully planned, so as to allow maximum economy in use of lights.

Where water pressure is available there should be provided for fighting fire, standpipes and hose racks not more than 150 ft. apart. By putting them on the fire and end walls they are thought to be more accessible and less liable to be blocked by freight than if located at other points, but by putting them about 40 ft. from the end of each section, fewer hose connections are necessary to cover the entire station. By putting them 100 ft. apart, 50 ft. of hose will be sufficient for each connection, more than this being somewhat inconvenient to handle. As there is no heat in the house, the valve controlling the water supply should be located below the frost line and controlled by a stem, with a hand wheel above the floor. The valve should be located in a pit, so as to be readily accessible for repair or renewal. It should be drained into the pit, and this in turn be connected to the sewer. A 2½-in. standpipe of wrought-iron should be run up to approximately 8 ft. above the floor, and to this should be attached a hose rack, equipped with 50 ft. of 2-in. rubber-lined linen hose.

In houses where electricity is available, there should be over each hose rack a small red light to designate the location of the fire-fighting apparatus, this light to be kept burning at all times.

Chemical extinguishers should be provided in addition to the hose and standpipes. As they are put out of service by freezing, some provision should be made for replacing them or keeping them warm. Tanks containing a solution of calcium chloride are used successfully.

Where a watchman is needed, a watchman's clock system, with a registering clock in the freight office and stations located at various places throughout the freight houses, should be installed.

In outbound houses sufficient scales should be provided so that all the freight can be weighed. From 50 to 80 ft. apart is good practice. In inbound houses where little of the freight is weighed, scales should be placed at least one in each section. The scales should have a minimum capacity of four tons. A successful dial scale expedites the handling of freight. Stalls for checkers should be located at least one in each section. These should be approximately 4 ft. 6 in. by 4 ft. 6 in., with a shelf along the back and drawers beneath. Sometimes they are left entirely open in front, and sometimes are closed up, and heated, depending on local conditions. Some roads make their checkers' stalls portable, so as to allow them to be moved in case of a special congestion of freight at certain points, but this is not ordinarily considered necessary.

In inbound houses a room should be provided to house "over, short and damaged" freight; this to be enclosed so that it can be kept locked.

In large layouts, particularly where there is considerable transfer business, a room should be provided for repairing broken packages, such as crates, boxes, barrels, etc.

In large houses a separate office should be provided for the foreman. If this can be an elevated structure, it will save floor space.

In large houses the general office for the clerks and the private office for the agent should be provided by a second story over the inbound house, and in the second story should also be a space for files and stationery cases, toilets asd locker facilities for clerks. This all should as far as possible be in view from the desks of the agent or chief clerk. The cashier and his clerk should ordinarily be located on the first floor.

Where possible, it is preferable to have the clerks' and agent's offices, the toilet rooms, etc., for the freight handlers and draymen, the room for "over, short and damaged" freight, and the cooperage room for repairing broken packages, etc., all in one section. In the larger terminals provision may be wanted to care for perishable freight, and when it is provided, it should also be located in this section.

The basement should house the heating plant, with room for coal, and is sometimes a good place for toilets for the freight handlers and draymen, and for locker and lunch rooms for the freight handlers.

Where both outbound and inbound houses are arranged in the same layout, a transfer platform is usually included. One of the best designs for covering these platforms is a butterfly shed, with the posts located in the centre of the platform. Where this design is used, the platform should not be less than 12 ft. wide, to provide room for trucks between the posts and the cars.

For loading and unloading agricultural implements and other large, bulky packages, platforms should be built, usually as extensions to the inbound and outbound houses, with ramps on the ends of the platforms. The

extension platform should be at least 8 ft. wide, and if possible, 16 ft. wide, especially if covered. A stub end track butting against a platform with a ramp is valuable.

Where no gantry crane is provided in the freight yard, a stiff leg or pillar crane should be provided on the end of the extension platform.

It is not good practice to put downspouts inside the house, and in placing them outside they should be properly protected.

On the team side of all freight houses a fender should be provided to protect the walls from the wagon wheels. A good type is one made up of an 8-in. by 10-in. timber set on brackets, with a spacer or separator to keep the timber approximately 2 in. away from the wall, so that dirt will filter through and not collect on the fender.

In large cities it is frequently advisable to build the inbound houses eight to ten stories high, using the ground floor for handling freight and the balance of the structure for storage, to be leased to shippers. Most of the material stored will not be affected by heat or cold, but provision should be made for cold and warm storage where conditions warrant.

GERMAN SUBMARINES.

The enemy's submarine is comprised of two classes. The Krupp submarine is of the following typical dimensions: Length 120 ft., beam 12 ft., depth 12 ft. 6 in., surface displacement 225 tons, submerged 280 tons. The vessel has an inner and outer hull. The outer hull has the lines of a torpedo boat with high freeboard forward to give seaworthiness. The inner hull is built up of three circular welded sections bolted together. The space between the two skins is divided up into ballast and fuel tanks.

Surface propulsion is effected by two sets of 4-cylinder vertical petrol motors developing 440 h.p. For submerged work two electric motors developing 250 h.p. are used. The conning tower contains all the devices for steering, submerging and working the boat. There are two torpedo tubes in the hull and one mounted on deck aft.

In the Lake type, heavy Diesel engines are used for surface work. These motors are from 200 to 220 h.p., and for under-water work electric motors are used. Special ventilating arrangements are provided. When submerged the vitiated air is drawn off and passed through various filters, oxygenated and cooled. By this means the craft can stay under water for twenty-four hours. The electric accumulator apartments are hermetically sealed to prevent the escape of poisonous gases. Two periscopes are carried, the tubes of which are 16 ft. 6 in. in length. The water ballast tanks can be emptied by means of compressed air in a very short time. The outer hull is fitted with shackles to facilitate salvage operations. A telephone wire is carried to communicate with the outside world, the outer end of the line being attached to a buoy which can be released automatically.

The later submarines of the German navy are said to be over 800 tons in displacement and capable of a speed of 16 knots on the surface, with a corresponding underwater speed of 8 knots. They are fitted with 18-in. torpedo tubes, submarine signalling apparatus, searchlights and small disappearing guns.

The city of Calgary is finding it more economical to shut down one of its incinerators and to operate the other 24 hours a day, on 8-hour shifts.

POLES AND CROSS-TIES IN 1913.

The Forestry Branch, Department of the Interior, has just issued a bulletin, compiled by R. G. Lewis, B.Sc.F., in which are tabled the purchases of poles and cross-ties in the Dominion during 1913. The former relate to 424 pole purchasers consisting of 218 telephone companies, 155 electric light and power concerns, 29 electric railways, 18 steam railways and 4 telegraph companies. For convenience the writer divides them into two main groups: (1) Steam railway, telegraph and telephone companies, and (2) electric railway, power and light concerns. The information relating to cross-ties is collected from the different railway companies of Canada, steam and electric, both jointly and separately. Reports were received from 47 steam railways and 32 electric railways.

In 1913 from a total of 534,592 poles, 49.4 per cent. were white cedar; 27.2 per cent. red cedar; 21.6 per cent. tamarack, while 1 per cent. or less of each of spruce, jack pine, balsam fir and white pine was recorded. Of this amount 469,521 poles were purchased by steam railways, telephone and telegraph companies, and 65,071 by electric railways, power and light companies.

Of the total 340,865 poles, or 63.8 per cent. were 20 to 25 ft. in length; 21.8 per cent. were 26 to 30 ft. in length; 7.1 per cent., 31 to 35 ft.; 4.4 per cent. 36 to 40 ft., and 2.9 per cent. 40 ft. or over. Of poles under 25 ft. in length, over 97 per cent. belong to the two cedar species and eastern tamarack.

As against 534,592 poles purchased in 1913, there were 608,556 poles purchased in 1912.

A total of 19,881,714 cross-ties were purchased in 1913 as against 21,308,571 in 1912. Of these 39.1 per cent. were jack pine; 12.3 per cent. white cedar; 12.2 per cent. Douglas fir; 6.2 per cent. western larch; 6 per cent. hemlock; 5.7 per cent. hard pine; 4.9 per cent. oak; 4.4 per cent. tamarack, and smaller percentages of western hemlock, spruce, chestnut, red cedar, red pine, beech, birch, maple, elm, ash and cherry. Electric railways used 391,233 of these.

The average value of poles of all kinds was $2.22 each, and of cross-ties 43c. each. A total value of $1,188,331 is accorded to poles, and $8,740,849 to cross-ties.

In Canada in 1913 about 10 per cent. of the cross-ties purchased by both classes of railways were given a preservative treatment to retard decay.

PRODUCER GAS PLANTS IN THE UNITED STATES.

The total horse-power of gas-producer power plants in the United States was 160,000 in 1911, of which 80,000 was obtained from bituminous coal, 70,000 from anthracite and 10,000 from lignite. The cost of producer-gas installations is about equal to that of reciprocating steam engines; the cost of maintenance is only about one-half, while the economy has been shown in several cases to be 2 to 3 times as great. The heat losses in typical steam and gas plants are given in the following table:—

	Steam plant.	Gas plant.
Heat lost in ashes	2.00	1.10
" " radiation and cooling	4.60	18.60
Heat lost in smoke	24.60	.....
" " radiation and friction	3.30	4.30
Heat lost in exhaust	53.50	23.70
" " jacket water	.....	33.50
" " auxiliaries	7.30	.....
Total losses in entire plant	95.30	81.20
Net efficiency of plant	4.70	18.80

AN EMPIRICAL FORMULA FOR THE DESIGN OF RETAINING WALLS.

Retaining Walls Backed With Earth to the Top of the Wall.

By C. P. Symonds.

WRITERS about these retaining walls give formulæ and rules requiring the weight per foot of the brick-work, and of the earth behind it. Bricks in one district may be light, and those in another may be heavy; though they may both be good, well made, and well burnt; therefore, their weight is a doubtful ele-

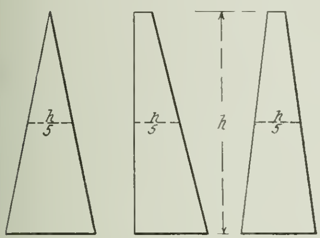

Fig. 1.

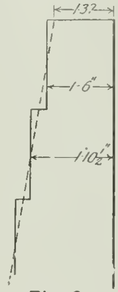

Fig. 2.

ment in calculation. And the earth behind the wall may be wet clay, dry earth, loose sand, or of varying composition, so that its weight is another uncertainty. Again, the backing is almost always heaped up behind the wall soon after it is built, and before the mortar is set.

Therefore engineers in England have, from practical experience, formed a general rule based upon the average thickness compared with the height of the wall. Thus,

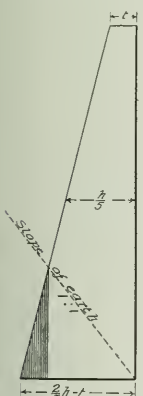

Fig. 3.

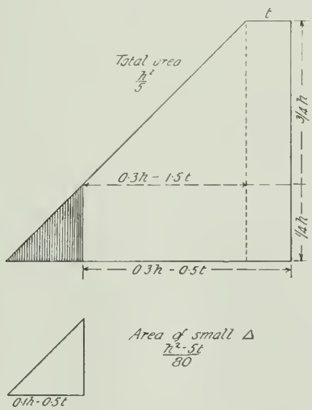

Fig. 4.

in a wall battering ⅛ of the height or 1½ inches in a foot, the average thickness of the wall is to be 1/5 of the height; in such case putting h for the height of the wall the average thickness will be $h/5$, and the area of the cross-section will be $\frac{h^2}{5}$. The section of the wall may be any of the shapes shown in Fig. 1, keeping the average thickness $h/5$.

In the following I have taken the top of the wall as 18 inches and the back of the wall is set off in steps of 4½ inches (Fig. 2). For an average line (dotted) for calculation, the thickness of the wall at the top is taken as 1.32 feet, this being an average line between 1 ft. 6 in. and 1 ft. 10½ in. Then, given h for height and t for thickness, keeping the average thickness of the wall 1/5 of h, the section of the wall will be as in Fig. 3.

Ordinary earth protected from the weather will stand at an angle of 45° or a slope of 1 : 1. It is evident, therefore, that the small shaded triangle is not wanted for supporting the earth, and may be cut off. But, as the height of this triangle varies with every height of the wall, it would complicate the calculations. I therefore take the height of this small triangle as ¼ of the height of the wall, or $\frac{h}{4}$ as a constant quantity, which is a close approximation and greatly simplifies the work. An ex-

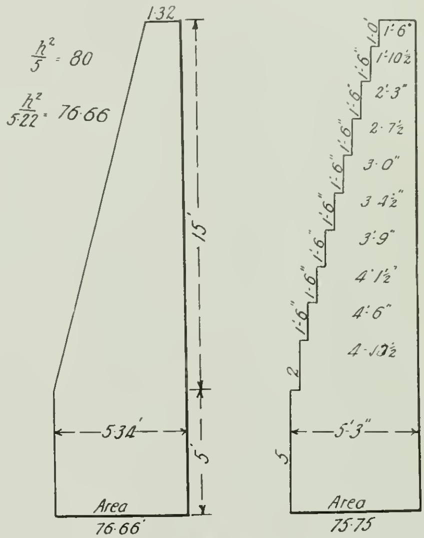

Fig. 5.

aggerated section will then be as in Fig. 4, and after deducting the area of the small triangle, the final area of the wall will be $\frac{3h^2 + ht}{16}$. If the foundation is not good, leave in this small triangle, but if good it may be cut off.

In the two diagrams in Fig. 5, the left-hand one is the calculated theoretical section in feet and decimals. The right-hand one is the same thing adapted to measurements in feet and inches for brickwork. Of the equations in each case, the upper one is $\frac{h^2}{5}$ for the area including the small triangle. The lower one is the area without it. The lowest number denotes the area of the figure in square feet.

Discussion by C. D. Norton.

A few years ago the writer was given the above empirical formula for the design of brick retaining walls, the principles of which are just as applicable to those

built of concrete or stone. The author, Mr. Symonds, was chief engineer of the Government Railways in Portugal. Later he had charge of the construction of a large

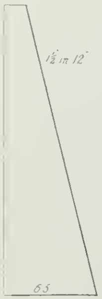

Fig. 6.

Fig. 7.

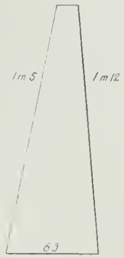

Fig. 8.

part of the South Eastern Railway in England, and was employed on the first tunnel to be built to a predetermined line. These walls were used principally in earth cuttings to avoid the purchase of valuable land, and were not called upon to carry a live load as is the case of an abutment for a bridge. Figs. 6 to 11 show a comparison of various standard types of retaining walls. Those designed by the above formula are the lightest, but it must be taken into consideration that the workmanship was of the best, and in the days that these were built speed was not the important factor that it is to-day.

One thing to which the writer takes exception is the remark about placing the material behind the wall, as given suitable conditions and a fair amount of carelessness, it is possible to wreck any wall except one designed to withstand hydrostatic pressure.

In a retaining wall the cheapest design is that which takes into consideration the placing of the backing in addition to the cost of the masonry. A minimum can only be attained by a due consideration of the material to be placed, and the labor and methods employed. It will be found in nine cases out of ten, that wrong dumping of material is due to mere laziness, either mental on the part of the employer or bodily on the part of the laborer; and it is the duty of the engineer to note these things and, if possible, to remedy them.

It will be noticed that Mr. Symonds does not take frost into account, possibly because in the south of England the mercury seldom falls below 0° F., and then only for a short period; so that the depth to get a good foundation is plenty deep enough to ensure against heaving.

In a small village near Toronto, the authorities received the sum of $500 to build a small retaining wall, which sum was hardly sufficient for one of standard design; so the wall was considerably lightened, and the foundation was sunk only 18 inches below ground level. After the wall was finished it was left for two months to cure, and then the backing was tamped in most carefully. A cross-section is shown in Fig. 11. When finished the amount of pressure against the back of the wall was almost negligible. The front of the wall was banked up to about 4 feet above ground level. The cost of this extra tamping and filling, about $10, was paid out of the road building fund.

The above procedure would not have been practicable but for two things: the contractor on the job did not profess to be an authority on retaining walls, and the writer was able to be on the work all the time, and to see that his orders were carried out.

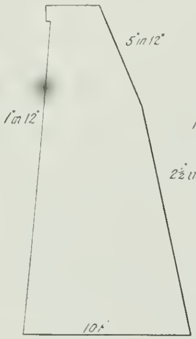

Fig. 9.

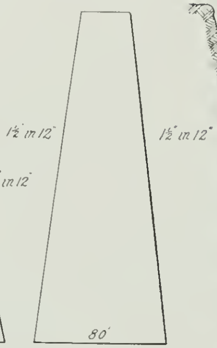

Fig. 10.

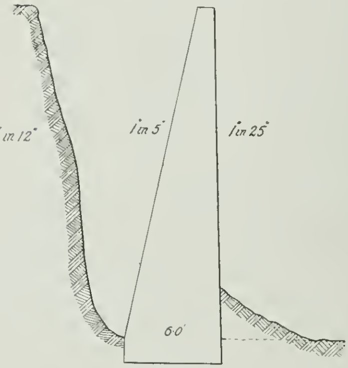

Fig. 11.

Figs. 6 to 11 show various walls; the three railway walls are designed to take care of the heavy superimposed load due to fast-moving traffic, although Trautwine considers his capable of taking care of these loads also.

VANADIUM STEEL IN LOCOMOTIVES.

The extent to which vanadium steel is entering into the manufacture of locomotives is indicated by the following table, showing the vanadium parts applied to locomotives built or ordered in the United States from Jan., 1913, to May 15th, 1914:—

Name of part.	No. of engines equipped.	No. of parts applied.
Driving axles	476	1,297
Main rods	377	822
Side rods	284	1,986
Frames	993	2,054
Crank pins	198	612
Piston rods	69	138
Springs (engine and tender)	366	....
Engine truck axles	62	62
Wheels	...	700
Tyres	...	1,150
Cylinders (vanadium cast-iron)	260	540

With the exception of wheels and tires this applies to new power only.

SYSTEM IN ROAD MANAGEMENT.*

By Charles J. Bennett,
Highway Commissioner of Connecticut.

In consideration of a topic of this character, it must be realized that there are certain principles to be applied in organizing or systematizing a highway department, which can be applied generally to the problem wherever a department of this character is to be formed. Further than that we cannot go. The particular methods of accounting, the minutiæ, the forms, types of books, methods of reporting and recording reports are in every instance a peculiar problem to be solved locally and in the manner best fitted to give a solution of the peculiar difficulties which arise on account of position and magnitude of the department geographically or financially.

Having in mind, therefore, that the detailed phases of the problem are local, there will be no endeavor in this paper to outline an ideal system of accounting, reports and records for a highway department, for such a system would apply probably only to that particular department with which the writer is more nearly familiar. There will be, however, an attempt made to show in a general way, what, in the estimation of the writer, are the broad principles which can be applied to systematic management of a highway department, whether it be town, city or state.

In the first place, it is necessary to realize that there are two results to be secured:

(1) The proper and economical spending of a certain amount of money in the way best fitted to serve the general public, and

(2) The presentation of the method of spending this money to the public, so that it may be thoroughly informed as to how its money has been apportioned and what results have been reached. Such a record or report made to the public should be in simple language so that the most uninformed may understand the results desired and the ends achieved.

In connection with the first proposition, *i.e.*, the spending of money to get the best results. The first requisite in organizing a system of this kind is the record or system of bookkeeping which should show at all times the condition of the accounts and keep a check on the expenditures made for specific purposes. Such a system should be simple and familiar to all the employees of the department and should show graphically, at a glance, the amount of the appropriations made for specific purposes and a summary of the definite projects on which this money should be expended with the total weekly or monthly expenditures for the purposes defined. This information should be available to all the employees and should be so plain as to make it possible for a change in the personnel of the office force without a consequent confusion arising from a complicated and abstruse system of accounts.

In connection with this system of bookkeeping and system of reports of work necessary, the orders for the work to be done should be immediately compiled and entered in the books so that the disbursements may be kept up to date. There should be no possibility of verbal orders which would call for expenditures of money without an accompanying written report and order, which should be entered at once in the ledger. This system of accounts should provide also for a periodic statement of the financial condition of the department, which statement or balance should show not only the cash available, but also the actual amount available after all the liabilities, bills and debts of the department were paid.

Having formulated such a system of accounting, a force of employees should be organized in such a manner that the system of accounts may be followed and in such a way also that the general idea of spending the money economically and well be firmly established.

The first idea which should be applied in the organization of a highway department is the military system; that is, the department should be subdivided so that each part might have certain duties with a definite amount of money to spend. Each subdivision should report directly to the superior officer and through this superior officer to the military head. The organization should be such that no orders should be passed around a subordinate, but should rather go through a subordinate. It is quite necessary in dealing with a force of any magnitude that the rank and file should know the purpose of the organization and the wishes of the chief. In other words, the department should be imbued with the spirit and aims of the man at the head, for in this way each man will work, so far as is possible, along the same lines and the results gained will be more nearly uniform and standard.

An effort should be made to build up patriotism in the department, which should work for the betterment of the road system rather than for the personal benefit of the employees or of the political party which is responsible for the appointment of members of the department. A modified civil service system is a good thing, in that it makes the men more sure of their positions than under a political system. Such a civil service should, however, provide for the removal of employees by the head of the department without applying to any outside body, such as a State or Municipal Civil Service Commission. The whole idea of such a department and the organization of the force, should be to secure the right men for the right places and keep them there while they give good service. There is nothing which can disorganize a department so much as the right of an employee to apply to some outside body which has no knowledge of conditions and which can only judge of a man's ability or his right to hold a position, by an examination on his technical knowledge or by a brief hearing. The measure of a man's value is in the results he gains in actual service and knowledge of a man's ability can only be secured by the record of his achievements from day to day.

In the organization of a force, a chart should be prepared showing the connection between employees, showing to whom an employee should report and stating distinctly what his duties shall be. The best results are to be gained by delegating authority to a man and placing confidence in him, having in mind the theory that men are by nature honest and will endeavor to do right and gain good results if given the opportunity. Allowance should be made for honest mistakes and a careful record kept of such mistakes so that a man may realize, when removed, that the reasons for his removal are sound and based on results showing his lack of ability.

In selecting employees to deal with the public, men should be sought who are tactful, intelligent and polite in their intercourse with people. The employee should be instructed that at all times it is necessary for him to be fair and reasonable and to keep his temper. A public employee is a servant of the public and in his dealings with citizens, should realize this fact, but he should also be firm and not afraid to refuse an unreasonable request.

Given, then, a system of accounting in the organization, the members of this organization must bear in mind that if they are kept informed as to the purpose of the

*From paper read before the 4th American Road Congress, November 9 to 14, 1914.

department in which they work, they should on their part, keep their superiors well informed of their own movements, the amount of work done and the character and cost thereof. In other words, a method of reporting work should be established and kept which should give plainly and simply, all the necessary information as to the actual physical operations carried on by the employees. The local situation will govern the extent and frequency of such reports but they should show primarily and in a clear way, the work which the employee is trying to do, the probable cost of the work to be done before it is started, and from time to time the actual cost, including remarks as to the success or failure of any particular experiment. There should not be an endeavor to make complicated reports which should show minutiæ to the point of the ludicrous, for a system of reporting which becomes so complicated that it is not simple of understanding, fails utterly in its purpose.

The recording of reports in connection with the accounting system should be made in such a manner that through these records the outsider, either layman or professional, may secure information as to the comparative cost of certain classes of work, the success or failure of certain types of roads and the financial value of expenditures for certain specific purposes. For instance, it might be possible to demonstrate in a certain instance, by a system of records that a larger first cost of construction would be very much more economical eventually than a small first cost with a corresponding large charge for maintenance in future years. The system of records should, therefore, show the ultimate result from an expenditure, which ultimate result should be gained from records made over a long term.

The above discussion has covered mainly the first principle which was stated, namely, the endeavor to get good work with the money appropriated.

A road department has, however, the duty of presenting its operations to the public eye, not only as results on the roads themselves, but in the success or failure of the department as a financial proposition. This presentation must be made in the form of a periodical report to some superior body, as the mayor of a city or the legislature of a State. The writer finds, in perusing many of the reports made, that there is an entire lack of system in presenting the information, and no effort made to make the report clear. Most reports are made in such a manner that an expert accountant would be needed to find out results gained and even then, these results would be of little value. The spirit shown most in reports is that they claim general excellence for the department and try to justify its continuance. Certainly there are some failures made by roadbuilders which should be reported for the good of the work. Reasons for failure should be stated, whether the failures be financial or physical.

It is quite possible and necessary to make an annual report which is readable and interesting to the layman. The text portion of such a report should be written in plain English without technical terms and with general results stated broadly and succinctly. Tabulation of records should be made as simple as possible and the cost per unit should give not only definite figures, but should state, furthermore, just what details were included in the units of work done. For instance, in one locality maintenance of roads does not include the oiling of the surface, while in other reports this oiling is included which, of course, makes it impossible to compare the two costs, and for this reason, and many others, as stated above, the reports should show definitely what details are included under each heading, and the cost might be analyzed accordingly.

The writer wishes to make clear again that there is no question in his mind that the system should be simple and operative rather than complicated and unwieldly. The simpler the method of bookkeeping, organization, reporting and recording, the more successful will be the results in spending the money economically and well and the more successful will be the opportunity of the official at the head to present his information so that it will be of benefit first, to the general public, and, second, to the profession of which he is a member.

CROSS-SECTIONING.

By J. A. Macdonald.

ONE of the most important problems that confronts the surveyor is the setting of "slope stakes," called cross-sectioning, from which may be determined the amount of earthwork in cut or fill, and which mark the extreme limits of the operations of the construction corps in building railways, highways, sewers, canals, irrigation ditches, etc.

The problem is as follows: Given the required width of finished roadbed or channel, with proper side slopes (depending upon the kind of material) it is required to determine where these side slopes will intersect the natural surface of the ground with reference to the centre line of the survey. The centre line is defined by stake, carefully aligned and levelled, and a profile of it is prepared upon which the grade line is laid down, showing the elevation of the finished roadbed or channel with reference to the natural surface of the ground.

Let us assume the ground to be level transverse to the centre line. Depth of cut at centre, 12 feet; side slopes, 1½ feet horizontal to 1 foot vertical; width of cut at bottom, 20 feet. (See Fig. 1.)

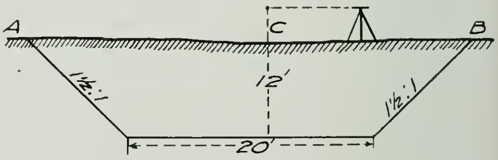

Fig. 1.

Set up the instrument in some convenient position that will command a view of as much ground as possible. Hold the rod at the centre stake and note the reading. Suppose it to be 3.5 feet. If the ground is level, the distance from C to B is evidently 10 + (12 × 1½), or 28 feet, and the rod should again read 3.5 feet when held at B. The point A would be similarly found.

The notes would be kept as shown below:

Sta.	Dis.	Left.	Centre.	Right.	Area.	Cu. Yds.
100	50	$\frac{+12.0}{28}$	+12.0	$\frac{+12.0}{28}$		
101		$\frac{+3.0}{14.5}$	+6.0	$\frac{+7}{9}\ \frac{+9.2}{23.80}$		
101	50	$\frac{+2.5}{13.75}$	+5.0	$\frac{+8.0}{22}$		

This example illustrates one of the simplest cases that occur in practice. Let us now take the case of a line located upon the side of a hill, as in Fig. 2.

Depth to grade at centre, 6 feet; width at bottom, 20 feet; side slopes, $1\frac{1}{2}$ to 1. As before, hold the rod upon the ground at C and determine the height of instrument above C. Suppose this to be 5.5 feet. If the ground were level through C it would be necessary to measure to the right $10 + (6 \times 1\frac{1}{2}) = 19$ feet to the point D, and the rod should read 5.5 feet. Instead it reads, say 2.8 feet. We know, therefore, that we have not gone out far enough by $(5.5 - 2.8)\ 1\frac{1}{2} = 4.05$ feet, if the ground were level through the point D, bringing us to the point E where the rod should read 2.8 feet. Suppose it reads 2.3 feet. We must then go out 0.75 foot farther, each move bringing us closer and closer to the point B. This operation may be repeated as often as is considered necessary, but with a little experience in this sort of work the instrument man can direct the rod closely enough to the point B for all practical purposes. We then enter the notes in the second line of the record shown above.

Upon the left of the centre, these operations are reversed. That is to say, we measure out 19 feet and instead of the rod reading 5.5 feet, it reads, say, 8.5 feet. We know then that we are out too far by 4.5 feet. We then move in toward the centre the required distance and read the rod again, noting how much it differs from 8.5 feet, if any, and enter the final results in the notes.

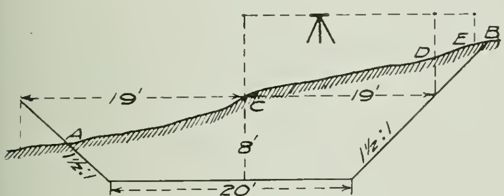

Fig. 2.

A third case is shown in Fig. 3, in which the transverse slope is not uniform. The method of procedure is the same as in the other cases, but the rod should be held at the point where the slope changes in order to find its height above grade. Enter this and the distance out in the third line of the notes.

The transverse section may be very irregular, in which case it may be necessary to take readings at several points in order to calculate the area of the sections with more exactness. At times a section will be cut partly in rock and partly in earth, forming a compound section. Each material will, of course, have its own proper side slope, and the depth and extent of each must be determined by soundings.

In case the section is in fill instead of in cut, the method is the same as in the preceding cases, as will be illustrated in the following examples.

Let us first take a section level transversely. (See Fig. 4.) In this case the finished grade is to be 9 feet above the point C. Hold the rod at C and suppose it reads 3.25 feet. Since the ground is level, we go out to the right and left $9 + (19 \times 1\frac{1}{2}) = 22.5$ feet, and set the stakes at A and B, entering the record in the notebook as before, except that the numerator of the fraction will be marked — instead of +.

We will next take the case where the surface of the ground has a transverse slope, as in Fig. 5. Hold the rod at the point C, and suppose it reads 9.25 feet. If the ground were level through C we would have to go out to the right $9 + (6.25 \times 1.5) = 18.4$ feet to some point D. But there the rod reads, say, 1.5 feet, hence we know we are out too far by $7.75 \times 1.5 = 11.63$ feet, bringing us back to some point as E, and the rod now reads, say, 3.5 feet, so we move out again $2.0 \times 1.5 = 3$ feet. We

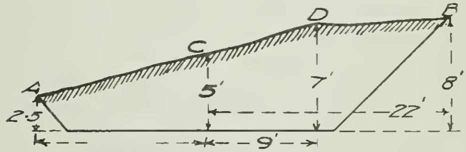

Fig. 3.

move back and forth until we find the point B, where the computed rod reading and the actual reading agree.

Sometimes it will be found that a part of the section is in cut and a part in fill (Fig. 6), but methods outlined will serve in any case.

Cross-sectioning Irregular Sections.—The prismoids have straight lines joining corresponding points in the two cross-sections. The centre line must be straight between two cross-sections. If a ridge or valley is found lying diagonally across the roadbed, a cross-section must be interpolated at the lowest (or highest) point of the profile. Therefore a "break" at any section cannot be said to run out at the other section on the opposite side of the centre. It must run out on the same side of the centre or possibly at the centre. Very frequently complicated cross-sectioning may be avoided by computing the volume, by some special method, of a mound or hollow when the ground is comparatively regular except for the irregularity referred to.

When the natural slope cuts the roadbed there is a necessity for both cut and fill at the same cross-section. When this occurs the cross-sections of both cut and fill are often so nearly triangular that they may be considered as such without great error, and the volumes may be computed separately as triangular prismoids without adopting the more elaborate form of computation so necessary for complicated irregular sections. When the ground is too irregular for this the best plan is to follow

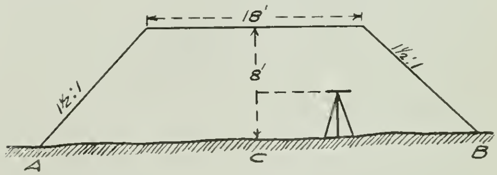

Fig. 4.

the uniform system. In computing the cut, as in Fig. 6, the left side would be as usual; there would be a small centre cut and an ordinate of zero at a short distance to the right of the centre. The area for fill may also be computed by a strict application of the rule.

Compound Sections.—When the cut consists partly of earth and partly of rock, as in Fig. 7, a compound cross-section must be made. If borings have been made so that the contour of the rock surface is accurately known, then the true cross-section may be determined. The rock and earth should be calculated separately, and this will require an accurate knowledge of where the rock

"runs out"—a difficult matter when it must be determined by boring. During construction the centre part of the earth cut would be taken out first and the cut widened until a sufficient width of rock surface had been exposed so that the rock cut would have its proper width and side slopes. Then the earth slopes could be cut down at the proper angle. A "berm" of about three feet is usually left on the edges of the rock cut as a margin of safety against a possible sliding of the earth slopes. After the work is done, the amount of excavation that has been made is readily computable, but accurate preliminary esti-

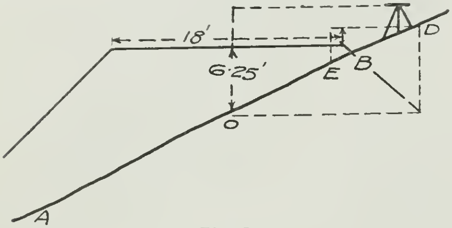

Fig. 5.

mates are difficult. The area of the cross-section of earth in the figure must be determined by a method similar to that developed for borrow-pits.

The distance between the sections longitudinally will depend upon the nature of the ground. On uniformly sloping or level ground they may be taken 100 feet apart. Over uneven ground it may be necessary to take them as closely together as 25 feet, or even less. In the sections themselves, a sufficient number of rod readings should be taken that the area of the sections may be determined with reasonable accuracy.

After the field work is completed, the notes are plotted, usually upon cross-section paper, and the areas determined either with a planimeter, by Simpson's rule, or some other method. These sections then divide the earthwork into a system of prismoids of which the volume

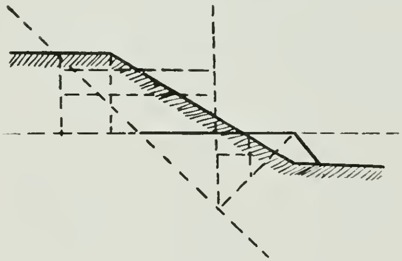

Fig. 6.

must be calculated. The formula for calculating volumes is known as the Prismoidal Formula, and is as follows:

$$\frac{l}{6 \times 27}(A + 4M + B);$$

in which l is the length between consecutive sections; A, one end section; B, the other end section, and M the section midway between the two. The result is given in cubic yards.

The mistake must not be made of assuming that M is a mean between A and B, but a theoretical section must be plotted whose dimensions are a mean between those of A and B. This often results in quite a complicated problem, and various other formulas have been devised to give sufficiently close results without the labor and time involved in the preceding.

It should be realized at the outset that the accuracy of the result of computations of the volume of any given mass of earthwork has but little relation to the accuracy of the mere numerical work. The process of obtaining the volume consists of two distinct parts. In the first place it is assumed that the volume of the earthwork may be represented by a more or less complicated geometrical form, and then, secondly, the volume of such a geometrical form is computed. A desire for simplicity (or a frank willingness to accept approximate results) will often cause the cross-section men to assume that the volume may be represented by a very simple geometrical form which is really only a very rough approximation to the true volume. In such a case, it is only a waste of time to compute the volume with minute numerical accuracy. One of the first lessons to be learned is that economy of time and effort requires that the accuracy of the numerical work should be kept proportional to the accuracy of the cross-sectioning work, and also that the accuracy of both should be proportional to the use to be made of the results.

Prismoids.—To compute the volume of earthwork, it is necessary to assume that it has some geometric form whose volume is readily determinable. The general method is to consider the volume as consisting of a series

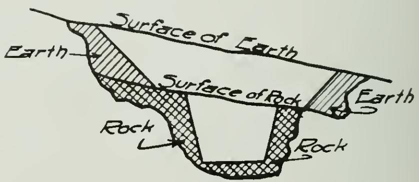

Fig. 7.

of prismoids, which are solids having parallel plane ends and bounded by surfaces which may be formed by lines moving continuously along the edges of the bases. These surfaces may also be considered as the surfaces generated by lines moving along the edges joining the corresponding points of the bases, these edges being the directrices, and the lines being always parallel to either base, which is a plane director. The surfaces thus developed may or may not be planes. The volume of such a prismoid is readily determinable, while its definition is so very general that it may be applied to very rough ground. The "two plane ends" are sections perpendicular to the axis of the road. The roadbed and side slopes (also plane) form three of the side surfaces. The only approximation lies in the degree of accuracy with which the plane (or warped) surfaces coincide with the actual surface of the ground between these two sections. This accuracy will depend (*a*) on the number of points which are taken in each cross-section and the accuracy with which the lines joining these points coincide with the actual cross-section; (*b*) on the skill shown in selecting places for the cross-sections so that the warped surfaces shall coincide as nearly as possible with the surface of the ground. In fairly smooth country, cross-sections every 100 feet, placed at the even stations, are sufficiently accurate, and such a method simplifies the computations greatly; but in rough country cross-sections must be interpolated as the surface demands. Carelessness or lack of judgment in cross-sectioning will introduce errors of such magnitude that all refinements in the computations are utterly wasted.

The process of cross-sectioning consists in determining at any place the intersection by a vertical plane of the prism of earth lying between the roadbed, the side slopes, and the natural surface. The intersection with the roadbed and side slopes gives three straight lines. The intersection with the natural surface is in general an irregular line. On smooth regular ground or when approximate results are acceptable this line is assumed to be straight. According to the irregularity of the ground and the accuracy desired more and more "intermediate points" are taken.

"Setting Up" the Instrument.—In setting up the level to secure horizontal sights, plant the legs firmly in the ground at approximately equal distances apart, so as to make the levelling plate horizontal. The level is, with few exceptions, never placed in line (except when being adjusted under the peg method). It is usually placed in some convenient spot where the greatest number of horizontal sights can be secured. As already stated, the tripod legs must be so placed as to make the plates horizontal. This will save time in bringing the bubble in its proper position. Should it be required to set up the instrument on the side of a hill, place one leg at an altitude and the other two in apparent line with each other, but where the tripod is adjustable the proper method is apparent.

After the instrument is set up and levelled, focus the eye-piece upon the wires and focus the object-glass on the rod by means of the screw placed for that purpose on the top or side of the telescope. Care should be taken not to take a reading until the bubble has been carefully observed and brought in the exact centre of the bubble tube. When this is completed, sight through the telescope and note the rod reading or set the target rod; again look at the bubble and see if it has moved away from its former position; if not, again sight on the rod and see if the first observation was correct. Should the intersection of the cross-hairs fail to coincide with the horizontal and vertical lines of the target or the centre of the rod, the rodman is to incline the rod by the signals of the observer, until it coincides or is in line of collimation.

PURIFYING PAPER AND PULP MILL WASTE WATER.

A means of dealing with any waste waters that offer considerable difficulties in their treatment, especially those coming from paper pulp factories, depends on the use of a mixture of hydrated silica and salts of iron and alumina prepared from ordinary clay by igniting it in a vacuum and treating the residue with such small quantities of sulphuric acid and water that the silica is obtained in a soluble form. The iron always present in common clay greatly assists the clarifying action of the soluble silica on the waste lyes, as does the sulphate of alumina also formed.

The novelty of the invention consists in the ignition of the clay (to destroy its organic matter) in a vacuum, otherwise it is difficult to get the silica in a soluble form, and the soluble silica is the main effective agent, the iron sulphate and aluminum sulphate being of secondary although considerable importance.

The details of the manufacture are as follows:—1,000 lbs. of the ignited clay is treated with a mixture of 400 lbs. of concentrated sulphuric acid and 1,500 lbs. of water in the cold with constant stirring for about one hour. It is claimed that the product will clear one thousand times its weight of waste pulp water sufficiently in from ten to fifteen minutes to permit of its discharge into a river. The sediment is collected and re-ignited for use again.

ENGINEERING SUPERVISION OF ROAD CONSTRUCTION.*

By W. S. Keller,
State Highway Engineer of Alabama.

THIS question confronts every commission that has the building of good roads, and it would appear to the business man that the wisdom of having an engineer supervise the expenditure of large sums of money on highway construction, would not be questioned any more than a railroad company would question the wisdom of employing an engineer to locate and supervise the construction of a railroad.

We may, therefore, for discussion, divide this subject under two general heads:

Is engineering supervision of road construction necessary?

Why is an engineer better fitted to supervise road construction than a practical road builder who is not an engineer?

Engineering supervision of road construction is absolutely necessary and this statement is proven every day, positively and negatively. A layman riding over the roads can tell at a glance a road that has been located and built under the direction of an engineer. When he rides over a road that has been constructed along the old trail, located by the Indians and early settlers, without any regard whatever for grades and very little for drainage, he sees the hand marks of the commissioner, who saves his country the salary of an engineer, and spends it thrice over in useless work and expensive maintenance.

Despite the fact that a majority of commissioners or supervisors have had no training whatever in road building, they will concede to no one that they are not as well qualified to direct road work as any engineer they can employ. They will often admit that an engineer should locate and stake off a road, but they think his duty ends there. It is just as necessary that an engineer supervise construction work as it is that he should locate the road. How many commissioners can tell how much it costs to move a yard of earth or how much it costs to install pipe of various makes—how much per cubic yard their concrete culverts are costing them? You may say we know how much per mile our roads are costing, why should we bother to know the unit cost? Why does a merchant keep the unit cost of his wares? Because he desires to buy from the man who sells the cheapest. So, a county should know if its roads are costing more than they should.

The commissioners of a certain county in Alabama claimed that they were building roads as cheap or cheaper than any contractor could do the work. They had an engineer estimate the cubic yardage of earth moved for a certain period of time and to their surprise it was costing 37½ cents per cubic yard when the average contract price in Alabama for three years had been 23 cents per cubic yard. Authorities should know whether they are getting value received for their money, and an official who overlooks such a vital question, is not true to the trust placed in him by the people.

Many counties are imposed on in the purchase of material and supplies and are actually paying more for such in large quantities than individuals have to pay for the same in small amounts. This is usually attributed to

*Extracts from paper read at the Fourth American Road Congress, Atlanta, Ga., Nov. 9-14, 1914.

either carelessness, politics, or a false idea some of the commissioners have as to their duty. I believe the duty of commissioners, in so far as road building is concerned (and it can equally as well be applied to other public matters) is to purchase with as much care and secure just as low prices as they would if buying for themselves as individuals, regardless of whether the goods purchased come from local or foreign merchants; of course, giving always the preference to local merchants, if their wares are as good and prices as low as those of outsiders. It is not the duty of road authorities to conduct county affairs so as to make money for individuals or to give jobs to political henchmen. If a competent man cannot be found within the borders of a county fit by experience for a position such as foreman, it is right and proper that a competent man should be secured from elsewhere.

The remedy for these ills is, unquestionably, to have some one in charge of road building qualified by education and training and free from political influences, who can be held responsible for results. Very few counties have commissioners or supervisors who devote all of their time and attention to their office, and it is self-evident that an engineer trained in road building will get better results than can any set of men who give only a few days in the year to their public office.

As to the second division of this subject, "Why an engineer is better fitted to supervise the construction of roads than a practical road builder who is not an engineer." First, an engineer is indispensable, even though you have a splendid layman to supervise the work. A large percentage of all roads to be constructed require relocation, profiles made, grades established and if the work is to be contracted, the road must be cross-sectioned and the yardage of excavation and embankment calculated and made to balance as near as possible. Such work a layman cannot do. Who is better fitted to supervise the construction of any job than the man who plans and specifies the work? The road supervisor is usually uneducated and it is practically impossible for him to correctly account for the expenditure of large sums of money and equally as impossible for him to keep cost account of his work.

This condition is usually brought about by a disposition on the part of the board of supervisors or commissioners to economize. Unfortunately, many county commissioners can see only the engineer's salary to be paid twelve times a year and the inevitable result that there will be quite a decrease in the number of days they can legitimately demand pay for laying off and superintending the building or repair of roads in their respective districts. In other words, the engineer is a usurper, taking away the salary of those guardians of the people's right who are so anxious to save money for the people that they save $200 per month engineer's salary and spend $500 per month in doing it. So long as we elect officials because of their popularity rather than fitness, and pay them a mere pittance for their services, we may expect many of them to be incompetent and often dishonest. A foreman in the employ of a certain county was discharged by the commissioner of the district in which he had been working. The commissioner gave as a reason for discharge, that he himself could look after the teams and hands and thereby save the county several dollars a month. The foreman resented his being discharged and took upon himself the investigation of the commissioner's record. He found that on a certain day this commissioner drove seven miles to a small bridge where he then and there made a contract with a party to repair the bridge at a cost of $1.50. A few days later he went back to this bridge to inspect the work he had ordered done. The record of the Commissioners' Court showed that cost of repairing was $1.50 and cost of inspection two days at $3 to $6. He certainly was entitled to pay for at least the time consumed by himself yet it is manifestly wrong for such a condition to exist that cost of supervision is four times that of construction or repair. This would have been a very small matter to an engineer who, while having the bridge repaired, would attend to many other duties.

It is almost impossible to convince many county officials that an engineer can easily save his salary several times over by making certain changes in location and grade and by economically administering the affairs of the county. As a general rule a county gets more in return for money spent for engineering services than for any other single item connected with road construction. A good engineer is a dividend producer for a county. In speaking along this line at the American Road Congress held in Atlantic City in 1912, Col. W. D. Sohier said:

"You will find if you look at any private corporation, that the ordinary engineering expenses for any work of the character of road building, any constructional work, is usually about 10 per cent., and that it is good money well spent."

A highway engineer should have a good technical education and to be successful, he must be practical and he must be a diplomat. He should be sober, honest, energetic and think more about the work he is trying to do than the pay check he will receive at the end of the month. When taking charge of a county's road affairs he should convince the commissioners that he knows more than they do about building roads and then proceed to prove it by doing good work. Unless an engineer can absolutely convince his Board of Commissioners that he knows his business, he had best resign. Trouble is often brought about by the engineer failing to have a thorough understanding as to his duties. This can easily be avoided if, when an engineer makes a contract with a county, he clearly sets forth in this contract what his duties are. If he is to be held responsible, and he should be, for the success of the undertaking, he should have full power to employ and discharge those under him. I think this is well expressed in Rule 2 of Rules and Regulations of the State Highway Department of Alabama, which reads as follows:

The functions of the Commission are judicial and those of the engineer, executive. The engineer will receive and carry out the directions of the Commission and shall, in turn, direct those under him. The engineer shall have full charge of construction work, directing it in all its details. Any orders the Commission wish to give an employee shall be given through the engineer, and the engineer shall have the right to employ, with the consent of the Commission, and to suspend, subject to discharge, without consulting the Commission. All suspensions shall be reported to the Commission for such action as they deem necessary.

The spandrel or face walls of a concrete arch may be carried up at the same time as the arch ring is laid, or may be connected with it later by leaving short lengths of steel projecting radially from the concrete of the arch. Some engineers require that arch centering shall be lowered sufficiently to allow the arch ring to assume its permanent set before parapet walls are placed.

The largest power transmission by means of chains, according to F. L. Morse, is one consisting of two drives, each of 2,500 h.p. capacity, for operating a 5,000 h.p. gnerator in an Idaho power plant. There are eight chains all told, 21 in. wide, and of 2 in. pitch. The sprockets have 71 and 47 teeth, and are of 45.59 in. and 30.31 in. in diameter, respectively, and each of a face of 92 in. The sprockets are 120 in., centre to centre, and each carries, as stated, four chains, each 21 in. wide.

ICE TROUBLES IN HYDRO-ELECTRIC PLANTS.

In Canada the designer of a water power development has before him the task of providing a means of eliminating or minimizing the effect of ice upon plant operation and power production. It is an important problem even though there be no direct liability of injury to the plant equipment. Apart from trouble due to ice blocking the water entrances, the presence of it in the river may have such a marked effect upon the power production that it should never be overlooked in the study of a development where ice conditions in winter are liable to obtain.

A good analysis of ice formation, its effect upon the operation of a plant, and suggested methods of overcoming the difficulty, are presented by Mr. M. C. Hendry, chief engineer for the Water Power Branch, Department of the Interior, in his report on Bow River power and storage investigations. His treatment of the subject is given as follows:—

There are three kinds of ice which, owing to their effect upon the operation of water-power plants, are of interest to the engineer. These are: Board or sheet ice, frazil ice and anchor ice.

Sheet Ice.—Sheet ice is that kind of ice which is formed upon the surface of lakes, smooth-flowing rivers, ponds, etc. The process of formation is an interesting one, and begins with the arrival of cold weather. As the season advances, the water on the surface gives up its heat by surface radiation, convection currents are set up, the cold surface water falls and the warmer water below rises; this in turn gives up its heat; by a continuation of this process, the temperature of the whole body of water is gradually lowered until it reaches 39° F.; at that temperature convection ceases, and the water on the surface is cooled down until freezing point, 32° F., is reached. The first indication of the formation of ice is the presence of long needle-shaped crystals on the surface. These rapidly increase in number and size until finally the whole surface is covered. This surface layer becomes more compact, and the ice increases in thickness, as the underlying water gives up its heat by conduction through the ice. The rate of growth diminishes, however, as the thickness of the sheet increases.

When the ice sheet is once formed, radiation to a very great extent ceases. This is due to the fact that the ice is seldom clear, and is generally snow-covered and the heat rays are unable to penetrate under such conditions. If the ice was clear and solid, the heat rays could then penetrate, and the loss of heat from the water below would go on at a much more rapid rate, and consequently the growth of ice would be more rapid.

The pressure of any sheet ice in a river immediately above a power plant has a beneficial effect upon its operation rather than the reverse. The reason for this will be understood after the subject of frazil and anchor ice has been dealt with.

Frazil Ice.—Frazil ice, known also as "slush ice," is perhaps the ice formation which has the most serious effects upon water-power operations. It is always formed in the open channels where the current is too swift or turbulent to allow the formation of sheet ice, and its formation is dependent upon disturbance or agitation, consequently swift turbulent streams are very prolific in its production; it occurs in needles, the fineness of which are due to the amount of agitation. In such places as rapids, and at the foot of falls, these needles are very fine, but they increase in size and thickness where the flow is less rapid and disturbed. Frazil ice is always surface-formed, but the ice crystals rapidly become distributed throughout the whole body of water. This gives rise to the saying that the water is "thick." This condition occurs only during a period of extreme cold, combined with great surface agitation, due to rapids in the river, or wind. The direction of the wind relative to the flow of the river has a varying effect on production of frazil, a wind blowing upstream produces more frazil than one blowing downstream, on account of increased surface agitation.

The conditions that make for the greatest production of frazil ice are a dull, stormy day, with wind upstream. A great amount of frazil may be produced upon a clear, cold night with wind, but on a clear, cold day with wind there is not so great a quantity formed, due to the absorption of heat from the sun's rays at the water surface. Professor H. T. Barnes, in his book on "Ice Formation," says that "a stretch of open water makes a very much greater quantity of ice in the form of frazil crystals than could be produced as a surface sheet, if the water were sufficiently quiet to allow such to grow." It is this production of frazil which gives rise to so much trouble, the steam becoming blocked with the mass. Where an ice sheet exists, conditions are often aggravated, the frazil blocking the waterway underneath, at times causing complete stoppage of flow.

Anchor Ice.—Anchor ice, "ground ice," the German name "Grundeis" and the French-Canadian term "moutonne" are among the many names given to this particular form of ice. As this list of names would indicate, it has attracted very widespread attention, and a number of scientists have published papers in which its formation has been discussed. The name "anchor ice" perhaps best describes it, and is the one by which it is most widely known in this country.

The peculiar feature which gives it this name is the fact that it is formed upon the bottom of the rivers or streams. Many theories as to the reason of the formation of ice upon the bottom have been advanced. That as set forth in a paper by Dr. Farquharson, which he published in 1835 and 1841 is generally accepted as the correct one. He attributes the formation of anchor ice to the radiation of heat from the surface of the stream's bed.

It is remarked that this cooling by radiation, and consequent formation of anchor ice, occurs only in streams whose beds are composed of gravel, stones and boulders, but not in clay or mud-bottomed streams; also that the formation of the ice is greatest on the rocks and stones of dark color.

The formation of anchor ice is most rapid during a clear, cold night (conditions which are favorable to rapid radiation). On a clear, cold day, the sun's rays affect the formation; in fact, it is universally noted that on the appearance of the sun in the morning, the ice becomes loosened from the bottom and rises to the surface. Its appearance when floating has given rise to the French-Canadian term, "moutonne," on account of its resemblance to the backs of white sheep.

It has been noted in connection with anchor ice, that its formation does not occur under cover. A bridge spanning a stream retards radiation and prevents its formation, and it is seldom found where the stream is covered with an ice sheet.

The names frazil and anchor ice are often confused and are frequently used as being interchangeable; the term "anchor ice" being used to designate ice found attached to the bottom, regardless of the method of formation.

Professor Barnes says that "in a shallow, smooth-flowing river, we are more likely to have anchor ice formed in excess, whereas in a deep and turbulent stream we are likely to have more frazil. It is hardly likely, how-

ever, that there will be a great difference in the amount of frazil formed in either case; it will probably be that more or less anchor ice will appear in proportion."

The Montreal Flood Commisson in their report deal exhaustively with the question of ice formation. The following is an extract from that report:—

"The terms 'anchor ice' and 'frazil ice' are indifferently applied to the same material, but the first evidently is most applicable to this ice when found in the bottom of the river. In one respect the two are identical; that is, both are exclusively the production of open water. There is no formation of either when or where the surface is covered with ice, and whereas large formations of both take place in the beginning of winter over the vast surface below Lachine Rapids, the further formation of this ice ceases as soon, and whenever the ice-bridge is formed. Frazil, as distinguished from anchor ice, is formed over the whole unfrozen surface above and below Lachine Rapids, between Prescott and the tide-water and wherever there is a surface current or wind agitation to prevent the formation of bordage ice, while anchor or anchored ice, except in the shallowest portions of the current, does not appear in the deeper water until zero weather sets in."

In this report the formation of anchor ice is not ascribed to radiation from the river bottom, but rather to the cooling of its surface through the contact with the frazil-charged water. Proceeding with the description on anchor ice, the report says:—

"On the approach of mild weather, it becomes detached from the bottom, sometimes bringing up with it gravel and stones, and may be seen as a dark-colored mass bursting up all over the surface with considerable force, and with a hissing sound, which rises a foot or more above the surface, but falling back, shows only a few inches floating above it. Out of the portion above the surface, the water quickly drains, and it becomes white as snow."

In respect to the name "anchor ice" being applied to frazil ice, this is due, in the case of water-power developments, to the action of the frazil under certain conditions. Where the head-race of a development is open, allowing the frazil direct access to the intake without having to pass under an ice sheet, it practically becomes anchor ice, because as it comes in contact with the racks and intake structure it adheres to them and rapidly cuts off the water. Under these conditions there is no difference between anchor and frazil ice, once the latter has become attached to the structures. As a matter of fact, it is this action of the frazil which causes the trouble, directly to plant operations, as it is generally formed in the greatest quantity. The action of the anchor ice proper is to cut off the flow of water in the stream bed; when the anchor ice is floating, the conditions are improving.

Winter Conditions.—One condition which requires the attention of hydraulic engineers is the effect of ice upon the discharge of the river, for the formation of frazil and anchor ice in the bed of these rivers and streams has a very marked influence upon their discharge. Lying, as they do, at considerable elevations, the temperature obtaining during the winter months is low and, owing to the steep slope of the streams, their flow is turbulent, thus the necessary conditions are present for the formation of frazil ice. The conditions for the formation of anchor ice are also good, for in many places the stream is too swift to allow an ice sheet to be formed. The water is clear and generally shallow, the nights are cloudless and cold; in consequence anchor ice is formed in great quantities.

The formation of frazil and anchor ice in the mountain streams causes their discharge to be very fluctuating, and accentuates the variation in flow during the low-water period.

Winter Conditions as Affecting Plant Operation.—The successful operation of a water plant in winter, on the rivers of Canada, depends in a large measure on the method of providing for or eliminating the ice troubles which are always to be met with.

In the foregoing, the conditions favorable to the formation of the several kinds of ice to be met with have been explained, also the relation of one kind of ice encountered, to another. Of the three principal kinds, sheet or board ice is the least detrimental to operation; in fact if board ice were the only kind to be dealt with, the trouble would be negligible. Where the channels are small, however, and where anchor and frazil have been formed above, great trouble may be experienced, due to the lodging of this frazil and loosened anchor ice, under the sheet, for frazil ice, in the presence of sheet ice, attaches itself to the under side of the latter, and where the channels are small, the whole flow of the stream may become blocked, overflow will then occur and a great proportion of the stream flow be lost.

One of the best methods, however, of avoiding frazil and anchor ice troubles, is by obtaining a pond of sufficient size and depth in the immediate vicinity and above the intake of the plant, which will readily freeze over. The ice sheet obtained will, to a great extent, eliminate any troubles with frazil or anchor ice.

If the entrance to the power plant is a channel restricted in size, the ice sheet will be a hindrance, rather than a benefit, if there is open water above. In such a case it is much better to be without a sheet of ice, and instead make provision for handling the accumulation of frazil and anchor ice in the head works. There have been many attempts made to deal with this problem, but it generally degenerates into a brute force combat. In many plants provision is made for passing masses of frazil ice through the wheels by raising the racks in sections, currents are then induced to pass across the face of the racks, so that the floating ice, etc., may be carried off.

The great trouble with frazil ice is due to its freezing on the racks and the wheels, finally stopping the supply of water. With regard to the racks, this has been usually due, in a large measure, to the fact that the upper ends of the bars composing them have been left protruding above the water for 2 or 3 feet exposed to the very cold air. In such a position these bars become chilled to the bottom, and even when only cooled to two or three one-thousandths of a degree below freezing point, it is sufficient to cause the frazil ice to adhere to the bars and commence the clogging process. This trouble may be eliminated to a great extent by making the upper part of the rack of wood, and keeping the metal bars entirely submerged, thus preventing the conduction of heat from bars to the atmosphere, and the consequent cooling below freezing point. Besides this method of submerging the metal of the racks, schemes have been brought forward for heating them, such as using hollow bars through which steam may be driven. In many plants instead of this, the head works are housed and heated, not only to provide a good working room for the men fighting the ice, but also to prevent the subcooling of the racks. One of the most successful schemes has been that employed by one of the plants in Ottawa. There the tops of the bars are encased with sheeting, steam pipes being also enclosed. By this means ice troubles have been prevented to a great extent. The use of a live steam jet in the wheel case and guide vanes to prevent the freezing or clogging up of the wheel entrance has been quite successful in several plants.

Editorial

FIXED CARBON TEST.

In view of the interesting series of articles on the fixed carbon test which *The Canadian Engineer* was fortunate enough to secure, some months ago, from a number of the leading bituminous experts in the United States and Canada, it is interesting to note that the City of Toronto has raised the limit for fixed carbon from 15% to 18%. For several years the works department of Toronto has insisted on a low limit for fixed carbon, but in the specifications issued for the supply of 1915, the limit is 18%.

After the appearance of the above-mentioned articles, the works department announced its intention of making an exhaustive investigation into the subject, in order to have more data upon which to base their future requirements in regard to this test. Pressure of other work, however, has prevented the department from making the investigation planned; but it was decided to raise the limit anyway, as there was a general feeling in the department that 15% was too low a limit, especially for asphalts refined from Mexican crudes. The department is of the opinion, however, that the fixed carbon test has value, and that some limit should be imposed in this regard by asphalt specifications.

BOW RIVER POWER POSSIBILITIES.

An extremely valuable report, known as Water Resource Paper No. 2, has recently been issued by the Water Power Branch, Department of the Interior, Canada. It covers investigations carried out on the upper waters of the Bow River by Mr. M. C. Hendry, chief engineer in charge of surveys, under the direction of Mr. J. B. Challies, Superintendent of Water Powers. This river was the first of the Rocky Mountain streams to be investigated by the Department as to its power-producing and storage possibilities. The work was commenced in April, 1911, and carried out with the consulting advice of Lieut.-Col. C. H. Mitchell, C.E., one of the board of consulting engineers to the Dominion Government. The present report covers the work for 1911-12-13, the study having been then completed.

The conservation of the waters of the Bow River is vital to the agricultural and industrial prosperity of a very large area of Southern Alberta. The investigation, with usefulness for irrigation and power purposes in mind, has furnished the Water Power Branch with some most valuable data relative to storage possibilities, climatic conditions, industrial development and meteorological phenomena of wide scope, and with all other essentials necessary for a complete knowledge of the area and its characteristics.

These investigations show that it is economically feasible to regulate the flow of the river, and that by means of six power sites, *viz.*, Kananaskis Falls, Horseshoe Falls, Bow Fort, Mission, Ghost and Radnor, to provide over 48,000 continuous 24-hour wheel horsepower, all within 50 miles of Calgary, as against 19,800 wheel horse-power from the natural flow. The study also shows that the utilization of these waters for power purposes above Calgary need not conflict with the consumption of the same water below Calgary for irrigation purposes. On the contrary, the proposed power regulation would be found of distinct advantage to the extension of existing irrigation systems to their ultimate capacities, and also insure in the future the instigation of additional irrigation projects.

The investigation has been similar to others that have been carried out, or are in progress, in Canada, the United States and other countries. The Hydro-Electric Commission of Ontario has made very extensive studies in this respect, on water powers in the province. There is a difference, however, between the two investigations, in that the latter has been carried on with the object of ascertaining what could be done in the way of power production by the Commission, whereas, the investigations of the Water Power Branch have been with the object of supplying information to the public, and procuring information upon which the best administration of the water powers could be based. Other extensive studies have been those of the United States Geological Survey, among which might be mentioned the investigations in states of New York, Maine, Minnesota, and Washington.

THE VENTILATION OF RAILWAY TUNNELS.

The Committee on Roadway of the American Railway Engineering Association has submitted a finding to the effect that the most practicable, effective and economical artificial ventilation for tunnels carrying steam-power traffic is to be obtained by blowing a current of air into one end of the tunnel for the purpose of removing, or of diluting and removing, the smoke and combustion gases at the opposite end. As practised in America, this way of procuring ventilation partakes of two methods:

(*a*) To blow a current of air in the direction the train is moving and with sufficient velocity to remove the smoke and combustion gases ahead of the engine;

(*b*) To blow a current of air against the direction of the tonnage train with velocity and volume sufficient to dilute the smoke and combustion gases to such an extent as not to be uncomfortable to the operating crews and to clear the tunnel entirely within the minimum time limit for following trains.

PRODUCTION OF STEEL DIRECT FROM ORE.

The conclusions reached in a paper by E. Humbert and A. Hetbeg, before the Iron and Steel Institute, are: That the economic manufacture of steel from ore is quite practicable; that the product, on account of its comparative freedom from hydrogen, nitrogen, and other impurities, is superior, especially in toughness, to steel obtained by present methods; that the electric furnace employed should be of a type permitting violent ebullition of the bath without overflowing; that either charcoal, coke or anthracite may be used as fuel; and that anthracite electrodes will probably be most economical.

Tests were made by the writers, with swedish and Brazilian iron ores in a Héroult electric furnace of 6 tons capacity, using coke as fuel.

ENGINEERS' LIBRARY

Any book reviewed in these columns may be obtained through the Book Department of The Canadian Engineer.

CONTENTS.

BOOK REVIEWS.

Carnegie Pocket Companion. Issued by the Carnegie Steel Company, Pittsburg, Pa. Bound in flexible morocco.

This is the sixteenth edition of the Carnegie Pocket Companion, which has been rewritten and reset throughout. The date of the last edition was 1903. Since that time, the art of bridge and building construction has changed a great deal, while the use of steel has extended into other lines than those covered by the previous edition. In the present publication obsolete forms of construction are eliminated, and the information tabulated is brought up to the present date and present-day practice.

Steel Construction—A Text and Reference Book Covering the Design of Steel Framework for Buildings. By Henry Jackson Burt, C.E. Published by American Technical Society, Chicago, 1914. 381 pages; profusely illustrated; $4\frac{1}{2} \times 7$ inches; flexible binding. Price $2.75. Reviewed by A. E. Davison, B.A.Sc., Hydro-Electric Power Commission of Ontario.

As mentioned in the introduction and largely repeated on page 2 of Part I., "This book is intended to give its students the facts and formulas needed in designing structural steel framework for buildings—accompanied by explanations of the underlying principles. The use of formulas is shown by illustrations of a practical nature, which serve not only to teach the proper application, but to illustrate current practice in this form of construction."

The earlier pages of the book are sufficiently carefully written to permit of anyone, with a reasonable control of mathematics, making practical calculations as outlined, intelligently. Referring to page 38 where "Radius of Gyration" is treated, we find that the information is scarcely as full as an ordinary student might require; that is, actual design practice will not proceed very far until it is necessary to calculate the "Radius of Gyration" for a made-up section such as cannot be taken readily from tables. The text at this point leaves considerable to be determined elsewhere by the student.

On pages 46 to 50, etc., an attempt is made to place the student designer in touch with the urgent need of a thorough understanding between the designer and inspector. In this regard the information on comparative elongation and reduction of area might have been given more attention; for instance, beginners are not generally familiar with the source of empirical data "Elong. 1,400,000/Ult." as indicated on page 50.

Safe units are always a trouble to the student as these may be readily confused with ultimate strengths. We find that in giving data on page 52 the writer, while speaking of "Ultimate Bearing" and "Bearing Values" states "Values below expressed in pounds per square inch taken from the building ordinances from the City of Chicago"; these, of course, are safe load values.

Part II., page 75, etc., deals with practical applications. On this page the matter of "needle" beam with which a new designer soon comes in contact is not mentioned.

On page 94 an attempt is made to give the moment values for a number of different types of beam loading. This tabulation along with those on page 190, etc., save considerable time for the average designer.

In the treating of cast iron columns as on page 232, etc., very little attention is given to the difficulty of lining up a column having a considerable number of splices at floor levels without causing failure at column flanges. Combined stresses with which the ordinary designer has to deal constantly, are briefly treated on page 266, and the matter of the relation of designer to inspector as mentioned above is brought up again on page 370.

Foundations. By Malverd A. Howe, C.E., Professor of Civil Engineering, Rose Polytechnic Institute. Published by John Wiley & Sons, New York; Canadian selling agents, Renouf Publishing Co., Montreal. First edition, 1914. 110 pp.; 55 illustrations; 6 x 9 in.; cloth. Price $1.25 net.

This is a text book on ordinary foundations, including a brief description of the methods used for difficult foundation work. The fundamental principles upon which proper design is based are stated in an elementary way. Separate treatment is given to the foundation proper and to the footing courses of walls and columns. As stated in the preface, many books do not show a marked line of division between the two.

The work is divided into six chapters, as follows: Supporting capacity of soils; wall footings and column footings; piles and pile foundations; chimneys and towers; bridge piers and abutments; and, methods employed for difficult foundations. The book is concluded with an appendix devoted to formulas and nomenclature. An exceedingly useful addition to each chapter consists of a carefully selected set of references, about twenty to each chapter. These refer chiefly to articles that have appeared in the technical press on the subjects under study.

The book will be found exceedingly useful as a text. Its illustrations refer to actual structures, and, although it contains little descriptive matter in the text itself, the references provide the student with a valuable source of

information for the details of any portion to which he may desire to give further study.

Rapid Earthwork Calculation. By C. E. Housden. Published by Longmans, Green & Co., London. First edition, 1914. 31 pp.; illustrated; size 4¾ x 7¼ in.; limp cloth. Price 50c. net.

The author of this book has published several small volumes on earthwork, water supply, drainage, sewerage, etc., that have been found most useful by the practical man in the solution of every-day problems in these branches of engineering. The present work will be found of similar service, as a number of improvements in earthwork calculation are found embodied in it.

In his preface the writer states, "With so many tables already in existence for a similar purpose, new ones may at first sight appear unnecessary and superfluous; actual trial will, however, prove that earthwork quantities can be estimated from them, as within explained, more quickly and with less labor than in any other way."

The tables give the end areas in square feet of bank and cut sections for their side slopes S and S′ to 1 added together, for values of 1, 1½, 2, 2½, 3, 3½, 4, 4½, 5, 6, 7, 8. The text explains how the tables are framed and their application.

Engineering Problems, Part I. By W. M. Wallace, Wh.Sc. Published by the Technical Publishing Co., London. First edition, 1914. 192 pp.; well illustrated; size 5 x 7 in.; cloth. Price 75c. net.

The author gives a collection of rules, relations and data on which are based the more usual calculations in some phases of engineering work. This takes up the opening pages of the text, and is followed by questions and answers illustrating the application of these rules, etc., to practical cases. No method of classification under different branches of engineering has been attempted by the author, and several branches appear to have been entirely ignored. The volume contains, however, some very interesting problems in machine design and in bridge work, while occasionally one encounters an isolated problem, such as earth pressure on a retaining wall, calorific value of petrol, strength of wooden spar, etc. One finds it necessary to state, however, that the subject matter of the book is hardly commensurate with the title chosen for it.

Steam Charts. By F. O. Ellenwood, A.M.Am.Soc.M.E., Professor at Cornell University. Published by John Wiley and Sons, New York; Canadian selling agents, Renouf Publishing Co., Montreal. First edition, 1914. 91 pp.; illustrated; 7¼ x 10 in.; cloth. Price $1.00. Reviewed by A. S. L. Barnes, Hydro-Electric Power Commission of Ontario.

The title of this book is better chosen than is frequently the case, for it gives a real indication as to what the book is—primarily, a collection of steam charts. These charts have been very carefully prepared and the book as a whole "intended to be of assistance to engineers and students when making calculations involving wet or superheated steam," should fulfil its mission without difficulty. An introduction dealing with "Fundamental Principles" forms a brief explanation of the main theoretical points to be dealt with by the steam engineer. The next section deals with the steam charts themselves and explains how they were prepared and how they should be used.

Following this is a short chapter setting forth how to make barometer corrections. There are corrections to be made for temperature, altitude, gravity and capillarity. Even the expansion and contraction of the scale must be taken into account, if a full length brass scale be used. Next come the charts themselves, of which there are nine. These are plotted to a very convenient scale and are exceptionally clear.

On the ordinates is given the total heat of the steam in B.t.u. per lb., while the abscissæ show the specific volume in cu. ft. per lb. Lines of constant pressure are plotted, as also are those of constant superheat. Lines of constant entropy and of constant quality are shown.

To simplify the using of the charts an index chart is given at the beginning of this section from which the range of the main charts can be readily seen and the correct chart thus easily chosen. In range the complete set of charts are amply sufficient to cover present practice.

The conclusion of the book proper consists of a considerable number of problems involving the use of the various charts and tables given, while the closing pages contain an index.

It is evident that a good deal of care has been spent in the preparation of this book in order to present the information in as useful a form as possible and the author may be congratulated on the result. To quote a couple of the problems will perhaps indicate better than anything else the purpose of the book.

"Find the total heat, volume, entropy, temperature, and heat of the liquid of a pound of steam having an absolute pressure of 180 lbs. per sq. in. and a quality of 98%."

All the items here asked for can be ascertained directly by reference to Plate 1 b.

"The Parsons turbine at the Fiske Street station of the Commonwealth Edison Co., Chicago, has an exhaust opening to the condenser of 252 sq. ft. If the water rate for a back pressure of 1 inch of mercury and a load of 25,000 kw. is 11.65 lbs. per kw. hour, find the velocity, through this opening, assuming the steam has a quality of 80%."

From Plate 6 b the specific volume of exhaust steam under the conditions stated is found and the velocity in ft. per min. is calculated directly by dividing the volume of steam by the area of the exhaust opening.

American Society for Testing Materials, Year-Book, 1914. Edited by Edgar Marburg, Secretary, and published by the Society.

This year the Year-Book includes the standard specifications adopted by the Society for steel, wrought-iron, pig iron, cast iron and finished castings; lime, cement and clay products; preservative coatings; road materials; timber and miscellaneous. Tentative specifications are given for coal drawn steel, quicklime and hydrated lime. Another section of the book is devoted to selected specifications from miscellaneous sources, chiefly American Railway Engineering Association; United States Steel Products Co., and the Association of American Steel Manufacturers. There is a special classification included of standard specifications applicable to locomotives. The volume closes with a valuable index of standard specifications.

Percentage Trigonometry. By John Coleman Fergusson, M.I.C.E. Published by Longmans, Green & Co., London. First edition, 1914. 155 pp.; 60 illustrations; size 6 x 9 in.; cloth. Price $1.25 net.

The author has in print a large volume entitled "Fergusson's Percentage Unit of Angular Measurement," which comes at a comparatively high price. Owing to this the present work has been published with a view to

provide at a low figure a book descriptive of the method of using the percentage unit in plane trigonometry. It is written especially for students and navigators. A considerable portion of the book is taken up by a description of how to use Fergusson's Percentage Compass.

The Calculus for Engineers. By E. S. Andrews, B.Sc., and H. B. Heywood, D.Sc. Published by Scott, Greenwood & Son, London. First edition, 1911. 284 pp.; 102 illustrations; size 4½ x 7½ in.; cloth. Price $1.25 postpaid.

This little work is published as Volume 8 of what is known as The Broadway Series of Engineering Handbooks. The importance of a working knowledge of the calculus is no longer a subject for controversy among engineers. The result has been the publication of many text books, more or less modified from standard courses, and prepared in conformity with engineering subjects. In this work, however, the writers endeavor to treat engineering calculus as a subject by itself, and the student will readily appreciate the value of this method when he undertakes to peruse its contents.

The text is supplemented with a number of exercises to test the student's knowledge of the various sections as he goes along. Many examples are specially designed as problems of particular interest to civil, constructional, mechanical, or electrical engineers, as the case may be. Further, the authors have arranged the work in such a way that students may deal systematically with the entire book, or may devote their attention to a shortened course, carefully selected.

Surveying Manual. By Howard Chapin Ives, Professor of Railroad Engineering, Worcester Polytechnic Institute. Published by John Wiley & Cons, New York, London; Canadian selling agents, Renouf Publishing Co., Montreal. First edition, 1914. 296 pp.; size 4¼ x 6¾ in.; illustrated; flexible leather binding.

This manual has been written for first-year students in surveying, with particular adaptation to the needs of mechanical, electrical and chemical engineers, and students in architecture and agriculture. It describes, with illustrations, each instrument, separate chapters being devoted to the chain and tape, the level, the compass, the transit, and another chapter to the aneroid barometer and the planimeter. The practice is very carefully discussed, the subject matter being arranged, in addition to the above chapters, under the following heads: Topographical surveying; railroad curves; computations; plotting; latitude; longitude and azimuth; and large surveys. There is also a chapter descriptive of the U.S. method of laying out public land. A distinctive feature of the manual is that the chapters are divided into sections, each outlining and solving a complete problem. These are replete with sample field notes and carefully explained methods and suggestions.

The information is supplemented by 100 pages of surveying tables, such as are required for ordinary work.

Cast Iron and Steel Pipes: Some Considerations Regarding. By John Sharp, M.I.Mech.E. Published by Longmans, Green & Co., London, Eng. 142 pp., with diagrams; size 6 x 9 ¼ in.; cloth bound, first edition. Price $1.25 net.

Probably in no previous publication has there been presented such scientifically compiled data regarding cast iron and steel pipes. The mathematics in which the book abounds is handsomely presented, and arranged, for the most part, quite logically. In some instances, however, the writer might be accused by many engineers of being biased in his calculations, and in parts the mathematical deductions appear to be derived from doubtful, or at least empirical, presumptions. The various problems are very well treated from a mathematical standpoint, however, and the whole book is well worth reading by engineers, especially as it is being sold at a very low price, considering its excellent typography and fine quality of paper, although readers will possibly be inclined not to accept some of the deductions without personal investigation or the confirmation of past experiences.

Altogether the book is certainly an important one and will probably involve as much discussion and argument in engineering circles as any other book published this year. After discussing the physical and chemical properties of cast iron, wrought iron and steel pipes, and giving figures regarding their strength and elasticity, the author calculates the resistance of pipes to bursting, the thickness and strength of pipes, the flow of water and conditions affecting same, interior and exterior corrosion and influences affecting same, electrolysis, etc. One's impression is that there is an obvious effort to extol the merits of cast iron pipe and to depreciate any value that might be attached to steel pipe. This is carried to an extent that may have an unfortunate influence upon the standing of the book as an independent treatise. Nevertheless, the arguments set forth are of great importance, and it is worth while for every municipal, waterworks and gasworks engineer to read the book and then form his own opinions.

PUBLICATIONS RECEIVED.

Department of Agriculture, Alberta.—Annual report for 1913; 260 pp.; 6 x 9 in.

The Lincoln Highway.—Several pamphlets descriptive of the scenic features associated with the scheme.

Poles and Cross Ties.—Canadian production in 1913, compiled by R. G. Lewis, Forestry Branch, Department of the interior.

Weights and Measures.—Bulletin No. 7, issued by Kansas City Testing Laboratory, containing definitions and tables of equivalents.

Preservation of Ties, Poles and Timbers by Antiseptic Treatment—Reprint of the paper read before the Central Electric Railway Association by W. F. Goltra.

Rubber: Wild, Plantation and Synthetic.—Reprint of an article from the Popular Science Monthly, by Dr. John Waddell, School of Mining, Queen's University.

Pulpwood.—A report on the pulpwood manufactured in Canada in 1913. Also on exports and imports. Compiled by R. G. Lewis for the Forestry Branch, Department of the Interior.

Production of Explosives in United States, 1913.—A 15-page bulletin, compiled by A. H. Fay, United States Bureau of Mines, classifying explosives and listing United States production.

Ventilation of Farm Buildings.—Bulletin No. 78, issued by Department of Agriculture, describing the Rutherford system of ventilation, in operation on all its experimental farms and stations.

Prevention of Accidents from Explosives in Metal Mining.—Circular 19, United States Bureau of Mines, prepared by Ed. Higgins, describing dynamite; method of handling explosives; thawing, and blasting by electricity.

Gold Fields of Nova Scotia.—By W. Malcolm, Geological Survey Branch, Department of Mines, Canada. Issued as

memoir No. 20 E., 330 pp.; illustrated; 6 x 9 in. The report includes a summary, general and economic geology, of the various deposits, and statistics of production.

Commission of Conservation, Canada, 1914.—Fifth annual report, containing proceedings of annual meeting, January, 1914, in which is included summary statements of the work done under the several committees of the Commission during the year ending March 31st, 1914. 286 pp.; illustrated; 6 x 9 in.; cloth binding.

Ontario Bureau of Mines, 1914.—23rd annual report containing statistical review, mine production, mining accidents and reports from the Pre-Cambrian rocks north of Lake Huron, the chemical composition of natural gas found in Ontario, and the Kirkland Lake and Swastika gold areas, 340 pp.; 6 x 9 in.; illustrated.

CATALOGUES RECEIVED.

Steam-Jet Air Compressors.—A 4-page leaflet published by Meldrums, Limited, Manchester, England.

Mine Hoist Equipment.—A 32-page bulletin issued by the Canadian General Electric Company, well illustrated.

Exide Batteries.—A 24-page catalogue listing type X batteries for automobiles starting and lighting service.

Portable Volt Meter.—A leaflet issued by the Canadian General Electric Company describing type P-8 portable volt meter.

Steam Railroad Electrifications.—Twenty-four pages issued by Westinghouse Electric and Manufacturing Co., describing various electrifications in the United States.

Steam-Jet Elevators.—A 4-page leaflet describing an improved design for lifting and forcing water, acids, etc. Issued by Meldrums, Limited, Manchester, England.

Ice Harvesting.—A 16-page illustrated booklet describing the basin saw and the bond feeder, important auxiliaries for natural ice plants. Issued by Gifford-Wood Co., Hudson, N.Y.

Modern Electric Railway Apparatus.—A handsomely-illustrated 30-page booklet issued by the Canadian General Electric Co., describing railway power apparatus and installations.

Direct Current Sub-Station Equipment.—A Westinghouse bulletin descriptive of high voltage generators, rotary converters and motor generators, as installed on various notable railway systems.

Portable Railway Plants.—A 68-page illustrated catalogue issued by Robert Hudson, Limited, Gildersome Foundry, Leeds, Eng., describing light locomotives, cars, trucks, switches, turntables, contractor's plant, etc.

Vertical Gas Engines.—Twenty-two pages of interesting information descriptive of Browett-Lindley enclosed, forced lubrication, gas engines of various sizes, speeds and powers. Issued by Browett-Lindley & Co., Manchester, England.

Feed Water Problems.—A 20-page leaflet circulated by Canadian Allis-Chalmers, Limited, Toronto, on reducing boiler room costs by heating and softening the feed water. It describes the Sorge-Cochrane hot process system of water softening.

BACK COPIES WANTED.

Requests have been received for a copy of each of the following issues of *The Canadian Engineer*:—November 30th, 1911; December 7th, 1911; and June 12th, 1913. As our supply of these has been exhausted, we will be glad to extend for one month the subscription of any reader who will supply us with any one of them.

Coast to Coast

Point Grey, B.C.—Plans have been sent to Ottawa for approval for a proposed wharf on the north arm of the Fraser River at Eburne.

Quebec, Que.—The reconstruction of the Dorchester bridge will be completed in a few weeks, according to the J. M. Gignac Co., Limited, contractors.

Toronto, Ont.—The temporary trackage now being laid on Bloor Street West from Dundas Street will be completed within a few weeks. The city has decided to operate this new line as a civic car line.

Sarnia, Ont.—The harbor has been dredged to a depth of 22 ft., and survey work by the engineers of the Department of Public Works, will be continued preliminary to construction work that will likely be completed next season.

Cobalt, Ont.—The lowering of the water in Cobalt Lake has progressed to such an extent that by the end of the month the water line will be over 6 ft. below normal. Practically all work in connection with the outlet has been completed.

Vancouver, B.C.—The completion in this city of a new pier and warehouses by the C.P.R., at a cost of $750,000, is one of the steps that are being taken in anticipation of the business expected with the commercial opening of the Panama Canal.

Toronto, Ont.—A memorial highway, 535 miles in length, extending from Windsor to Montreal, is the subject of considerable discussion. It is estimated to cost $3,000,000. Mr. W. A. McLean, provincial highways engineer, suggests a permanent base 9 ft. in width, and estimates the cost at approximately $8,000 per mile.

Bruce Mines, Ont.—Work may be started in January on a 325 miles extension from Bruce Mines northerly, a contract having been let to the Ontario Northern Construction Co., on a percentage basis. The maximum grade north will be 1 per cent., and south .6 per cent. The heaviest curve will be 6 degrees. It is expected that about 50 miles of the line will be completed early next fall.

Penticton, B.C.—The Kettle Valley Railway has been linked up between here and Midway and construction work is well advanced towards Princeton, where the line will join the V. V. & E., and use a joint section to Otter Summit, where connection is made with the Nicola branch of the C.P.R. Construction work is now well advanced on the Kettle Valley bridge on the line linking the new Hope Mountain route with the C.P.R. on the north side of the Fraser. Grading has also been completed on the Hope-Coquahalla Summit section of the Hope Mountain route, and it is anticipated that the new line will be ready for traffic to the coast next summer.

Toronto, Ont.—The announcement that the Hydro-Electric Power Commission of Ontario is making a survey of the route of the Ontario West Shore Railway between Kincardine and Goderich, recalls to mind the noted case of the would-be engineer and capitalist, John W. Moyes, who has managed to escape, up to the present, the arm of the law, while a score of municipalities in the counties of Huron and Bruce are paying interest on a multitude of worthless bonds. The engineers of the Commission went out last week to appraise the line and to make an estimate of the material on hand. It is understood that they will report upon the eligibility of the route with a view to incorporating it in the provincial radial scheme. It will be remembered that a little grading had been done before the windup of the ill-fated scheme.

PERSONAL.

H. THOMPSON has been appointed electrical inspector for Belleville, Ont.

CHAS. JOHNSTON has been appointed assistant engineer on the Toronto-Hamilton highway.

G. J. SMITH, of St. Catharines, has been chosen by the Hydro-Electric Power Commission as electrical inspector for that city and district.

J. M. WILSON, formerly assistant resident engineer at Toronto for the Department of Public Works, succeeds Mr. J. G. Sing as resident engineer.

A. W. ELLSON FAWKES, until recently waterworks engineer for the city of Calgary, has opened an office and will carry on a general engineering practice in that city. His address is Burns' Building.

W. E. BRADSHAW, of the Dominion Bridge Co., lectured the Engineering Society of the University of New Brunswick on the design and construction of the new bridge over the Reversible Falls at St. John.

J. G. SING, for many years resident engineer in Toronto for the Department of Public Works, Canada, has resigned, and will continue his practice of consulting engineer. He will also retain his position as consulting engineer to the Toronto Harbor Board.

ARTHUR SURVEYER, Consulting Engineer, Montreal, read a paper before the Electrical Section of the Canadian Society of Civil Engineers on the 19th inst., entitled "Making our Water Powers Valuable." The paper is extracted elsewhere in this issue.

ROBERT W. ANGUS, Professor of Mechanical Engineering in the University of Toronto, and consulting engineer to the city on the Victoria Park water proposal, addressed the Royal Canadian Institute last week. He traced the city's campaign for a better water supply, and described in detail the Victoria Park proposal.

SIR ADAM BECK, chairman of the Hydro-Electric Power Commission of Ontario, gave an illustrated address to the members and friends of the University of Toronto Engineering Society on November 18th. The subject was a general review of the work of the Commission with particular attention to the hydro-electric developments at Wasdell's Falls and Eugenia Falls, Ont. Mr. F. A. Gaby, chief engineer of the Commission, addressed the Society on the technical features of these developments.

GEORGE J. BURY has been appointed vice-president of the C.P.R. to succeed Mr. David McNicoll, resigned. Mr. Bury is a Montreal man, 48 years of age. He joined the C.P.R. as a clerk in 1883, and has since filled the following positions:—Assistant superintendent in charge of division, Chalk River to Cartier and the Soo; superintendent at Fort William; superintendent at Cranbrook, B.C.; assistant general superintendent Lake Superior division; general superintendent of that division; general superintendent of the western division, with headquarters at Winnipeg; vice-president and manager of western lines (1907), and vice-president (1911).

DAVID McNICOLL, who has recently resigned the vice-presidency of the C.P.R., owing to ill-health, will remain on the board of directors of the company. Mr. McNicoll was born in Scotland in 1852. He entered the service of the North British Railway in 1866, and went to the Midland in 1873. He came to Canada shortly after and in 1874 became a chief clerk for the Toronto, Grey and Bruce. He was general passenger agent, 1882-3; from 1883-9 was general passenger agent of the eastern division of the C.P.R., then till 1896 general passenger agent of rail and steamship lines of the C.P.R. Later he became passenger traffic manager, and in 1899-1900 was assistant general manager, becoming vice-president and general manager in 1900. He held this position till 1903, and has since been vice-president and one of the directors of the company. Mr. McNicoll is also president of the St. John Bridge and Railway Company, and a director of the Molsons Bank.

OBITUARY.

Mr. J. S. Ferguson, of the Northern Development Branch of the Ontario Service, died suddenly at North Bay, Ont., last week. Mr. Ferguson was 50 years of age, and for the past three years had been associated with Mr. J. S. Whitson on road construction in Northern Ontario.

The death has been announced of Hon. Wm. Templeman, former minister of mines and of inland revenue for the Dominion Government. Mr. Templeman was also a member of the Royal Conservation Commission in 1909.

CALGARY BRANCH CANADIAN SOCIETY OF CIVIL ENGINEERS.

Mr. William Pearce, M. Can. Soc. C.E., executive assistant, Department of Natural Resources, C.P.R., gave a very interesting address before the members of the Calgary branch of the Canadian Society of Civil Engineers, on Friday evening, the 6th instant. The speaker made a trip around the world about two years ago, and made a special study of irrigation and forestry, in foreign countries. On Friday evening he chose as his subject "Irrigation in Egypt," and, in a very interesting manner, described the various irrigation and other engineering works there. His numerous observations on the habits and manners of the people, the various means of transport, etc., were also very interesting.

The annual meeting of the Branch and the election of officers for the ensuing year will be held on Saturday, December 5th.

COMING MEETINGS.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

AMERICAN ROAD BUILDERS ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

CANADIAN NATIONAL CLAY PRODUCTS ASSOCIATION.—Annual Convention to be held at the King Edward Hotel in Toronto, January 26, 27, and 28, 1915. Secretary, G. C. Keith, 32 Colborne Street, Toronto.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

AMERICAN WATERWORKS ASSOCIATION. — The 35th annual convention, to be held in Cincinnati, Ohio. May 10th to 14th, 1915. Secretary, J. M. Diven, 47 State Street, Troy, N.Y.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.—Annual meeting to be held at the Iowa State College, Ames, Iowa, June 22nd to 25th, 1915. Secretary, F. L. Bishop, University of Pittsburgh, Pittsburgh, Pa.

Volume 27. Toronto, December 3, 1914 Contents of this issue on page 3

STREAM FLOW INVESTIGATIONS

NOTES ON METEOROLOGICAL PHENOMENA WITH REFERENCE TO GOVERNMENT POWER AND STORAGE INVESTIGATIONS OF THE BOW RIVER—FROM REPORT OF M. C. HENDRY, CHIEF ENGINEER.

THE various relations which exist between precipitation, altitude, run-off, temperature, evaporation, etc., make the study of stream flow exceedingly complex. While the influence of each is not in all cases a direct one it is frequently of such magnitude that to regard it lightly leads to inaccuracies of serious nature. In hydro-electric development work all factors influencing the discharge of the river or stream demand closest investigation over a period of years in order that their valuable characteristics may be measured to a degree providing mathematical limits within which lie the data to form the basis of the proposed design. The value of an exhaustive study of these physical characteristics and their causes, is rightly emphasized by Mr. M. C. Hendry in his recent report on the power and storage investigations of the Bow River. These investigations were made by him under the direction of Mr. J. B. Challies, Superintendent of Water Powers in the Dominion. In our issue of last week the work which the Water Power Branch has accomplished on the water resources of the Bow River basin was chiefly outlined. The following notes respecting meteorological phenomena are from the above report.

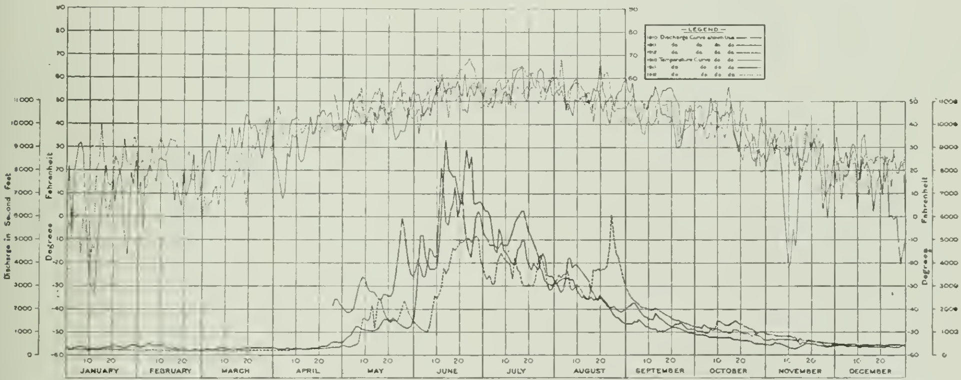

Fig. 1.—Daily Discharge and Mean Temperature, Bow River, Banff, Alta.

The importance of a study of precipitation in connection with the flow of streams cannot be emphasized too much; its influence on stream flow is a very direct one and, without study, the erroneous conclusion is reached that the relation between precipitation and run-off is a simple one. A little time spent in the study of the question soon reveals the fallacy of this assumption, for the relationship is anything but simple, being influenced by a great many physical features of a rather indeterminate nature.

The collection of precipitation data all over the country has been carried on for a comparatively long term of years, whereas data regarding the run-off of streams are rather meagre. If, therefore, some general relation can be established between rainfall and run-off, the study of the streams from the standpoint of power production can be placed upon a more satisfactory basis. In the West, run-off data have been collected for a very short term of years, and only during the last three has a continuous record of the discharge been kept; thus the importance of a general relationship between recorded precipitation and run-off is all the more apparent.

The distribution of rainfall in any district or part of the country is not uniform. The records throughout Canada, generally, except in the eastern provinces, do not extend over a sufficiently long period, nor are the stations widely enough scattered to define areas in which certain amounts of rainfall may be expected. In the West, an examination of the available records seems to indicate a general conformation to conditions found to the south, in the United States; that is, that the lines of equal rainfall are generally north and south, or roughly parallel to the mountain ranges. There are, of course, divergences due to local influences.

Relation of Precipitation to Altitude.—Generally speaking, precipitation decreases with the increase in altitude. It has been found in travelling westward away from the Atlantic that as the country rises, the rainfall decreases. This general rule, however, does not seem to apply to the precipitation in the valley of the Bow River; in fact, the direct opposite is apparently the case in practically all the territory forming the eastern slope of the Rockies. An examination of the records will show that as the altitude increases on the eastern slope, the precipitation increases. Special local influences are at work here, however, the mountain ranges in which are situated the sources of the rivers, causing this reversal of the general rule.

The warm, moisture-laden winds from the Pacific are first intercepted by the mountains of the Coast range and deflected upwards to mingle with cold air currents or to come in contact with land at a lower temperature; becoming chilled below the temperature of saturation, they deposit some of the moisture as snow or rain as they pass over the mountains, giving rise to the heavy precipitation near the coast, the greatest recorded on the continent.

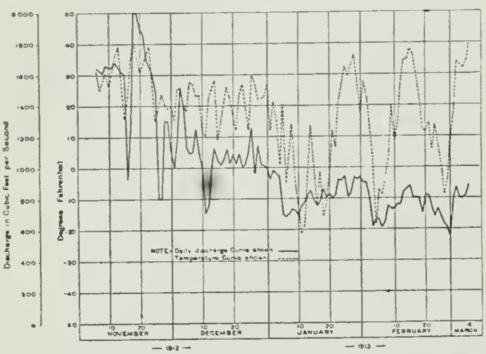

Fig. 2.—Daily Discharge (at Horseshoe Falls) and Mean Temperature (at Banff, Alta.), Bow River.

They then pass over a stretch of low-lying land, depositing but little moisture until the Selkirk range is reached, where the process is repeated. When the Rocky mountains are reached the humidity of the air has become much reduced, but the low temperatures reached at the higher altitudes is sufficient to cause more precipitation; there fore, in the Bow River basin, with which we are dealing and which is on the eastern slope of the Rockies, it is at the higher altitudes that the greatest precipitation occurs. The alteration of mountain ranges with stretches of country of low altitude is accepted as the cause of the arid and semi-arid regions to be found to the east of the continental divide.

Value of Records.—In making a study of rainfall in any district, it should be borne in mind that the average precipitation gives only a relative view of the question, as great variation from the average annual precipitation may occur at different points in the district. In this regard no general law can be made to apply. The number of conditions contributing are so great and variable that, for special purposes, a detailed study of the rainfall in the locality is necessary.

When studying precipitation records extending over a given period, it is necessary to know what value may be attached to them. Sir Alexander Binnie has given this question careful consideration in a paper published in the proceedings of the Institution of Civil Engineers (Vol. 109, pages 89 to 172). He reached the conclusion that for records extending over a period of 25 years, the mean obtained would be within 2 per cent. of the true mean. The conclusions reached by Mr. Rafter in a discussion of this paper were: that, for a period of 5 to 10 years, the probable extreme difference from the mean would be 15 per cent., and of 10 to 15 years, 4.75 per cent. Other authorities have expressed the opinion that it is necessary to have records for a period as great as 40 years in order that the mean may represent the true mean precipitation within 5 per cent.

Accuracy of Records.—In Canada, the recording stations are all under the direction of the Meteorological Service, and a standard method of obtaining the records is adopted. It is to be noted, however, that the placing of the recording instruments can have a very great influence upon the accuracy of the records. To arrive at the average precipitation upon a district, it is necessary that as many records as possible in the area to be considered should be available, as conclusions based upon records from a limited number of stations are liable to be considerably in error. An ideal condition under which to study rainfall data would be attained if the stations were uniformly distributed over the territory, or placed along each branch of the stream of which the relation between run-off and precipitation was to be established.

Distribution of Precipitation.—A study of the periodical distribution of the rainfall is interesting. Generally this distribution throughout the year, from year to year, is fairly constant in any district, but is different in different districts. For instance, there is a similarity in the distribution in the different localities along the Pacific coast; the same may be said of the territory to the east of the Rockies, while that portion around the Great Lakes has its typical distribution.

Tables showing the fluctuation in the annual precipitation recorded at Banff and Calgary have been prepared. At Banff, the records are available at intervals from 1890 to 1896, from which year they are continuous to date; during that period, the maximum precipitation occurred in 1902, 30.59 inches being recorded, and the minimum was 10.33 inches in 1903. The mean yearly precipitation for twenty years is 19.13 inches. At Calgary, the records are available from 1885 to date, during which interval the lowest recorded annual precipitation occurred in 1892, 7.91 inches being the amount; and in 1902, the maximum precipitation occurred, 34.57 inches being recorded. The mean yearly precipitation over the period of 27 years is 16.10 inches.

Owing to the scattered location of the recording stations in the district—at Banff, Calgary, and Jumping Pound (from the latter, only partial records are available)—they do not truly represent the conditions obtaining in the basin.

As has been mentioned before, the precipitation increases in this locality with the altitude. The altitude of the station at Calgary is approximately 3,400, that at Jumping Pound about 4,200, and at Banff 4,525 feet, and an examination of the records will show a greater precipitation at Banff and Jumping Pound than at Calgary, that recorded at Banff being the heaviest of the three. The sources of the Bow River and its tributaries are at much greater altitude than is the gauging station at Banff; in fact the greater part of the drainage area above Kananaskis Falls lies above this altitude, so that the stations are by no means representative of the greater part of the drainage basin.

Relation of Precipitation to Run-off.—If the records of precipitation are compared with those of the run-off on the basin, it will be found that the recorded run-off exceeds the precipitation as recorded at Banff, by as much as 25 per cent. This condition is by no means uncommon for mountain districts. Mr. John R. Freeman, in his report on the Hetch Hetchy water supply for San Francisco, says:—

"In regard to the excess of run-off over precipitation, the fact that depth of run-off exceeded depth of rainfall at outlet simply proves that the average precipitation for the catchment as a whole was far greater than at this comparatively sheltered spot of lower altitude at the outlet of the valley."

This condition holds in the Bow basin, and emphasizes the need of more stations for the recording of precipitation.

On account of the short period over which complete run-off data are available, and the few precipitation recording stations in the catchment area, no definite relation can be established between run-off and precipitation. The only conclusion that can be arrived at from a study of these data is that for the water years from 1909 to 1911, the mean precipitation has been nearly equal to the mean yearly precipitation for the last sixteen years, as recorded at Banff. It is fair, therefore, to assume that the run-off during the same years represent approximately the mean run-off conditions during a like period.

Division of the Year.—In considering the relation of precipitation to run-off, a period known as a "water year" is made use of, instead of the calendar year. This period for the Bow Basin district may be assumed as extending from October 1 until September 30, for practically all of the water is obtained from the mountains, and from October 1 on, the precipitation in the form of snow is stored in the mountains to be held until the warm sun of the following early summer releases it, to form the summer freshets which occur during May, June and July.

Temperature.—Temperature in the Bow River drainage area is one of the great factors influencing the discharge of the river. In the upper part of the catchment area there is not a month in the year in which frost cannot be expected. The range of temperature is great, the range of mean temperature at Banff is from $56^\circ.9$ in July to $13^\circ.7$ in January, or $43^\circ.2$ of difference; at Calgary, the range of mean temperature is from $70^\circ.7$ in July to $14^\circ.2$ in January, or a range of $66^\circ.4$; and the maximum and minimum temperature greatly exceed these. From these two records it will be seen that the one at the higher altitude registered the lowest temperature. At the higher altitudes it is to be expected that low temperatures will be encountered, and that the period during which conditions of low temperature obtain will be longer than at the lower levels. The records are taken at an altitude which is low, considering the drainage area of the Bow River as a whole, and hence do not represent truly conditions in the upper part of the valley of that river. They give, however, an indication of the conditions to be found and, upon study, reveal some interesting facts with regard to the bearing of temperature upon the discharge of the river.

Influence Upon Evaporation.—The influence of temperature upon evaporation is one which is constant and unmistakable, but is one for which, so far, no relation has been established. Sufficient data are not available for a study of the question in the district, but in passing it seems well to note the work that has been done in this regard, and which is well summed up in a paper by Mr. Rafter, published by the United States Geological Survey. In this paper Mr. Rafter had made a careful analysis of the available data, and he reached the conclusion that no definite relation exists between evaporation and temperature, but that the influence is a constant one, and cannot be disregarded.

Influence of Temperature on Discharge.—There is no other single condition which plays such a vital part, or has such a direct influence upon the discharge of the rivers of the district as temperature. A diagram (Fig. 1) has been prepared, showing graphically this relationship—the daily discharges of the Bow River at Banff have been plotted continuously, and on top of this has been plotted the mean daily temperature as recorded at Banff from April, 1910, to December, 1912. Another diagram (Fig. 2) has been prepared for the period November 6, 1912, to March 6, 1913, showing the mean daily discharge for the Bow River at Horseshoe Falls, and the mean daily temperature as recorded at Banff.

A study of these diagrams will reveal how direct is the influence of temperature upon the discharge of the river; during months of low temperature the discharge is shown to be low. On the other hand, high temperature corresponds to large discharge, although within the limits of the record, the highest temperatures occur in the month following the highest discharge. This can be explained by the fact that, except upon the mountains permanently covered, the snow has nearly all been melted during June and the early part of July.

The second diagram shows clearly that the influence of low temperature on the discharge is unmistakable. The period selected is that covering the low-water stage of the river, which corresponds to the period during which extreme low temperatures are most encountered throughout the interval covered by the curve. It will be noted that the mean temperature is above freezing on only eighteen days, consequently it affects not only the source of the river but also the actual flow in the river itself.

PORT ARTHUR WATER SUPPLY.

The new water supply for the city of Port Arthur, Ont., was turned on last week. The installation includes two 24-inch steel intake pipes supported by piles and extending from a point in the lake 2,550 ft. from the shore, and in 45 ft. of water, to a well at the pump house. The intake is 10 ft. above lake bottom. The plant is equipped with 3 pumps each of 2,880,000 gallons per day capacity. Each pump is operated by a 250 h.p. motor. Two 24-inch mains extend from the pump house to the corner of McDougall and Algoma Streets, and from here the water is conveyed by 12-inch pipes to the city mains. The 24-inch pipes provide for ample extension of the distribution system as future needs may require.

The system is equipped with a chlorinating plant. As to the quality of the water, the provincial board of health reports it to be free from bacteria, and in every way satisfactory.

The total cost of the work has been $585,000. It was divided into a number of contracts, the chief of which was awarded to the Thunder Bay Construction Co. This contract included the construction of the pumping station, the laying of the intake, and the driving of a 530-ft. tunnel through rock between the pumping site and the lake.

The work has been executed under the supervision of Mr. L. M. Jones, city engineer.

PUBLIC WATER SUPPLY FOR CITIES—SOME GENERAL CONSIDERATIONS.*

By W. H. Dittoe,
Chief Engineer, Ohio State Board of Health.

IN the modern sense the waterworks of a city includes the source of supply and the equipment required to deliver the water through a distributing system to the point where it is utilized. The development of public water supplies in accordance with this interpretation has been of comparatively recent occurrence. In the United States there were only 53 public water supplies in 1850. Since that date, however, the installation of public water supplies has been general and it is estimated that at the present time there are fully 6,000 public water supplies. Prior to the invention of pumping machinery for lifting water the development of water supplies was practically nil. In 1582 in London the first pumps for water supply purposes were placed in operation. An important development in assisting the installation of public water supplies was the introduction of the steam pump in London in 1761. An impetus in water supply development came in the latter part of the 18th century when cast iron mains were introduced as a means of distributing the supply. Previous to that time wooden pipes only had been used.

In the early development of water supplies little attention was given to the quality of the supply. It was not until 1829 that serious consideration was given to the quality of the water. In that year the first filter was installed for the East Chelsea Water Company at London. About 1850 the germ theory of disease was seriously advanced and it was at this time the claim was made that typhoid fever was caused by a specific organism transmitted in sewage. This marked the beginning of the use of filters as a sanitary precaution in the improvement of water supplies, although definite proof of the existence of the typhoid germ was not secured until 1880 and 1881. The early development was the so-called slow sand filter which is still now extensively used in European countries and also in the United States. It was not until 1893 that studies were made leading to the development of the so-called mechanical or rapid sand filter. This process is known as the American system of filtration, although its origin was in England. At the present time it is estimated that there are 350 municipalities in the United States utilizing mechanical or rapid sand filters to purify their water supplies. The slow sand filters have not met with such favor in this country due no doubt to the fact that they are less suitable in the treatment of muddy water. At the present time there are about 50 municipalities using slow sand filters in the United States.

Sources of Water Supply.—The original source of all water is the rainfall which precipitates upon the surface. A portion of this rainfall is absorbed by the soil and percolates into the underlying formations. Another portion flows from the surface through streams and rivers to their points of discharge. An appreciable amount is lost by evaporation and another portion is utilized in the support of plant life. The portions in which we are interested for water supply purposes comprise that which percolates into the soil, becoming a source of ground water supplies, and that which passes off into the streams, becoming a source of surface water supplies.

*Read before Conference of Health Officers, Ohio State Board of Health.

Ground water may be obtained by means of wells, springs, or collecting galleries. Depending upon the elevation of the ground water with relation to the surface of the ground, it will require one or two sets of pumps to deliver it into the mains. The quality of ground water is dependent upon the formations from which it is obtained. Thus, by passage through a limestone formation the water will absorb hardness. If it comes in contact with iron salts, which are almost always present, it will absorb the iron by solution. It may also take on objectionable tastes and odors due to the absorption of sulphur compounds. In general, ground waters are less desirable than surface supplies, judged from their mineral characteristics.

Surface water supplies are derived from streams, lakes or reservoirs. With lakes or large rivers it is unnecessary to provide storage of raw water for a continuous supply for the pumps. With small rivers and creeks, however, it is frequently necessary to construct impounding reservoirs to store a sufficient portion of the excess flow of the stream to serve during dry weather. The quality of surface water supplies is dependent upon numerous factors, the most important of which is the density of population upon the drainage area. Theoretically every dwelling on the drainage area contributes to the pollution of the stream. The degree of pollution is, therefore, determined by the population. It is, of course, possible to reduce the extent of pollution by proper disposal of sewage. Regardless of the treatment of sewage, however, it is generally conceded that no surface supply collected from a catchment area which is populated is safe for drinking purposes without purification. This is particularly true in Ohio and in other densely populated localities where the streams are almost universally used as carriers of sewage.

Conditions Governing Choice of Source of Water Supply.—Statistics of public water supplies of United States show that a large percentage of the supplies are obtained from ground water sources. Practically all of the villages and small cities of Ohio obtain their supplies from wells, springs or collecting galleries. As the population increases, however, it is found that the ground water supplies will not furnish a sufficient quantity of water. Of the cities in Ohio with populations of 25,000 or more, five obtain their supplies from wells and nine are provided with water supplies of surface origin. Four of the well supplies are inadequate and two of them are supplemented by surface water. The indications are that unless unusually favorable conditions are encountered a city of more than 25,000 population must depend upon a surface source of water supply. In any case the most serious consideration must be given to the question of quantity in determining the choice of a ground or surface source of water supply.

It may be stated generally that the fundamental condition governing the choice of the water supply is the quantity available. It is obviously unwise to develop a source of supply which within the life of the installation will fail to furnish a sufficient amount of water. In determining upon the quantity available assumptions must be made to estimate the growth of the city and the increased use of water. The quantity thus determined must be supplied during the most extreme dry weather conditions which can be anticipated. It is not enough to supply a sufficient quantity of water for 350 days of the year and meet a deficiency during the remaining short period.

Of almost equal importance to the question of quality is the quality of the supply. Having two supplies pro-

posed equal as regards quantity available, the quality consideration will determine the selection. Troubles associated with poor quality are not confined to surface water supplies but are also experienced in water from ground sources. With the established modern methods of water purification it is probably true that improvement of the quality of surface water supplies is more easily accomplished than is the improvement of quality of an objectionable ground water supply. In the consideration of quality it is well to give attention to the value of pure water. It has been shown that improvement of the hygienic quality of the water supply fully repays the community in many ways for the expenditure incurred in the establishment of a water purification plant. The saving of lives and reduction of morbidity from typhoid fever alone will reduce the expenditures of the citizens of the community to such an extent as to repay within a few years the financial outlay for a plant. Thus it can be shown that the city of Columbus has saved for its citizens over $500,000 per year since its water purification plant was established. Cincinnati has saved for its citizens $1,750,000 per year by purifying its water supply. In like manner it can be shown that it is economical to provide a soft water supply for a city even at a greater expense than would be incurred in the development of a water supply containing objectionable hardness. Modern standards of purity of a water supply require that its physical hygienic and chemical properties be satisfactory. Using this standard a pure water supply is an asset and an impure water supply an expense to a community.

Another consideration to be given in selecting a source of water supply is the cost of its development. It frequently happens, however, that a source of supply costing more to develop is the more economical selection. It will readily be seen that a supply cheaply developed which does not furnish an adequate quantity is really an expensive selection. It is well to keep in mind that the cost of development is purely relative, and within the financial limits of a community consideration of cost must be subservient to those of quantity and quality.

Purification of Water.—Having decided upon the development of a water supply which is not of satisfactory quality in its raw state, some means must be provided to produce a water of good quality. If the water is obtained from wells it may require aeration, softening and iron removal. The softening of water is expensive in proportion to the original hardness. Few attempts have been made in this country to soften well water supplies of municipalities. Aeration and iron removal are, however, well recognized methods of water treatment to improve the quality of ground water supplies. In Ohio we have about six plants for the purpose of reducing an objectionable iron content.

The purification of a surface water supply may be brought about by one or both of two general methods, namely, filtration and disinfection. Purification by storage and sedimentation has been advanced as an efficient means of correcting the pollution of water supplies but thus far has gained little recognition. Filtration improves the physical quality of the water as well as its hygienic quality. Disinfection removes the pathogenic organisms but does not affect the appearance of the water. It will, therefore, be seen that the field of disinfection as the only treatment is confined to water supplies of good physical quality. There are two well-known methods of filtering water. The first and older process is the so-callled slow sand filter and the other, a more modern method, is the so-called rapid sand or mechanical filter. As has been stated, the slow sand filter is a development of the early part of the nineteenth century, while the rapid sand filter has come into use during the past thirty years. The slow sand filter is more applicable to the treatment of a moderately clear water while the rapid sand filter can successfully treat a very muddy or turbid water. The slow sand filter consists of a watertight basin usually one acre or less in area, provided with suitable underdrains over which is placed the filtering material. In the northerly climates it is customary to provide a roof for the filter. The filtering material comprises three feet or more of sand, resting upon gravel surrounding the underdrains. The water to be purified is applied at the surface of the filter. It fills the voids of the filtering material and stands to a depth of about three feet above the surface of the sand. Its flow through the sand is controlled so that it passes downward at a rate of 0.4 foot per hour, corresponding to 69 gallons per day per square foot of area or 3,000,000 gallons per day per acre of area. This is a low rate of filtration. The water passing through the filter is stored in a reservoir from which it is pumped to the distributing system of the city. The mechanical or rapid sand filter differs from the slow sand filter in the preliminary treatment of the water as well as in the rate of filtration.

The rapid sand filter is a development of the last thirty years. It first attracted attention in 1885, when a plant of this type was constructed for the treatment of the water supply of Somerville, New Jersey. For the first fifteen years it was principally used in the treatment of water supplies for industrial use, such as paper mills and allied industries. In 1902 the first large municipal rapid sand filter plant was constructed for the East Jersey Water Company at Little Falls, New Jersey. Since that time the development of rapid sand filters in the United States has been very important. Among the largest plants in the country may be mentioned those at Cincinnati, New Orleans, Louisville, Columbus, Toledo, Harrisburg, Minneapolis, and Grand Rapids. The cities of Cleveland and St. Louis are now constructing plants of the rapid sand type.

The rapid sand filter plant differs from the slow sand plant in many respects. With the use of a rapid sand plant the water is always given preliminary treatment by a coagulant. It is passed through filters of much smaller area at much higher rates. Roughly speaking, the rate of filtration is forty times that used for the slow sand filter. The filtered water is received and stored in a covered reservoir in the same manner as is the case with slow sand filters. The cleansing of the rapid sand filter is accomplished by a reverse current of filtered water passed upward through the sand removing the layer or silt and coagulant collected at the surface. This differs from the cleaning of a slow sand filter, which is usually accomplished manually or by mechanical means.

The principal features of a rapid sand filter plant are the intake and low lift pumping station, the primary sedimentation basins, the coagulation basins, the filters and the clear well. The raw water is received through the intake, elevated to the primary sedimentation basins by the low lift pumps, and from this point passes by gravity through the plant to the clear well.

Primary sedimentation is required for turbid water carrying large quantities of silt. Thus the Cincinnati and Louisville plants have large basins where the water is allowed to settle for several days before it is passed through the purification plant proper. The use of primary sedimentation basins is not always required.

The coagulation basins are provided with a two-fold purpose, namely, to furnish a period for the reaction of the coagulant in the water, and for partial sedimentation of the suspended matter. The chemicals generally used as coagulants are alum and copperas. Alum, or aluminum sulphate, is readily soluble in water and if applied in proper proportion to the ordinary surface water will form a sticky gelatinous precipitate called the floc, which in its formation collects the suspended matter and bacteria into heavy masses which readily precipitate. The action of copperas, or sulphate of iron, is quite similar, but this compound requires the addition of lime or soda ash to bring about coagulation. Where alum or copperas are used a portion of the coagulant will pass through the coagulation basins to be removed from the water at the surface of the sand in the filters. Coagulation basins are designed to furnish an ample period for the formation of the floc and an additional period for its partial settling. The necessary time required for this purpose varies with the character of the water to be treated. The modern plants which have been installed in Ohio provide periods ranging from three to twelve hours in the coagulation basins.

The water containing a small portion of the floc next passes through the filters. These are generally constructed as rectangular concrete boxes. A 1,000,000-gallon per day unit will have an area of about 360 square feet. Large plants are laid out with units having a capacity of from 2,000,000 to 5,000,000 gallons. The bottom of the unit is covered with a strainer system over which is placed a layer of graded gravel which supports the sand layer with a thickness from 30 inches to 3 feet. The water is applied at the surface of the sand over which it stands to a depth of two to four feet. It passes downward at the rate of 16 feet per hour, which is equivalent to 2,880 gallons per square foot per day or 125,000,000 gallons per acre per day. The rate of passage of the water through the filter is of prime importance in securing proper efficiency. This rate is regulated and controlled by the use of apparatus which prevents excessive rates of filtration, still permitting the use of the head necessary for operation. The efficiency of the rapid sand filter depends largely upon the collection of the floc at the surface of the sand. This gelatinous substance forms a mesh through which the suspended matter and bacteria contained in the water cannot pass. The resultant effluent from the filter is therefore purified, clear and sparkling. After the filter has been in operation for a certain length of time, depending upon the condition of the applied water, it becomes clogged and will no longer pass the proper quantity of water without excessive loss of head. It is then necessary to wash the filter. This is accomplished by passing purified filtered water through the strainer system and upward through the sand at a velocity of vertical rise of 15 inches or more per minute, the overflow being carried from the filter box through a gutter and connection to the sewer. The washing requires about five minutes and in large plants entails a loss of water of about two per cent. of the water filtered.

Whatever method of filtration is used, the purified water must be stored in covered and watertight receptacles to protect it from secondary pollution. It is customary to construct a clear water reservoir adjacent to and as a portion of the filter plant, where the purified water may be stored before it is pumped into the mains. The size of these clear wells is dependent upon (1) the relation between the capacity of the filter plant and the daily consumption, (2) the period of pumping, and (3) the storage provided on the distributing system.

What Filtration Accomplishes.—The filtration of a public water supply accomplishes beneficial results which can be with difficulty measured. The apparent result, which is appreciated by the citizens of a community in general, is the greatly improved appearance of the water. Instead of a muddy and often foul liquid a clear and sparkling fluid is drawn from the tap. The ordinary operations of the household are facilitated and the people are generally well satisfied, whereas frequent complaints against the previous condition of the water had been received. The most important result of filtration of a public water supply is the improvement in health conditions. Normally it may be expected that the introduction of a filtration plant will accomplish a reduction of 75 per cent. in the mortality from typhoid fever. The reduction at Cincinnati has been over 90 per cent. and at Columbus over 80 per cent. Accompanied with the reduction in deaths from typhoid fever there is also a noticeable reduction in deaths from general causes. It has been universally observed that the reduction of typhoid fever immediately follows the installation of a filtration plant.

Of lesser importance than the benefit to public health the financial advantage resulting from the purification of a water supply receives some recognition. With a water supply of good appearance and of satisfactory quality the inhabitants of a city will use it universally. This will increase the income of the waterworks department and will in turn decrease the cost of furnishing water. Each individual who uses a purified water supply will derive a financial advantage over the use of a polluted and muddy water. The saving resulting from the improvement of the physical quality of the water is also important and will in time assist in paying for the treatment of the supply. It has been previously shown that the saving of lives by the reduction of typhoid fever is amply sufficient to pay for the cost of purifying the water. Considering the question from a financial aspect alone and without regard to humanitarian considerations, a city provided with a water supply of poor quality can ill afford to maintain it without improvement.

SOOKE LAKE WATER SUPPLY.

The engineering staff of the Sooke Lake waterworks project for Victoria (see *The Canadian Engineer*, July 23rd, 1914), reports that a length of 6 miles of the 10¼-mile steel pressure pipe line has been laid, and that the most difficult portion of the route has been dealt with. It is expected that the whole pressure main from Humback reservoir to Smith's Hill service reservoir in the city will be completed in January.

The reinforced concrete flow line, 27.3 miles in length, has been laid for a length of 14 miles, or over half its distance. By the end of the year it is expected that the contractors, The Pacific Lock Joint Pipe Co., will have another four or five miles in position. To date the rate of laying has averaged 3½ miles per month.

The tunnel work within the city limits has progressed very favorably, the third tunnel being practically completed.

REPAIRS TO RIDEAU CANAL.

The Deputy Minister of Railways and Canals has announced that improvements to the extent of $50,000 will be made by the government on the banks of the Rideau Canal. The canal will be unwatered at an early date for this purpose.

THE CONSTRUCTION OF DAMS.*

By A. E. Walden,
Chief Engineer, Baltimore County, Water and Electric Co.

THERE are many things to be considered in designing dams, and especially one of the commonly called "gravity type," or, rather, of the solid masonry type, which will be here called the mass type; the gravity type will be that as constructed by Beardsley and Ambursen and Ransome.

In making examination of a dam site, test pits or borings should be made for a good distance above the dam site to determine the composition of the soil or strata under the dam, the trend of the stream, if on rock, noting if these are at right angles to the stream or with the stream, and if the stone is subject to water holes; also the character of the ledge, whether seamy or not, and if it shows rapid disintegration where exposed to the atmosphere, and if under water, that it is easily worn away by the action of the water, as in some limestones.

In some cases it will be found that in the bed of the river there are two classes of stone, one portion of which is soft and the other hard.

A careful examination of the banks should be made for suitable abutments and abutment foundations, and the quality of the soil composing them; also the slope of the underlying rocks, so that steps may be taken to prevent seepage through and eventually a washout.

There are several ways that have been employed by engineers in determining the proper length of crest, all of which are more or less efficient when properly applied,

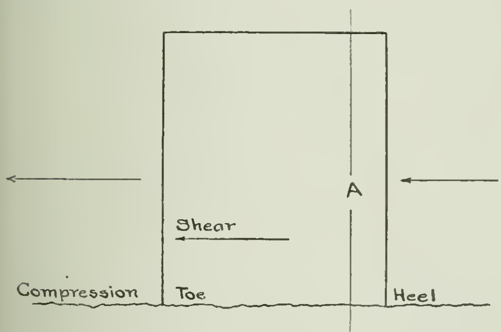

Fig. 1.

as are also certain empirical rules, where run-off data cannot be obtained, such as basing the run-off on a certain number of feet per second per square mile, certain instances of which will be given here.

In one case that came to the writer's notice the dam was constructed on a basis of three feet of crest per square mile of area which is hilly and steep, based on a rule that there should be on normal conditions at least one foot of spillway length for each square mile of drainage area, and this multiplied by three can take care of flood conditions. This dam failed many times, causing great property damage, but was finally constructed so that the spillway section would have a crest equal to taking the run-off at 20 cu. ft. per sq. mile at a velocity of one foot, and dividing this result by an assumed depth at the crest, considering it as a rectangular section, no allowance being made for the well-known weir action and of velocity of approach over such a crest. No trouble has since been experienced. This determination was made after an examination of the stream's banks for height of water, its depth at this point as compared with the width and depth of water at other points and for several hundred feet above and below; also noting the heights to which débris had landed; from information given by people living along the stream as to flood heights; from the drainage area and from rainfall data which had before for some

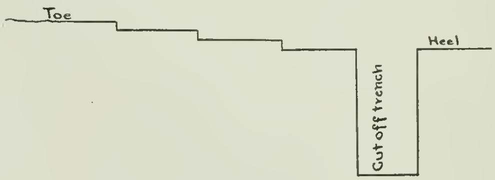

Fig. 2.

reason given results too small, to some extent probably due to the character of the drainage area, its topography, and the condition of the soil at certain times.

With 20 cu. ft. at a velocity of one foot per second and the banks 5 ft. high, it was assumed that the water reached 5 ft., but with 20 cu. ft. used as a basis and the dam lengthened to 146 ft., and estimating a crest depth under these conditions of 3 to 4 ft., this stream has since been measured for surface velocity during high water and an average velocity, on the surface, of 10 ft. per second obtained, with a depth of 20 in. at a point far back of the crest so that the increased velocity of the water at the crest of the dam did not affect it. Undoubtedly the velocity of the water varied at various depths, but this could not be obtained.

Assuming the average velocity at 10 ft. per second, and a sectional area of 146 ft. by 20 in., the approximate discharge per square mile in this case was 99 cu. ft. per second, and the greatest depth of water so far noted on the crest of this dam has been 3 ft. It is possible under these conditions that the velocity was from 15 to 20 ft. per second, but this could not be measured at the time, on account of lack of preparation.

In another case a dam was constructed for a crest depth of 5 ft. for a drainage area of about 300 sq. miles. This dam was 200 ft. long at the spillway, with about 1,000 ft. of earthen embankment about 18 ft. higher than the spillway section. The 5 ft. depth at the crest has been exceeded many times, and the gauge has shown a depth of 11½ ft. on the crest, which was beyond data based upon the government report's gauge readings at that time, and would be about on the approximate basis of 7 cu. ft. per second per sq. mile.

From an examination of many streams, watersheds, and dams, it would seem that one may expect to find that the run-off will vary from 50 to 100 ft. or more per second, and in some cases it has been considerably more than the maximum amount noted for a hilly section, that will give a quicker crest rise than a flat section will do, owing to the fact that the water cannot spread over any large area.

It may be assumed that a certain portion of the flood reaches the crest in the first hour, a certain portion in the second hour, and so on to five or six hours, or more, but this cannot be accurately determined beforehand with the data we have to-day.

Every effort should be made to obtain data from other dams on the same watershed, if any, or on similar water-

*From a paper read before the New England Waterworks Association, September, 1914.

sheds in the vicinity, as to the rise in a given length of time after a heavy rainfall, so as to determine the lapse of time between either the beginning or the maximum rainfall and the maximum crest rise. Rainfall data show that a maximum rainfall of 4 in. in one hour may be looked for, and from 8 in. to 10 in. in twenty-four hours. On this basis there would fall for each square mile in the first hour, 9,288,800 cu. ft. (1 in. equals 2,322,200 cu. ft.). Then the question would arise as to what part of

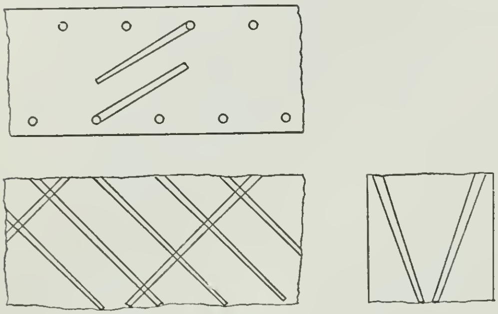

Fig. 3.—Method of Drilling.

this reaches the dam the first hour, and each succeeding hour until the maximum crest height is reached, and the effect the condition of the soil and the ground water content has on this. From J. B. Francis' records, the indication would seem to be that a depth of rainfall varying from 6 in. to 11 in. or more, with rates about as follows, may be looked for: 4 in. in two hours, 6 in. in about twenty hours, and 9 in. to 10 in. in thirty hours, etc.

For the rainfall and flood conditions, Fanning's formula has been much used, as well as others, but must be applied with care for the particular location, the period of the year in which the rainfall occurs, as on frozen ground or with a light fluffy snowfall it requires 15 in. or 20 in. to equal 1 in. of rainfall. While assuming 4 in. to 5 in. of wet soggy snow to equal 1 in. of rainfall, the rainfall combined with the water from the melting snow with the frozen ground underneath will give quite sudden changes in the flood conditions, which will exceed any rainfall obtained from hourly rainfall records; recording gauges at dam, however, would show this.

The effect of impoundings or pondage in reducing flood conditions, if the area is sufficient, where there is one or more dams above the one to be designed, should be considered. The crest of the dam under design should be proportioned to care for the failure of at least one, or more, of these dams in addition to that of flood conditions, depending on the location of towns and villages below, and the property value and loss of life likely to occur in case of such failure.

In the design of a dam of the mass or solid section type, as shown by section, Fig. 1, the dam may be considered as a beam fixed at one end and having an uniform load, and as such may have shear at the joints, tension in the upper face and at the heel, with compression at the toes, etc.

Then to care for tension in the upper face, steel may be provided, but its calculation would be to some extent theoretical. In any event, if securely anchored to the rock formation in drilled holes, and the steel provided with split ends and wedges, and afterward grouted in carefully, this method would certainly add to the stability of the dam, especially when the dimensions were properly proportioned to care for shear. Steel bars may be embedded at an angle of about 30 degrees, as shown in Fig. 4, or some other angle, with the horizontal so that the steel will take tension as far as it is possible to make it do so under these conditions.

In preparing the foundation, care must be taken to remove surface rock that has deteriorated, to a depth that test holes show to be safe, and then the surface under the dam should be roughed, either toothed or sawtoothed, or in a similar fashion, so that pressure will tend to force the dam downstream and against the toothed or roughed surface, as shown.

This work should be carefully performed, either by the use of dynamite or steel points and wedges. But dynamite should be used in the hands of an experienced man, who understands placing shots. Especially is this true of the cut-off wall at the heel, for if such placing is done it should be carried out in the manner described.

Care should be taken to so set the upper drill holes to line for a narrower cut than is required, then removing the shattered stone by wedges and points, as it is necessary that the cut-off wall should not be shaken to such an extent that there will be liability of leakage to the downstream side.

A careful note should be taken to see if seams run at right angles with the stream, or partially with the stream; also the character of the stone and of any change in the composition, as there are cases where there are one or two different rock formations in the same river bed.

One or two test holes should be exploded with various charges, at some other point, to determine the proper charge to be used, but vertical holes should not be used, unless absolutely necessary. In this respect it might be said also that a regular 500-volt current will explode twenty holes, and such a number of holes exploded simultaneously will do better work than three or four holes ex-

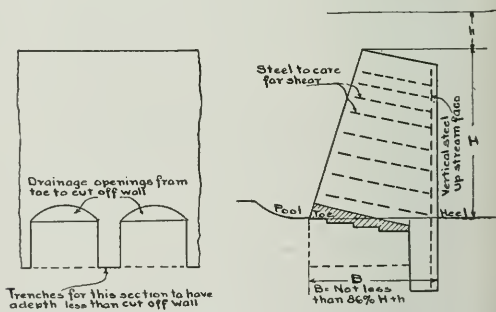

Fig. 4.—Solution of Solid Dam Showing How the Arch Can be Used for Drainage from Cut-off Wall to the Toe.

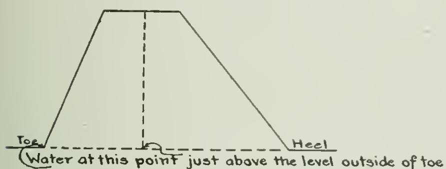
ploded at a time. Holes may be placed as described below:—

Holes running with trench on each side, about 4 ft. apart and at an angle of 45 degrees, with extra holes at each end at same angle, looking the other way. The depth of these holes will depend on the depth of trench required and the width of the same. In addition to this, holes may be drilled from side to centre as shown in the end section, Fig. 3.

The writer has seen trenches cut in this manner, by men who understood tunneling and channeling, that would meet the conditions required in every respect.

Test holes should be drilled to sufficient depths, 10 to 20 ft., more or less, to be sure that no seams or underlying strata of clay underly the rock, and tested with compressed air or water to at least 100 lb. pressure, and pressure maintained for such a time as will surely determine the condition in these test holes. Shale formations are liable to large seams; overlying strata of clay and limestone formations to water channels or recesses. The holes should be drilled from 10 to 15 ft. apart, more or less, depending on the conditions found to exist.

There seems to be no reason why solid section dams should not be constructed in the form of arches that extend from the toe to the cut-off wall, and the spaces under these arches would effectually care for any uplift due to water seeping through or under the dam, supports to the arches, or haunches of the arches, of course, being carried sufficiently below the surface to effectually protect them from wash and undermining, and would be more satisfactory than large pipe placed 8 to 10 ft. apart, more or less. Or 10-in. split tile may be employed for this purpose, which would be more satisfactory than a solid tile, but in any event should be covered with loose stone so as to allow free access to the tile from all sides.



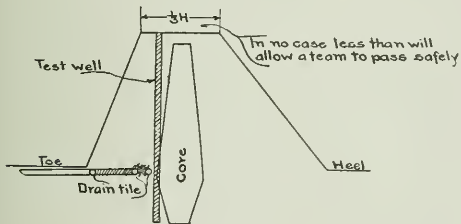


Fig. 5.

There is another condition that must be given consideration in this work, and that is, at the toe of the dam there will usually be found a pool cut out in the rock or other surface, that at or near the centre of the spillway section will have a depth of from one-third to one-fourth of the height of the dam; and it will be found that if this pool is filled with concrete, it will eventually wear to this same depth and there remain about stationary. It would seem to be good policy to retain these pools, unless some other method were taken to care for the action of the water at this point. Some types of dams would probably be less affected than others.

The solid dam may be reinforced and tied to bedrock in the cut-off portion, as described before and as shown here, and thus would take tension in the upstream face of the dam, in addition to which the diagonal bars at some angle would tend to take the tension due to sheer and prevent any tendency to sheer in the horizontal plane, or where new work was tied to old, in case that the joint was not properly cleaned.

The trenches for the haunches for the supports of the arches should have a depth at least equal to the pool and the cut-off wall, preferably somewhat below this. These arches should extend back to the cut-off wall, which should be made sufficiently strong for the purpose, and will give a more efficient drainage than it will be possible to obtain with pipes of any kind.

Referring to the earthen embankment as employed at the abutment ends of some dams, the following construction was employed by the writer, and tests carried on every day for several years to see if there was any increase of the water in the test well (Fig. 5) but no increase was found.

Again, from the core out to the toe every 20 ft., double lines of porous drainage tile were laid from the double line of tile that skirts the core to the double line that skirts the embankment just under the toe and to the outside of the embankment to some suitable disposal plant that would allow of the amount of water running to waste to be measured, from time to time, these drains being covered in turn with crushed stone to a depth of 6 in.; the reason for this being that the writer excavated on one such embankment to the centre of the same, the embankment being composed of a gravelly soil, and found no water until the centre of the embankment, or core, was reached, showing that the drainage kept the embankment dry from a point above the centre to the outside.

As before stated, the surface or foundation on which the dam or embankment is to be constructed should be excavated either in trenches or as shown, as this gives the foundation a greater frictional or sheering resistance.

Table I. gives data on dams, the depth and velocities of waters at the crest for which these were designed; and the actual depth obtained will give an indication of the conditions as they actually exist.

TABLE I.

1	4,185	8.5	9	16.5	1,000	50

18	320	...	5	8	119	..

Dam No. 18 was designed to care for 4,400 sec. ft.; had a total crest length of 450 ft. and a spillway section of about 120 ft., and under flood conditions water rose 8 ft. above spillway section and 3 ft. over the crest, the estimated discharge being 14,500 sec. ft.

There is one other point in the case of gravity dams (Fig. 6) in that the factor of safety of 4 for deck loads has been used, but consideration should be given the following sketch (Fig. 6), also the cost of such work. It is manifestly certain that no load will ever be obtained that would stress the deck to call for a factor of 4, or even a factor of 2, and that a factor of $2H$ would be amply safe even for ice, as with a sloping deck such a factor would protect it from floating blocks or a plane of solid

ice, as the blow would be glancing; and again, the silt which fills in on the deck would act as a cushion. Then again, floating objects are most apparent at flood when the water on the crest is deepest, which would tend to carry these floating objects safely over the crest. And in any event, the stress in the material would not exceed the normal load stress effect. It may be said that load stress is uncertain. This may be true of some dams.

Now, the writer is not advocating a construction that would be unsafe under any consideration, but that more careful consideration be given these conditions on account of cost in a safety factor for loads that would be both safe and economical in so far as the cost of material and construction were concerned, but without going to extremes for a condition that will never be reached.

Records should be kept of the depths of the waters on the crest of the dams at all times, and the cost of an efficient instrument for this purpose is small. Such records, together with the records for rainfall, depth of

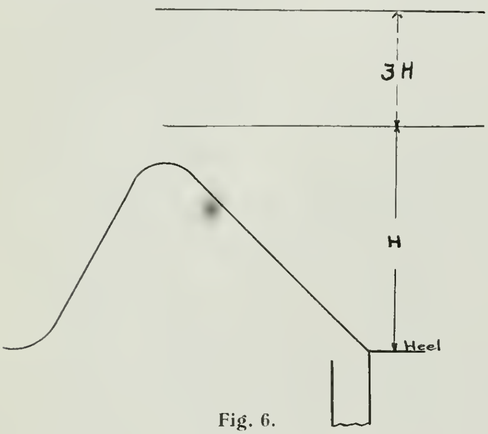

Fig. 6.

rise on the crest of the dam and the time relative to the maximum rainfall, would give data that would be invaluable, in a short time.

Records should also be kept of the soil strata through which excavations for test pipes and test holes pass.

The question of frost at times may have to be considered.

Every available record should be used to determine the run-off from the rainfall on a given watershed, as the run-off and the time of the maximum run-off are affected by so many conditions that there should be as few guesses as possible, and even the records should have a reasonable percentage added.

IMPROVEMENT WORK IN VANCOUVER.

The following is a summary of the street work during the past year in the city of Vancouver, according to a recent report of Mr. F. L. Fellowes, City Engineer. The various works are given in miles:—Pavements, 6.98; concrete sidewalks, 8.78; curbs and gutters, 1.44; curbs, 2.54; gutters, 4.41; clearing and rough grading streets, 11.79; clearing and rough grading lanes, 8.93; clearing and rough grading boulevards, 0.33; grading streets, 20.65; grading lanes, 3.26; grading boulevards, 11.89; rocking streets, 12.24; rocking lanes, 4.45; planking streets, 16.19; planking lanes, 5.87; three-plank walks, 18.03; sanding and oiling streets, 46.88.

BLAST FURNACE SLAG IN CONCRETE.

WITH the rapid growth of concrete construction, the advantage of blast furnace slag as an aggregate in reducing the dead weight has made a strong appeal to many engineers. The result has been that the building codes of several large cities have permitted the use of furnace slag equally with any other material ordinarily used for aggregate. An extended series of tests involving the manufacture of five hundred 6-in. cubes, 100 of these to be crushed at each of the several periods, 28 days, 3 months, 6 months, 9 months and one year, has been recently undertaken. Commenting upon these tests the Iron Trade Review states that as the work progressed, results were such that the number of cubes tested at the 9-month and one-year periods was reduced to 50 each, and it is proposed to crush the remaining 100 cubes at 6-month intervals up to 6 years, 10 cubes at each period. The materials used in the test were all produced commercially, and the work of making the specimens was no better than under ordinary field conditions of construction. Thorough mixing was assured, the work being done by hand.

The cement used was standard Lehigh Valley brand, complying with the standard specifications of the American Society for Testing Materials. The sand used was Jersey gravel. This is not an ideal gravel, but was used because it was the material of the market. The coarse aggregate commercially called three-quarter-inch material all passed the 1¼-in. sieve and were retained on the 1½-in. sieve. All material was in the proportions one part cement, two parts sand and four parts coarse aggregate. The concrete was mixed to the ordinary work consistency, rather wet than dry. The cubes were air stored in a dry cellar, being sprinkled with water once a week. The average compressive strength in pounds per square inch for the various tests are as follows: 28 days, 1,561 lb.; 3 months, 1,952 lb.; 6 months, 2,589 lb.; 9 months, 2,841 lb.; 1 year, 2,797 lb. A study of the test results shows that while at 28 days, 3 months and 6 months, if the number of individual tests fail to agree closely with the general average, the large percentage show considerable greater strength than the general average. A similar study of results at 9 months and one year shows that of the results not in close agreement that the general average, a somewhat larger percentage falls below this general average than runs above it. However, as the results which are above the general average are much more above the average than the low results are below, it may be assumed that the average results are conservative. This is more evident when it is considered that the sand used was not what could be considered as first-class material. Also, the comparatively small size of the slag aggregate must have lowered the strength of the concrete.

The findings seem to point that slag may be employed as an aggregate in competition with broken stone or gravel, since the crushing strength of broken stone or gravel concrete, made under ordinary field conditions, will not generally average much over 1,500 lb. per sq. in. at the age of 30 days. From the actual strength of the concrete developed in these tests, its weight per cubic foot, the recognized solubility of slag which permits it to act as a puzzolanic material, its alkaline nature which is especially conducive to rust-proof in the case of reinforced concrete, and from the relatively high combined percentages of silica, alumina and iron, which make for permanency of the resulting concrete, the conclusion is that slag is satisfactory for use as an aggregate in concrete.

ROAD ECONOMICS.*

By J. E. Pennybacker,
Chief of Road Economics, U. S. Office of Public Roads.

ROAD economics may be defined as that branch of economic science which treats of the cost and use of a road as a public utility. Cost and public utility, in a comprehensive interpretation, are the determining factors with reference to the amount of money to be expended, the method of its procurement, the liquidation of any indebtedness incurred in connection therewith, the location of the improvement, the character of the work, economy in the management of the project, and the utilization of the completed road for the economic benefit of the public.

The subject is logically comprised in two divisions, the first of which deals with those larger questions of legislation, finance, organization, road classification or selection, the utilization of collateral agencies, and the management of the road as a completed project. The second division of the subject, although more limited in scope than the first division, is important from the standpoint of economy and efficiency, as it relates to the various activities in connection with the actual work of construction. Examples under this division would be the lowering of cost by the intelligent use of labor-saving machinery; the keeping of adequate and efficient cost records so as to detect extravagance, incompetence or dishonesty; the systematic purchase of materials, and the use of such other measures as would serve to produce a satisfactory road at the lowest practicable outlay.

Legislation, to be effective, must be economically sound, and it is necessary to the intelligent framing of road laws that the economic considerations applicable to the subject should be known and accepted by the legislators. A system of financing road improvement is largely the outcome of legislation, but is often modified by the exercise of administrative discretion. Organization, like finance, is to a great extent prescribed by statute, but here again the personal equation enters largely in the determination of efficiency or inefficiency. The utilization of collateral facilities of the state, such as convict labor and the aid of state institutions for investigative and educational work is largely determined by law, but here again administrative discretion and the personal equation play an important part. The classification and selection of roads for improvement, although resting upon legislative enactment, are much more largely an administrative question that those to which I have already referred, and the same holds true with reference to the use of the road after completion so as to best serve its purpose as a public utility.

It is thus evident that these basic factors should be correlated and that the undertaking as a whole should conform to those economic considerations which may be regarded as fundamentally sound. I have, therefore, formulated ten fundamental propositions which I hold to be incontrovertible and so self-evident as to be axiomatic. I shall, therefore, first submit these ten axiomatic propositions, and then endeavor to explain to you their practical application.

1. That all who share in the benefits of road improvement should share proportionately in the burdens.

2. That the degree of improvement should be proportionate to the traffic importance of the road improved.

3. That the rate of payment or the rate of accumulation of the sinking fund on any public debt contracted for road improvement should approximately equal the deterioration of the improvement.

4. That road building and maintenance comprise work requiring special qualifications on the part of those who direct it.

5. That responsibilities should be definite as to persons.

6. That continuous employment is more conducive to efficient service than intermittent and temporary employment.

7. That the specialists who direct road work should be appointed instead of elected; and that they should hold office during efficiency instead of for a fixed term.

8. That no road is wholly permanent and that it requires continuous upkeep, for which financial and supervisory provisions must be made.

9. That cash is a much more satisfactory form of tax than is labor.

10. That all agencies at the disposal of the state, capable of use in works of public improvement, should be so used, rather than in such commercial production as would conflict with private enterprises.

The practical application of these ten axiomatic propositions does not involve intricate or impracticable procedure. Under the first proposition, that burdens and benefits should be shared proportionately, I would call attention to the fact that the country road is no longer a mere local utility. The product of the farm is absolutely essential to the existence of the city population, while, conversely, the product of the city factories finds its way to the most remote country districts. There is an interdependence which should carry with it a co-operative sharing of the burdens incident to improving the facilities of transportation between country and city. Legislation should, therefore, be framed so as to provide for city taxation in aid of country road improvement. Automobile owners should individually pay a material portion of the cost of our public roads, and they are already cheerfully doing so in many of the states. Last year the state revenues derived from automobiles amounted to about eight million dollars applicable to roads, out of a total from all sources, state and local, of about $205,000,000. The exact method of apportioning the road taxes is a detail which can readily be worked out by each individual state.

The second proposition, which calls for the improvement of roads in proportion to their traffic importance, strikes at the very root of our present method of apportioning road improvement. Too often have we seen examples of costly improvements distributed according to the dictates of a few influential citizens or according to some arbitrary arrangement of political units or for sentimental reasons, or through a cheerful, haphazard indifference. It is now generally believed that four-fifths of the traffic of this country is carried on one-fifth of the road mileage. It should be manifest that the most heavily traveled roads should first receive attention and should be improved in the most substantial manner. It is entirely feasible to make an expert study of a county road system and indicate graphically the traffic areas for each important road, much as you would show drainage areas for waterways. The yield and the probable traffic in ton miles for these traffic areas can be readily determined so as to establish with reasonable exactness the amount of outlay which the traffic would justify. The relative cost of such a determination would be almost negligible if in-

*Paper read at the Fourth American Road Congress, Atlanta, Georgia, November 9-14, 1914.

curred as a preliminary to a large outlay for actual construction.

The third proposition, that debts should be liquidated in proportion to the deterioration of the road, is intended to prevent the incurring of a debt which will outlive the utility which it was designed to create. There are two extremes in the controversy which rages over this question of public debt. There is the one faction which either opposes debt in any degree, or contends for an indebtedness of such short term as to make it almost a cash transaction, and asserts that the road is entirely destroyed long before the debt becomes due. The other extreme faction contends for long-term indebtedness, on the theory that as posterity will reap the benefits it should bear the burdens, and that a road well maintained never wears out. As a matter of fact, location, if intelligently made, should be permanent; likewise all reduction of grades. The drainage features, if honestly and efficiently constructed, should be reasonably permanent. The road, except under extraordinary conditions, should, therefore, be considered reasonably permanent as to these features. As a general rule, the foundation of a road should not require renewal if the road is subjected to adequate and continuous maintenance. Avoiding any detailed consideration of the exact proportion of the total cost of a road represented by these features, I should say that in general the permanent features would average at least 50% of the total cost. So that, if the other 50% must be figured as perishable and subject to renewal, the debt should not cover a period longer than twice the length of this perishable portion. For example, if a macadam road is constructed at a cost of $6,000 per mile and has an estimated life of ten years, the bonds could run twenty years, because, at the end of ten years the depreciation is $3,000 and the actual value is $3,000. Another expenditure of $3,000 is made and at the end of twenty years when the bonds become due, there has been a total outlay of $9,000, against which should be credited the permanent value of the road at $3,000, making the net outlay $6,000, or the face amount of the bonds. This is merely an example and a generalization. It would be desirable to ascertain the permanent and perishable portions in each undertaking.

The fourth proposition, which calls for the employment of specialists in road work, is so nearly self-evident in its application as to require very little explanation. I should say, however, that if the laws of the state would require that all persons selected to have immediate direction of road or bridge construction and maintenance must possess practical knowledge and experience, and if this fitness should be tested by some sort of competitive examination to be prescribed by a state highway department, acting either directly or through a civil service commission, the net result would undoubtedly be the saving of many millions of dollars of road revenue and a wonderfully increased efficiency in our road system.

The fifth proposition, that responsibilities should be definite as to persons, is aimed at the elimination of our present complex and cumbersome system of road management. If all of this antiquated organization could be swept aside and in its stead one or a few officials endowed with authority and charged with responsibility in each county, the beneficial effects could not fail to be most marked. If the people, individually or in a representative capacity, could immediately place their finger, so to speak, upon the man responsible for the discharge of public duties we should have no more political juggling and the passing of responsibilities and duties onward in an endless chain.

The sixth proposition, that continuous employment is more conducive to efficiency than temporary employment, finds its antithesis in our present annual or semi-annual junket which we call "working the roads." It is so self-evident that a minor defect in a road can be repaired at its inception with little effort, and that if allowed to go on it may require the entire reconstruction of the road surface, that is seems scarcely necessary to urge the soundness of this proposition. If a small force of laborers with necessary tools and teams were employed throughout the year on the roads it would not cost any more money than to call out a small-sized army of road hands twice a year, and would not only result in quick repairs where needed but would also insure that the most work would be done at the places where it was most needed. The force would be small, mobile, trained, interested, subject to effective discipline and altogether infinitely more efficient than the unwieldly forces now employed.

The seventh proposition, which calls for appointmen rather than election and for the holding of office during efficiency instead of for fixed terms, is designed to attract to the work men who look upon road-building as a life profession or occupation. A good engineer may be a very poor politician and a good politician may be a very poor engineer, but in a contest in which votes are essential the good politician will usually defeat the good engineer, although the position requires engineering ability rather than political ability. Do not spoil a good highway engineer or superintendent by making him cater to the popular fancy. If he is the right man in the right place, it is absurd to limit him to a fixed term, for his position is not a reward. The county is purchasing his services and is supposed to get value received, and it should continue to purchase so long as he delivers the goods.

The eighth proposition, that no road is wholly permanent and that it requires continuous upkeep, is intended to impress upon legislators and administrative officials the necessity for making adequate financial provision to care for roads, no matter how costly or efficient their construction. A house is not permanent without repair, a railroad track is not permanent without repair, then why should public funds in a large amount be expended in road construction which, without adequate maintenance, may deteriorate to the extent of 50% in a few years? It would seem almost a reflection upon your intelligence that I should urge upon you these conclusions which are so generally understood and accepted, were it not for the fact that their acceptance is very largely in theory and not in actual practice.

The ninth proposition, that cash is a much more satisfactory form of tax than labor, is put forward as a protest against the continued cherishing that old heirloom known as "statute labor." If A owes B $10 and B has the option of collecting that $10 in cash or taking the amount out in labor which A shall select and which is totally unfamiliar with the character of work which B requires and which would be semi-independent of any control by B, we should consider it very unsound business judgment if B were to accept the payment in labor instead of cash. If you provide an efficient highway engineer or county superintendent with a modest amount of cash and let him select competent, efficient laborers, he can quadruple the effective results obtained by the same number of laborers under the old statute system. I know that there are sections of country where it is almost impossible to collect a cash tax. A certain amount of discretion might in such cases be entrusted to the county authorities to accept payment in labor.

The tenth proposition, that state agencies which may be used in works of public improvement should be so used instead of in commercial undertakings, is directed partially toward the convict labor question, and is based

upon the assumption that offenders against society owe a debt to society which should be paid in such form as will most benefit society, and the further assumption that honest labor should not be discriminated against through the sale or disposal of products created by criminal labor. The practical application of this proposition would mean the employment of convicts in road-building, the preparation of road materials, or in other works of public improvement so far as practicable. This proposition is intended also to emphasize the necessity for correlation of the states' various agencies in the interest of road improvement. For example, a state geologist should be helpful in the selection and location of road materials, the laboratories of state universities should be useful in the testing of materials, the university staff should be helpful in the givng of theoretical instruction and in many cases in practical extension work, state bureaus of statistics and agriculture should be helpful in accumulating essential data for the road improvement work in the state, and state civil service commissions should be of very great use in the inauguration and conduct of the merit system in the filling of positions requiring technical or practical qualifications and experience.

PROPOSED CAR LINE EXTENSIONS FOR TORONTO.

Four by-laws providing for the expenditure of $500,000 for transportation utilities are likely to be presented to Toronto ratepayers on January 1st. The works and expenditures involved are as follows:—

(1) Construction of civic car line on Lansdowne Avenue from St. Clair Avenue southerly to connect with the northern terminal of the Toronto Street Railway line on that street at a cost of $105,000.

(2) Construction of a double track civic car line to serve North Toronto, commencing at or near Yonge Street and Shaftesbury Avenue, easterly across the Reservoir Park ravine parallel to the C.P.R. tracks, northerly on a proposed street to the corner of Rosehill and Clifton Road, north on Clifton Road and Erie Street through Mount Pleasant Cemetery, on Alberta Avenue and Mount Pleasant Road to near Broadway Avenue at a cost of $320,000. The above definition of the route has not been definitely settled upon by the works commissioner and will probably be subjected to one or two minor changes. Before work on the line could commence the works commissioner has thousands of dollars of sewer work to lay on the proposed route and a road to construct through Mount Pleasant Cemetery. This road is to be permanent and must be sewered the whole length before the roadway can be constructed.

(3) Proposal to purchase all the tracks of the York Radial Railway from Queen Street within the city limits at a cost of $52,000. The company's franchise on this portion of the line ran out last year.

(4) A proposal to purchase $100,000 worth of motor buses to establish services at unspecified sections in the city.

M. Beatty and Sons, Limited, Welland, Ont., announce that they have opened a district office in Toronto with address 154 Simcoe Street, where they are represented by Mr. K. M. McKee, formerly of the head office. Previously this company has been represented in Toronto by H. W. Petrie, Limited.

ADMINISTRATION OF WATER RIGHTS IN BRITISH COLUMBIA.

By William Young,
Comptroller of Water Rights.

THE history of water administration of British Columbia for the past 50 years may be said to be the history of water administration of several of the Western States of the Union south of the International Boundary. From the time when the province became a Crown colony the ownership of the waters in the rivers and streams has been vested in the Crown, and in the circumstances, water rights were granted through a period of well over forty years, unfortunately in those early days in an unmethodical manner. The result is that there are streams that have been over-recorded many times, and again, many of these records are a hundredfold in excess of the requirements for which they were taken out. Although throughout these years there was a water law that provided for granting of rights, such law contained no machinery for administration afterwards. With this weakness in the law and the fact that records were granted by government agents in different sections without reference to a central authority, the final condition became one of chaos. Just as some of the states to the south have faced a similar condition and set things in order, so have we had to set about this work, a beginning being made in 1909 when steps were taken to terminate the growing confusion; but no organized effort was made until the summer of 1912, when the Hon. Mr. W. R. Ross called in able advisors to formulate a system and advise the best method of undertaking the work.

There is now nothing new to present in the administration of water rights in British Columbia. In taking up the many problems that confronted us we went about it in the same manner that the trained scientist undertakes some new field of research. An effort was made to ascertain what had been done in other countries. While amendments to the Water Act were made in 1913, the results of organized expert effort may be said to have crystalized in the amended act of 1914. We do not claim that this act as it now stands is perfect, far from it; for during the preparation of amendment of the act complete organization of office and staff has been well advanced, current work taken care of, an order of work established and the problem of handling the large quantity of work in arrears commenced. As regards investigating the work that other countries have done, it may be said that we have just entered on the border of a vast realm; for of all applied sciences irrigation may be said to be the oldest, not to say anything of water power or waterworks.

The foundation of our administration of water rights is our water law. What follows hereinafter is a brief analysis of this law, an outline of our order of work, and a few remarks with respect to administrative problems and of how the administrative staff deal with the work.

The basic principle of our water law is set out at the beginning in the declaration that all the unrecorded water in any stream is vested in the Crown in the right of the province. The purposes for which water rights may be acquired are there given. Organization and administration are next taken care of. Procedure in the acquirement of water rights follows, then the organization of communities, associations and municipalities, and lastly the Board of Investigation, its functions and procedure.

Under the chapter "Organization and Administration," the law briefly authorizes the appointment of the

comptroller of water rights, and the Board of Investigation, each with specific powers; the appointment of district engineers, also with specific powers; the division of the province into water districts and the appointment of water recorders. The law then sets out the administrative duties and powers of the minister, also those of the Lieutenant-Governor-in-Council. With respect to the latter, one of the most important powers is the making rules and regulations for the carrying out of the spirit, intent and meaning of the law. With this basis to work on, the organization is elaborated.

The comptroller of water rights issues all licenses and administers the act in accordance with the rules and regulations in their application to the various purposes in which water may be used. He is also empowered, with the approval of the minister, to carry on such topographic or hydrographic surveys and other engineering investigations as may be in the public interest. The Board of Investigation was formed for the purpose of hearing claims, determining old rights and adjudicating thereon. The Lieutenant-Governor-in-Council or minister may, however, refer any matter, question or thing to the board for the purpose of obtaining information or making any enquiry thereon. As constituted, the board normally consists of three members, two of whom shall form a quorum. The comptroller of water rights is a member of the board in all matters excepting those pertaining to old records.

The division of the province into water districts is in the interest of efficient administration and the engineers appointed to supervise such districts have stated powers to enable them to enforce "beneficial use" of water and settle disputes; in other words, the district engineers represent and are deputies for the comptroller of water rights. The water recorders, usually the government agents, act as representatives to the comptroller to the extent of receiving applications for water rights, such applications are advertised and then filed with him, so that the neighbors of the applicant may have an opportunity of ascertaining if their interests are affected. The rules and regulations deal particularly with petitions, surveys, plans, fees and rules covering the use of water rights.

It is not the intention at this time to enter into any description of how water rights may be acquired for the reason that there is a marked similarity to the procedure that obtains in many of the water laws of other parts of North America. Suffice it to say, however, that the procedure is now simplified in the interest of the settler so that it is no longer necessary for him to call in a lawyer. Already this feature has proven a boon to many a pre-emptor or small owner to whom a lawyer's fee would be a charge he could ill afford.

The purposes for which water rights may be acquired are fourteen in number and, although they are all important, three great purposes stand out with prominence:

(1) Irrigation, whether by individual, community, company or municipality;
(2) Power;
(3) Waterworks.

A broad distinction in purpose may be said to exist: "Purposes that affect the public interest" and "purposes that affect the individual." Around these groups our administrative machinery may be said to be constructed and in their light the department is in a process of organization for effective and efficient administration.

The creation of the organization we now have may be said to date from 1910, when the administration was centralized in Victoria. During 1911 and 1912 considerable progress was made in the creation of a system adapted to the business of administration, in expert investigation of conditions, and in formulating an order of work. 1913 witnessed the division of the province into water districts, the opening of branch offices and the appointment of district engineers; also a united effort in the preparation of rules and regulations for the administration of the act, and important amendments to the act, among which may be mentioned a chapter dealing with irrigation, whether by community, company or municipality. Very important amendments to the Railway Belt Water Act were also made, whereby the administration of water rights in the railway belt finally passed from the Dominion to the province, and as an outcome of this the British Columbia Hydrographic Survey was organized for systematic work throughout the province.

The effective work of administration may be said to have begun in this year, and that there might be uniformity of effort, the order of work referred to as having been adopted in 1912 was slightly revised to meet the conditions. This order is as follows:

1. Investigation of old records.
2. Systematic and continuous work in stream gauging.
3. Study of the proper duty of water.
4. The prevention of wasteful use of water.
5. Policing of streams.
6. Economic distribution and delivery of water.
7. Inspecting water systems to determine their efficiency and safety.
8. Determination of storage possibilities.
9. Investigation of water powers.
10. Investigation of source of domestic water supply.

This order of work involves the three great groups of purposes referred to, and which are, in each particular district, of greater or less importance.

Investigation of old records comes first, and necessarily so, for the very good reason that effective administration was quite impossible until the chaos of almost 50 years had been cleared up. Under these circumstances the efforts of our district engineers have been largely concentrated on engineering investigation of those records, although every line of work has been given more or less attention. There are about 8,000 of these old records, practically all of which have now been reported on. These preliminary reports have been of great value to the Board of Investigation. The hearings now held by the board are very different to those first held without such preliminary engineers' reports. The success resulting from the efforts of this tribunal during the past two seasons is as much due to these reports as to anything. Decisions on 2,000 records have been rendered, and to date but five appeals have been filed, two of which are now in default. We are hopeful this measure of success will continue. In some of the districts the board work is complete, and we are now fortunately in a position to follow more fully and carefully the various other lines of work, with results that have been most encouraging.

I have referred to three great purposes as being of public interest, *viz.*: Irrigation, water power and waterworks. Since the difficulties met with in administration centre around these, we will refer to them in due order.

The Administration of Water for Irrigation.—Prior to 1914 there was no provision in the law that would enable the officers to cope with the conditions that already existed, and under the circumstances their hands were practically tied. The Water Act of 1914, however, included new sections which involved basic principles and

made administration for irrigation possible and effective. These principles are:—

(1) "Limiting the quantity to beneficial use," that is to say the quantity of water used per acre shall be limited to such quantity as experience may from time to time indicate to be necessary for the production of crops in the exercise of good husbandry.

(2) "Rotation in use," when a number of water users may arrange a system of rotation that will best meet the requirements of growing crops and at the same time secure an economic use of the water.

(3) "Consideration of the particular crop grown," a provision which opens the way for adjustment that is in the interest of the community as a whole.

As to what kind of crops should be grown, I do not consider myself qualified to discuss such an important subject; but as regards these principles and their administration I am reminded of a statement credited to Sir William Wilcocks in reference to the control of use of water in the prevention of deterioration of land: "In this respect the government is autocratic and can and must enforce the regulations devised by its experienced advisors. It need not await the slow education of the great body of water users before adopting those practices which experience has shown are necessary for the general prosperity."

For the administration of these principles the powers of the district engineers were enlarged, and in carrying out "rotation in use" they may arrange when necessary for the appointment of water bailiffs whose duties are clearly set out in these sections and whose authority is backed up by the Police and Prisons Act. These principles and the provision for their enforcement are not new. In referring to the history of irrigation, particularly in countries where it has been practiced for centuries, we are told that the water that irrigates your field has to flow in a channel which passes the field of all your neighbors and cannot be maintained in a state of efficiency unless all do their duty, and it is easy to understand how method, order and obedience to a properly constituted authority very soon developed themselves. We are also told how autocracy was introduced into a free community of irrigators on small, independent canal systems and in times of difficulty the irrigators chose from among themselves a dictator for the whole period of scarcity of supply and his orders are obeyed and respected as though he were an absolute monarch, and further, that they invariably chose a good man."

In short, success here may be said to depend upon the human equation and we have kept in mind these facts of old-world practice in the appointment of bailiffs, insisting upon these men having the confidence and respect of the communities in which they reside. The result of the introduction of these principles in some districts where water feuds have existed for years has been most encouraging. Irrigators have again become friends and neighbors, realizing that their individual success and prosperity meant the prosperity of the community. In one particular instance where an order of rotation of water was instituted, as the water became scarce it was found that some of the prior record holders had ditches that absorbed all the water in the creek before it reached their land. As this state of affairs became obvious the bailiff eliminated these record-holders from the order of rotation in the use of the creek, and to the credit of these men it may be said that, although in other years they had caused trouble, they now acknowledged the justice of the bailiff's ruling, they could not make beneficial use of the water, and it was not in the interest of the community that they should prevent others from doing so.

Then there are other important features in the interest of irrigation that permit of effective administration and encourage organization that will mean not only development, but greater co-operation among farmers. These are:—

(1) The organization of water users communities;

(2) Organization of mutual water companies;

(3) Organization of public irrigation corporations, or irrigation municipalities.

Time will not permit of reference to these, other than to state that enterprise has been stimulated in different farming sections. Irrigation communities are being formed and the department have now under consideration a number of petitions for the formation of irrigation corporations in respect of which the preliminary engineering work is well advanced. It is expected that the various conditions required by the act as regards organization and management will be fulfilled during the coming winter, and that another year will see several irrigation corporations or municipalities in operation.

Administration of Water Rights in the Development of Power.—This purpose and its administrative requirements has received quite as much consideration as the purpose of irrigation. Recent amendments to the act in this respect were but few, but of great importance. It is no longer possible for a company to organize with the minimum of capital permitted by the Companies Act for the purpose of carrying out an undertaking requiring several millions of dollars. It is now impossible for a purely speculative element to secure and hold indefinitely a valuable franchise. The administration in this respect is largely governed by rules and regulations that the Lieutenant-Governor-in-Council may from time to time make for carrying out the spirit, intent, meaning and purpose of the act. In respect of power, these rules deal with surveys, construction, the operation period and fees. In regard to the companies now operating the determination of the fees to be charged is now occupying our attention. How such fees should be arrived at is clearly set out with an alternative; this alternative being that the fees may be based on a reasonable station output. For the present, we are taking this as the average daily horse-power arrived at from the total output in kilowatt hours at the power house switchboard. As the old records are eliminated and licenses substituted therefor and the organization for effective administration progresses, we shall in due course go more fully into the question of fees, basing such on the several factors set out in the rules rather than on the basis which has been adopted for the current year.

Hydro-electric power is essentially a specialty and to deal with it in a proper way, a section of our staff will, in due course, give its whole time to its administration and study.

The problem of water power administration and policy is one of economic importance and the question that confronts us is to what extent should the Crown become interested. On the one hand we have the example of the Hydro-Electric Commission of Ontario, the progress of which we must carefully follow, analyzing the reports and criticisms pro and con. Then there is, on the other hand, the necessity for encouraging investments of private capital, subject, however, to the principle that public utilities as natural monopolies must be under regulation by the Crown. What the ultimate result will be only the future can tell.

As the province must know something of its assets in water powers the work of stream investigation has been taken up. This work for the season now closing has been more especially in the Okanagan Valley and, comprises topographic work, and stream investigation for power, reservoir investigation, stream gauging already having been arranged for. Small powers are not overlooked. It is only necessary that data be made available in some instances to bring about development, as a small power may mean an important industry to some community.

Administration of Water Rights for the Purpose of Waterworks.—Administration in the issue of licenses and collection of annual fees is usually plain sailing in this purpose. There is, however, a phase of it that is of great importance and in the public interest, "The investigation of the sources of domestic water supply, particularly for large centres of population." Many of these watersheds are still Crown lands, and the Crown, as the land and water lord, is in a position to introduce practical conservation. During the past two seasons a field party has been continually at work following a set order in:—

(1) Determination of timber area.

(2) Cruising to determine how much timber is merchantable and whether the timber as a whole is a factor in the regulation of stream flow.

(3) Cruising of alienated timber.

(4) Extent of run-off.

(5) Obtaining the area of alienated land and the purpose for which it is held.

(6) The investigation of other rights, whether water or mineral, and the use to which they are put.

In a new country like British Columbia the value of this work must become of greater importance as time goes on. With the co-operation of an active Provincial Board of Health there will, in due course, be available data for the various centres of population that will be a guide in securing and guarding their sources of pure domestic water. The most important work in this respect now in hand is the survey investigation of the watersheds from whence comes the domestic water supply of Greater Vancouver. The results already obtained have enabled us to make equitable decisions in respect of licenses held by the municipalities who were at variance with one another. It is obvious that Vancouver must become a large city, a great railway and shipping centre. With this in mind we are compiling all the facts. The protection of Vancouver's source of domestic water supply has been rounded out to such an extent that when the time comes to provide for larger demands there will be few difficulties in the way.

Hydrographic Investigations.—When the province assumed from the Dominion the administration of water rights in the railway belt the latter decided to continue its hydrographic work in this section. It was, however, considered that it would be advantageous to the province if it could co-operate with the Dominion along lines similar to those in operation in the United States. An agreement accordingly was arrived at, and and we now have the British Columbia Hydrographic Survey. The officers of this organization have no administrative powers in respect of water rights. Outside the railway belt their whole time is devoted to hydrography, results of their work being available to the Water Rights Branch for administrative purposes. Our district engineers are thus to a large extent relieved of this work, except in sections where irrigation is practised, and proper administration depends on a direct knowledge of stream flow. In this respect we have, to some extent, adopted the system in use in Oregon, charts being prepared to show graphically the relation of records to stream flow, from which it may be seen at a glance those licenses that have to depend upon storage, and to what extent a stream may be recorded on.

I have referred to the lines of work of the district engineers as covering these three great purposes. And while I have stated that every line of work laid down has received attention in one or other of the districts, it has been impossible at the present date to give all the lines in each district the full attention they merit. For example, take "Duty of Water," a work that will demand the whole time of one man, who must specialize, and whilst this is so, it is not the intention to relieve the district engineers of their responsibility. On the contrary, their co-operation is essential, and they will be required to keep in touch with all work within their districts and to be here and there in the event of contentions arising.

In conclusion, if the administration of water rights is to count for anything, the requirements of the different sections of the country must be anticipated. To this end we have concentrated our efforts on the Okanagan Valley. By the end of another season every stream will have been traversed, every reservoir surveyed, every watershed determined, and the timber cruised; stream gauging all the while having been carried on. In fact, a thorough water investigation will have been completed in anticipation of development that is bound to come. The problem of well drilling in its application to bench lands is also under investigation; also the problem of irrigation by pumping with a view to obtaining and marshalling all the experience of other countries that we may apply them to British Columbia.

In the general conduct of the administration of water rights, whether at headquarters or in the field, we are endeavoring to follow the principles of good business by giving prompt attention to enquirers and water users; unbiased decisions where there is dissension; and in being thorough and comprehensive in field work and other investigations that we from time to time may undertake.

THE REGINA ENGINEERING SOCIETY.

At the annual meeting of the society, held recently, Mr. L. A. Thornton, works commissioner, Regina, was elected president, and J. M. Mackay, superintendent of waterworks, Regina, was re-elected secretary for the year 1914-15.

About 30 members took part in a visit to Moose Jaw on October 17th, where the city engineer, Geo. D. Mackie, had made elaborate arrangements, including a special street car and a group of automobiles, for showing the party about the various works of engineering interest in the city. Amongst those visited were the power station, where a demonstration of the recently installed high-pressure water system was given; the sewage disposal plants; the new Dominion Government internal storage elevator, and the Robin Hood flour mills.

The society's annual dinner was held in Regina on November 5th, the guests including His Honor Lieut.-Gov. Brown, Chief Justice Haultain, Wm. M. Martin, M.P., Regina; J. F. Bole, M.L.A., Regina; Robt. Martin, mayor of Regina, and Jas. Pascoe, mayor of Moose Jaw.

The next meeting of the society is being held in the Regina College at 8 p.m. on Thursday, December 3rd, the president delivering his inaugural address.

Editorial

PURIFYING RESERVOIR WATER WITH COPPER SULPHATE.

Interesting results have been achieved at the City of Gloucester (Eng.) in dealing with the nuisance, in the city's reservoirs for the supply of potable water, caused by the excessive growth of weeds which, decaying, created an offensive odor and gave an objectionable color to the water. At one time it was necessary to reduce the excessive growth of the weeds by the use of rakes—a process which involved considerable annual expense. As a consequence of experiments conducted by Mr. Geo. Embrey, F.I.C., the analytical chemist to the Gloucester County Council, the nuisance from the weed growth has now been effectually combated. The Witcombe reservoirs of the corporation were at the time choked with "Chara Vulgaris," a plant which is propagated by means of spores contained in an archegonium and fertilized by antheridia. The bursting of the archegonium sets free myriads of minute greenish cells which, with the countless anthrozoids, give the water a distinct color and a fishy odor. It was found that the use of copper sulphate in quantities of 1 to 1,000,000 was eminently successful in destroying the lower forms of plant life without injuring the fish or rendering the water toxic to human beings. One of the methods of applying the copper sulphate is to place the crystals in a canvas bag and trail this at the stern of a moving boat. Another method is to scatter the fine crystals over the surface of the water as in sowing seed, the crystals falling rapidly to the bottom of the reservoir before dissolving. This has an advantage over the former process where the solution is much diluted before reaching the bottom.

The three reservoirs of the Gloucester corporation have a total capacity of 120,000,000 gallons and the quantity of sulphate used is 400 pounds on each yearly application, or 1 to 3,000,000, which is found to be adequate to keep down the weeds. Each reservoir so treated is allowed to stand at least 3 days, and where possible a week, after the application, at the end of which period it is fit for domestic use and no trace of sulphur can be found in the water. The treatment, it has been found, is best carried out in the month of February, when the bottom of the reservoirs is usually covered with diatoms only; in March and April, under ordinary conditions, the confervæ make their appearance and later the Chara begin to grow. But if the sulphate treatment be applied in the early stages the diatoms are destroyed and neither the confervæ nor the Chara appear. Moreover, if the operation be performed with care and under proper supervision no danger need be feared.

NEW STEEL PLANT IN OPERATION.

Along with the encouraging reports of increased activity among steel companies has come the announcement from the Armstrong, Whitworth of Canada, Limited, that its new mill at Longueuil, Que., is practically completed and will commence business in all its branches before the month is ended. Although controlled by English capital, this company is essentially a Canadian manufacturing concern, employing Canadian workmen, and manufacturing grades of steel which, up to the present, have been scarce commodities in this country. A high-grade crucible steel for the manufacture of drills, taps, cutters, dies and other tools belonging to machine shop practice, will mark the initial activities of the new plant. Drop forgings will be started early next year, and it is the intention of the company to extend its present plant by the construction next season of a projectile shop.

Sir Percy Girouard is president of the company and the other directors are the Right Hon. Sir George Herbert Murray, P.C., C.B.; Saxon William Armstrong Noble, George Green Foster, K.C., and Matthew Joseph Butler, C.M.G.

PLANS TO REBUILD BELGIAN BRIDGES.

An important conference was held in Toronto last week by representatives of the Canadian Pacific, Grand Trunk and Canadian Northern railways, and of the Allan, Canadian Pacific and Canadian Northern steamship lines. The project under consideration was the rehabilitation of the numerous railroad bridges in Belgium and France, that have been destroyed in military operations. It was felt that the reconstruction of these bridges meant to Canada the employment of great numbers of men and the outlay of millions of dollars. Communications from the seat of war pointed out the enormous task which European engineers had before them in replacing railroad bridges in the shortest possible period of time, and bridge builders are of the opinion that field fabrication will largely give way to the transportation of entire sections of steel bridges from other parts of the country to the desired location. Discussion centered upon the steel bridges in possession of the railroads and not in use, since their removal to make way for heavier structures. It was stated that these released bridges, if laid down in Europe, could be of great service, as they might be immediately installed to replace those destroyed.

Those who took part in the conference were: J. L. Perron, solicitor for the C.P.R. and Montreal Tramways Company; Wm. Lyall, of the P. Lyall Construction Company; Timothy Foley, E. T. Foley and O. W. Swenson, of Foley, Welch and Stewart; W. F. Tye, civil engineer of Montreal; Patrick Dubec and Jno. Jenkins, Montreal railroad men; C. W. Allan, of the Allan Line, and Hugh Sutherland, of the C.N.R.

PROGRESS ON THE HUDSON BAY RAILWAY.

From Le Pas to Thicket Portage, a distance of 185 miles, the new line has been practically completed. It will be remembered that a year ago this portion of the line, known as Section 1, was graded for a distance of 130 miles and had received steel for 60 miles. Section 2, extending from Thicket Portage to Split Lake, a distance of 68 miles, has been graded and steel is now being laid. On Section 3, the remaining 165 miles between Split Lake and Port Nelson, considerable clearing and grading has been done. Officials of the Department of Railways and Canals, Ottawa, state that the work will be continued throughout the winter, and that completion of the Hudson Bay Railway may be looked for early in 1916.

SASKATCHEWAN LIGNITE.

THE sole sources of fuel in Southern Saskatchewan are the brown deposits of coal, which, in quantity, is estimated in billions of tons lying east and west of the Souris River. It is of marked woody structure, but its character throughout practically all the deposits is a true lignite of cretaceous age. A full report will shortly be presented by Mr. S. M. Darling, who is in charge of the government's lignite experiment station at Estevan. It will be looked forward to with interest, as this source of fuel and power premises bright prospects for the industrial future.

This lignite, as it is found in Saskatchewan, requires drying to eliminate a 30% content of water. It is then crushed to about 1 inch in size, the larger sized lumps of dried fuel being then suitable for burning on automatic stokers, while the smaller sized lumps pass on to the carbonizing oven for treatment before being briquetted.

Mr. Darling states that at Superior, Wisconsin, he recently dried a carload of lignite, briquetted it and burned the briquettes in a boiler test under the boilers at the Parliament Buildings, Regina. The amount of water evaporated per pound of fuel as fired was 6.36 pounds. Temperature of feed water 57° F. Last January in a test at the city power plant, using a good Alberta coal, under like conditions, the amount of evaporation was 6.5 pounds per pound of fuel as fired. "With equipment designed specially to handle this lignite," states Mr. Darling, "we can make briquettes that will be fully equal to the western coals is evaporative efficiency."

The lignite dust is very explosive. The drying plant must be equipped with explosive safeguards, and a plant equipped for the purpose can remove practically all of the moisture.

No byproducts are, of course, obtained where the lignite is simply dried.

The most profitable way to utilize the lignite is to carbonize it; that is, to distil off all volatile matter.

On carbonization, the products, in round numbers are:

1. Gas, per ton of lignite......	10,000 cubic feet
2. Oil or tar per ton	15 gallons
3. Ammoniacal liquor	35 gallons
4. Carbon residue	1,200 pounds

The gas has a heating value of 400 British thermal units per cubic foot and makes a good "town gas," for use in stoves and ranges. It is not a good illuminating gas; it is serviceable principally for fuel and power.

There is more gas in one ton of lignite than is required to carbonize the next ton. This surplus gas has a very direct bearing upon the matter of cheap power. Six thousand cubic feet of gas are required to carry on carbonizing, leaving a surplus of 4,000 cubic feet per ton to be used for power.

The market for domestic fuel, states Mr. Darling, is very large and it is not unreasonable to expect that the demand for carbonized lignite, for gas producers and domestic fuel in the shape of briquettes, will be sufficiently large to yield from the surplus gas all of the power required within a wide range of the lignite fields. The power derived from this surplus gas costs less than Niagara water power, $8 per horse-power year. If necessary, the amount can be augmented by using carbonized lignite in gas producers.

The oils and tars extracted from the lignite can be put to many uses—fuel oil, creosoting oil, leather preservative, water proofing, tar paper, roofing pitch, etc. The pitch makes an excellent binder for briquettes and will go far towards reducing the cost of this item. Almost all our coal tar dyes and other coal tar products have heretofore come from Europe, principally Germany. Several million gallons of creosoting oils for preserving timber have been imported annually. That supply is now cut off and the value of these materials on this continent greatly enhanced.

From the ammonia compounds is derived a substantial quantity of valuable fertilizer.

Lump carbonized lignite is the ideal gas producer fuel. The amount of gas is equal to that from anthracite pound for pound, but the gas is richer, has less tar and less clinker and burns more freely.

The 100 horse-power producer gas plant in the Leader Building, Regina, has used six carloads of this carbonized lignite, and on anything approaching a full load they got a horse-power on each pound of fuel. There are two dozen gas producer plants in this territory that will use this carbonized lignite when it can be supplied in sufficient quantities. It means a reduction of 30 per cent. in their fuel bills.

As a domestic fuel the carbonized lignite briquettes are fully equal to anthracite, ton for ton. They have a heating value of 12,000 British thermal units per pound as against anthracite's 13,000 British thermal units. But there is no clinker from the lignite briquettes, no loss in burning, and they can be used nicely in kitchen ranges, which is impracticable with hard coal.

This drying, carbonizing and briquetting of the lignite results in substantial economies from the standpoint of the mine owner. There is not the large waste in screenings as at present; every pound mined is used for some purpose. The product is put into such a condition that it can be stored indefinitely and shipped any distance without deterioration. This is not possible with the raw lignite, which can be mined only as it is used. The lignite mines are therefore idle a large part of the year. This ability to operate at a steady rate throughout the year, storing the products during the summer for shipment in winter, will effect a decided reduction in the cost of production.

To sum up:—

1. For domestic fuel for heating and cooking there are dried or carbonized lignite briquettes.

2. For steam raising purposes there are dried lignite for automatic stokers, dried lignite briquettes for hand-fired furnaces and powdered fuel.

3. For electrical power there is the carbonized lignite for use in gas producers at local points in different parts of the country; and, when the time comes, if it is not already here the surplus gas from the carbonizing process will be adequate to generate current at Niagara rates for distribution over a wide area from a central station at the mine.

4. Finally there is the utilization of the byproducts, which is bound in time to be a large industry in itself.

RAPID LINE WORK.

A construction gang of 9 men belonging to the engineering staff of the Hydro-Electric Power Commission of Ontario, is in possession of an excellent record for speedy construction. Between October 26th and November 10th it erected 450 steel transmission towers, and strung 8 miles of wire.

THE STRENGTH AND DESIGN OF WASHERS IN REFERENCE TO THE BEARING ON WOOD.

At the present time very few washers are designed with any idea of obtaining economy of design. An amount of metal is cast in a certain shape and trusted to hold the load to which it is to be subjected. But owing to lack of definite knowledge on the subject it is customary to add considerable unnecessary metal to a washer simply to insure safety. In the casting of washers, however, the cost varies directly with the weight and the question of an economical design should be a vital one. The common washer is essentially an uneconomical one in design and it seems possible that a design with less metal and sufficient strength could be obtained. It was with this in view that a careful study was undertaken by L. R. Rodenhiser, whose results appeared in a recent issue of The Cornell Civil Engineer.

The objects of his investigation were two-fold: (1) To determine the safe bearing value and ultimate strengths of different woods under different washers. (2) To determine the economic size of washers and their weights in order to make the first aim as high as possible and yet keep the weight of washers down to a minimum.

Four kinds of wood were selected and tested by the end test with the following results: Douglas fir, 9,000 lbs. per sq. in.; oak, 9,000; whitewood, 4,500; and white pine, 3,600 lbs.

The conditions of the test were as nearly like actual conditions as possible. A hole was bored in the wood the size of the hole in the washer and the two holes placed concentric. The loads except in two cases were applied by a nut. In those two cases an edge was used to apply the loads. The depression of the washer into the wood was very accurately measured.

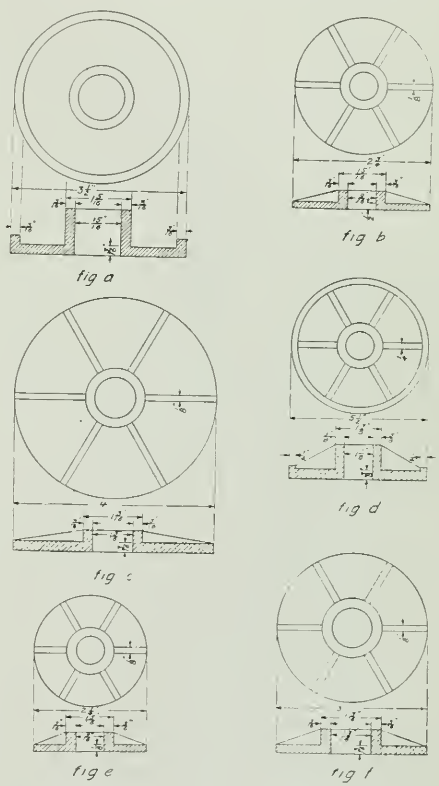
The timbers used in the testing were four feet long and were all 4 in. x 6 in. except the Douglas fir, which was 6 in. x 6 in. The wood was not selected but was taken at random from the stock of a local lumber-yard. From the results, however, the wood appears to have been well seasoned.

Professor Johnson's rule for determining the elastic limit was used. That is: the apparent elastic limit is the point on the stress of any material at which the rate of deformation is 50% greater than at its origin. In other words, it is the point of tangency of a line whose slope is 50% greater than that of the tangent through the origin. The washers that were designed for economic ones were designed for a bearing of 500 lbs. on soft wood and 900 lbs. on hard wood, these being just half the values found for the elastic limits by experiment. In the application of results it should be remembered that in commercial casting the bearing surface of the washers may be irregular and so cause uneven stresses in the wood. Also the quality of the metal used in commercial foundries is poor and variable.

Discussion of Results.—Tests were made to determine the advantage of spools on washers with the result that spools were found to increase the strength of the washer from 50 to 100% according to the size of the spool, without a proportionate increase in the weight of the washer. A test was made for a spool of greater height than that indicated in the above specification but no appreciable increase in strength was shown for the added metal.

An interesting set of tests was made with round-edged washers. It was expected that the round edge or the contact face of the washer would reduce the amount of the cutting and consequently the amount of the depression. On the first test the washer turned up on the edges so no satisfactory results were obtained. Further tests were made on stiffer washers but the results did not indicate any decrease in depression of the washer due to the rounded edge. In these tests the outside edge was rounded and no advantage was observed. It is thought possible that rounding the lower edge of the inside of the bolt hole may work to advantage by relieving the pressure from the fibers which were cut by the bit. However, no tests were made to determine this.

In the first tests the load was applied on a line but in each case the ultimate strength of the washer was so much less than when applying the loads by a nut that the



Some Practical Designs of Washers.

method was discarded and all subsequent tests were made with the load applied by a nut.

An important result was obtained from the tests on square washers. The ultimate strength of the washer was observed to be actually less for a square washer than for a round one of diameter equal to a side of the square one. On the tests on square washers the corners turned up and so caused the failure of the washer. It is supposed that the pressure on the corners, though being lower per unit area, has such an increased lever arm about the bolt that the bending moment in the washer is greater than it would be if the corners were cut off. In no case were square washers found to be of advantage. This information could be applied, it would seem, to the

design of plates for more than one bolt, where the corners could be rounded to increase the strength of the plate.

Two similar washers were tested, one with a rim 3/16 in. high and 3/16 in. wide around the edge, and one without the rim. The tests showed an increase in strength of 45% with an increase in weight of only 25% for the addition of the rim. The bearing at the elastic limit was 92 lbs. per sq. in. and the ultimate strength 1,050 lbs. per sq. in., the break occurring radially. The design for this washer is shown in Fig. *a*. Another test was made with the rim moved in ¼ in. from the edge but no advantage was discovered in the change and if ribs were used the rim on the edge would serve as a brace for these.

A ribbed washer with a 1/16 in. plate, and a 3/8 in. spool was found to stand a load of slightly less than 1,000 lbs. per sq. in. Considering the thinness of the plate this was remarkable. However, this washer was carefully made in Sibley foundry and can not be fairly compared to a similar commercially cast washer. While this design for a ¾ in. bolt weighs only 53 lbs. per 100 and is consequently economical, yet it is impractical to cast such a thin plate and the design should not be considered for commercial purposes. A similar washer with a ¼ in. plate and a ¼ in. spool cast in a local foundry proved about equally strong and much more practical. The weight of this design was 70 lbs. per 100.

An attempt was made to design a series of economical washers by using the features of advantage found in the above tests. Fig. *b* shows a soft wood washer for a ½ in. bolt. A ½ in. bolt will hold safely 2,000 lbs., the ultimate strength being from 6,000 to 8,000 lbs. The washer broke at 7,400 lbs. and may therefore be considered as an economical design since washer and bolt fail at about the same load. The weight of these washers is 30 lbs. per 100 while that for an Ogee washer for the same bolt is 37.5 lbs., thus showing a saving of 25% in cost. The wood was not stretched to its elastic limit so this design may be considered a safe and economical one.

Fig. *c* shows an economical design of a soft wood washer for a ¾ in. bolt. Such a bolt will hold safely 4,600 lbs., and on the first design with a ⅛ in. plate the washer stood only 8,500 lbs., which might be considered sufficient if all washers were uniform but as a factor of safety of at least four is desirable, it was thought advisable to raise the thickness of the plate to 3/16 in. This raises the weight from 63 to 75 lbs. per hundred but the Ogee washer for this bolt weighs 100 lbs. per 100, so that a saving of over 30% is effected by the use of this more economical design.

The tests for the 1-in. washers did not prove as satisfactory as the others. However, from the results obtained, it was considered that a washer of the design shown in Fig. *d* would be satisfactory. This design is also for a soft wood washer.

Fig. *e* shows a design of washer for a ½-in. bolt for hard wood. The washers were all in perfect condition at the end of the test, the failure occuring in the wood at 7,800 lbs. This washer weighs only 26 lbs. per 100 and may be considered as both safe and economical.

A design of a hard wood washer for a ¾-in. bolt is shown in Fig. *f*. The plate has been increased 1/16 in. in thickness over the one used in the test as that one did not prove quite strong enough for all purposes. The design shown would hold from 15,000 to 18,000 lbs. and as the safe stress on the bolt is 4,600 lbs. this is sufficiently strong for all purposes. The washers used in the test broke radially under a load of 1,820 lbs. per sq. in. The weight of the washer shown in the design is 50 lbs. per 100, which is 22 lbs. lighter than the Ogee washer for the same bolt.

The results have shown that the present design is uneconomical, and for three common sizes of bolts, designs for very economical and satisfactory washers have resulted from the experiments.

Conclusions.—The three main conclusions arrived at in the design of economical washers were:—

1. For bolts of less than ½ in. in diameter no reinforcement of the washer is necessary; a flat plate large enough to provide sufficient bearing area being all that is required.

2. For each inch of diameter of the plate there shall be 3/16 in. in height for the spool but no spool shall be less than ¼ in. in height.

3. For each inch of diameter of the plate there shall be 1/16 in. in thickness for the spool but no spool shall be less than 3/16 in. in thickness.

PUBLIC WORKS ON THE PACIFIC COAST.

OVER and above the expenditure connected with the construction of the new 1,150-ft. drydock at Lang's Cove, Esquimalt, B.C., the Department of Public Works of the Dominion Government has under construction in the province improvements amounting to $4,500,000. The Ogden Point breakwater, 2,530 ft. long, is under construction by Sir John Jackson (Canada), Limited, and is to be finished in about 15 months. It will cost about $1,800,000. The government has awarded a contract to the firms of Grant, Smith & Co., and McDonnell, Limited, for the construction of the first two piers. One side of the pier, the nearest the breakwater, will be 1,000 ft. long. The other side, and the sides of the adjoining pier will be 800 feet each. The width of the piers will be 250 ft. and they will be separated by 300 ft. of water of a minimum depth of 35 ft. at low tide. The piers will be of concrete cribbing filled in with rubble. The time limit of the contract is March, 1916. The amount of quarry run and rip-rap, which has been deposited for the foundations of the breakwater, is 673,197 tons, and the pier contractors have dumped 148,241 tons of similar material for levelling off a base for the cribs. A total of 12,940 tons of granite blocks has so far been laid by the breakwater contractors, and in connection with the land excavations 54,847 tons cubic yards of earth and rock have been removed.

The core of the breakwater has been built for the entire length, 2,500 ft. The core consists of 233,611 tons of small rock. The foundations on which the granite blocks will be set have been completed to within 700 ft. of the outer end of the breakwater. In connection with this work 439,586 tons of rubble has been dumped. The foundations are 20 feet below low water, and the rubble deposited included rocks of weight from 200 pounds to 16 tons. These foundations have been levelled off on the exposed side of the breakwater for a distance of 800 ft. from the shore. The granite blocks, weighing 15 tons, have been set in position by divers to a mark 500 ft. from the shore end and to a point 5 ft. above low water. The concrete superstructure has been prepared out 300 ft., and the contractors are now finishing the first block of this, which is 26 ft. in length.

Grant, Smith and McDonnell are concentrating all their work on pier No. 2. The western side of the pier is to have a length, as stated, of 1,000 ft. and rubble for the foundation of this face has been dumped to give a depth of 34 ft. below low water. The last foot of the

foundations is of very fine gravel in order to form a good bed on which the cribs will rest. On the western face of the pier, which is to be 800 ft. in length, rubble has been dumped for three-quarters of the distance. A portion of the foundations on the eastern face is now ready for the cribs. These cribs, each weighing 3,500 tons, are being built on a floating drydock of 8,000 tons capacity, which is now moored off the newly acquired quarry at Royal Bay. Earlier in the year the drydock was chartered from a Seattle corporation and during the past few months a large force of men have been engaged in equipping it with machinery and appliances to facilitate rapid progress in the construction of the cribs. Two cribs are to be put together simultaneously, the total weight when completed to be 7,000 tons.

Plans call for cribs of reinforced concrete 100 x 35 ft. in plan, with walls 39 ft. high and floors 2 ft. in thickness. In each there will be two longitudinal walls, 11 ft. 8 in. apart c. to c., and transverse bulkheads 10 ft. apart and 10 in. thick. Sea cocks will be provided in the floors for the purpose of admitting water to sink the cribs after they have been put afloat.

Twenty cribs are required for Pier 3, 22 for Pier 2, and 3 for the bulkhead between the piers.

The floors of the first two cribs have been constructed, forms for concrete are in place, and concreting has made extensive progress. It is expected that the pair will be ready for launching in a few weeks.

Mr. John S. MacLachlan is engineer-in-charge for the Government of this harbor work.

In the inner harbor, adjacent to the new Johnson Street bridge, the Dominion Government has under construction a wharf, which is to be completed by the erection of a new agency building for the offices of the Department of Marine and Fisheries, on a similar design to that of the building at St. John, N.B. Work on the building has been delayed by the indefiniteness of progress in the construction of the bridge.

At William Head quarantine station, where the passengers of inbound overseas vessels are examined, much needed alterations are being carried out.

For the Militia Department nearly $300,000 will be expended on the new drill hall, occupying a site on Bay and Field Sts., and McBride Ave. This building is now well on towards completion. The post office extension is also advancing rapidly, and will complete an imposing block in the heart of the city.

At Little Saanich mountain, near the city, an astronomical observatory is soon to be built to house a 73-in. reflecting telescope, the largest of its kind in the world.

The Provincial Government is completing the extensions to the legislative buildings, which will, when completed, represent a total investment of nearly $3,000,000 in Parliament Square. Some of the extensions have already been occupied by the various departments. The provincial goal, five miles out of Victoria, has just been finished, and the Normal School for Vancouver Island, situated at Mount Tolmie, overlooking the city, will be finished at the end of this year. Very large works are contemplated by the government on the old Songhees Indian reserve, which lies in the heart of the city. The Canadian Pacific Railway has constructed its terminals there, except the depot, while the Canadian Northern Pacific Railway also plans to erect for its island line, a depot connected with the Canadian Pacific Railway structure, the two joined to the city by the new bridge and a road through the reserve. To protect the area from erosion the two governments are co-operating on building a revetment wall costing $150,000.

MAINTENANCE OF EARTH ROADS.*

By George W. Cooley,
State Highway Engineer of Minnesota.

IN the consideration of this subject, it is presumed that the fundamental principles of road construction have been followed, *i.e.*, that an ample drainage system has been provided, and that the sub-grade or foundation has been built up without the use of perishable material. Unless the road has been so primarily constructed, weak spots will develop when the drainage is imperfect or where sods or vegetable matter has been used in its construction, and the cost of proper maintenance will become excessive.

In the construction of a new earth road made in an open level or rolling country, the use of an elevating grader is quite common and under suitable conditions its use is justified by economy in construction work, but its value as a road builder is lessened if the too frequent result is obtained of casting the sods into the road bed, and depending on the regular traffic to thoroughly consolidate the mass so built up. This can be avoided by the use of a tractor in hauling the grader, which thoroughly pulverizes and packs the material cast in by the grader.

We may safely take if for granted, then, that in any road bed carelessly constructed with a large percentage of vegetable matter, the future bills for repairs and maintenance will be governed largely by the quantity of unsuitable construction material used, and in case of a lax system of construction, a more elaborate system of maintenance must be adopted.

I quote the following from Mr. L. W. Page, director of the office of public roads:

Overtopping all other road problems in its importance is that of maintenance. The destructive agencies of traffic and the elements are unceasing in their activities, and it is idle to talk of permanent roads any more than to speak of a house, a fence or railroad ties as permanent. The public roads to-day, by reason of the exceptionally obstructive traffic conditions, are more costly in construction and this cost is continually increasing with the advance in the prices of labor and material. It is criminally wasteful, therefore, to invest large sums of public money in building the highways demanded by traffic, unless the investment is conserved by adequate maintenance.

We conclude, therefore, that continuous maintenance being such an important factor in the general scheme, especial effort must be made to install a satisfactory and economical system as soon as a road is opened to travel. In some of our western States, the plan has been suggested of requiring contractors on surfaced roads to provide for maintenance as soon as any section is completed, and continue the same for at least thirty days after the work is accepted, thus giving time for the engineering department to provide for the organization of a maintenance crew without overlapping or interfering with the work of construction; and in Minnesota the plan has been adopted in the construction of earth roads to require the continual use of a drag or planer on grade building. This latter plan has been found very efficient and renders future work on the surface less expensive, besides tending to produce a more compact road bed. The tool found most satisfactory in this work is that known as the "Minnesota Road Planer," which consists of the two blades of an ordinary road drag, fixed between a pair of runners about 14 feet long, the blades set at an angle of about sixty

*Read at Fourth American Road Congress, Atlanta, Georgia, November 9-14, 1914.

degrees to the runner and made rigid or adjustable as may be deemed best. The planer is hauled on a line parallel with the axis of the road and its operation is similar to that of the ordinary drag, with the additional advantage of making a smoother surface. The old style drag without runners has a tendency, especially on new work, to increase the "waves" or undulations frequently occurring on road construction, while the planer eliminates these faults, and as a general maintenance tool has proven the most satisfactory.

An important feature of maintenance is prevention of the growth of sod and weeds along the travelled track. When sod is allowed to form along the highway, it has a tendency to catch the dust and wash from the road surface, and soon becomes a high, tough shoulder, preventing drainage. The use of a spring tooth harrow along the roadside two or three times a year will prevent this growth.

The State of Minnesota has given special attention to the matter of maintenance and in the present road laws has made adequate provision for the care of all roads. Township and county roads constitute approximately 90 per cent. of the road mileage of the State, and of these roads, about 90 per cent. are earth roads. To care for the town and county roads, a one mill tax is levied on all property in the town, the proceeds of which constitute the town dragging fund. This fund is expended under the direction of an overseer, appointed by the town board, for the purchase of drags, and in dragging all roads of the town, excepting State roads. This appears to be the most satisfactory method of caring for the earth roads under control of the local authorities, but there should be a provision in such cases for general supervision of the work by the county highway engineer.

For the care of State roads in Minnesota, 20 per cent. of the State road funds, with a due proportion of county funds, are set aside and may not be used for any other purpose than maintenance of State roads. As the State roads include all types of construction, different systems of maintenance have been required in the different localities. In general, three systems have been established: The patrol system on macadam and well built gravel roads, and the maintenance section system, and road drag system on other roads, all being under the direct supervision of the district highway engineer.

Under the patrol system, one man is assigned a section of from 5 to 7 miles of road and works with hand tools. It has been found necessary to supplement this work with the occasional use of a team and in that manner it has proven satisfactory on macadam and gravel roads.

Under the maintenance section system, one man is given charge of a section of from 20 to 30 miles of road and is employed continuously with his team on the care of his section. He is given authority to employ additional help, both teams and men, and usually has two teams and four or five men at work. Contracts are also entered into by the section foreman with residents along the road, for the dragging of same after each rain, or when ordered to do so by him. The section crew takes care of all minor items of construction, such as placing culverts, etc., and we have found that the work when properly done, is really of a constructive nature. This system is without doubt the most effective, and is being adopted generally throughout the State.

The dragging system requires the employment of a superintendent of maintenance, who for convenience should be one of the engineer's assistants, whose duty is to contract or make arrangements for the dragging of all roads under his charge, and to see that the work is done at proper times. This system is suitable for slightly undulating prairie country, where most of the roads are of earth, and to get best results, the superintendent should have at his disposal light graders to re-shape the road bed at least at the beginning of each season.

On earth or gravel roads, no maintenance system is complete which does not contemplate the use of planers or similar devices, and a combination of work as outlined under the section system is recommended.

SUMMARY OF TUNNELING PRACTICE.

THE following has been adopted by the American Railway Engineering Association in accordance with the findings of its Committee on Roadway with respect to methods of tunnel construction.

Tunnel Construction.—Railway tunnels, as ordinarily constructed, are more economically built by driving the heading entirely through, first, but such method usually requires a greater length of time for completion of the tunnel.

For material requiring support, the top heading should usually be driven.

It is economical and expedient to use an electric shovel or an air-shovel, for the removal of the bench where the section of the tunnel permits the safe operation of the same; and where the material does not require support there are advantages in low cost and quick removal of the bench in driving the heading at the sub-grade line.

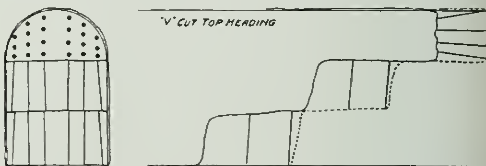


Fig. 1.—Construction in Hard Rock With Few Seams.

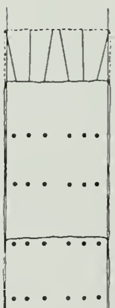

Where the time limit is of value, the heading and bench should be excavated at the same time, the heading being kept about 50 ft. in advance of the bench. Where the material of the roof is not self-supporting and timbering is to be resorted to, the bench should not be removed until the wall-plates are laid and the arch ribs (or centering) safely put up.

Opposing grades should preferably not meet between the portals of a tunnel, so as to put a summit in the tunnel, and where practicable the alinement and ascending grades in the tunnel should be in the same direction as the prevailing winds.

Figs. 1, 2 and 3 are representative of American practice in single-track tunnel construction, where the time limit is of value. Fig. 1 relates to tunnel construction in hard rock with few seams.

Heading in material of this kind is usually driven by a "V" cut, using from 16 to 22 holes about 8 ft. deep. The holes near the middle of the heading are drilled so as to nearly meet at the end. These holes are the first row shot, then the second row and outside holes last. The arrangement of these holes will vary slightly according to the way the material breaks.

Bench in hard material of this kind is usually taken out in two lifts of almost equal weight. Sub-bench is drilled from 20 to 40 ft. in advance of the bench. From 4 to 8 holes in a row, with about 6 to 8 ft. face, are used in both sub-bench and bench. One or two rows of holes may be used. Centre holes are shot first, round and side holes last.

In Fig. 2 the method of construction in moderately hard rock with seam, is illustrated. Heading in material of this kind is usually driven by a "hammer cut," using

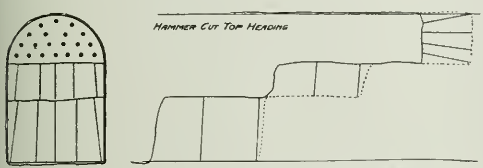

Fig. 2.—Construction in Moderately Hard Rock With Seams.

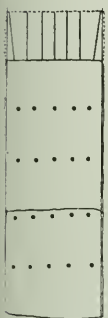

from 14 to 20 holes 6 to 10 ft. deep. The bottom row of holes is inclined at about an angle of 30 degrees. The bottom row is shot first and each row shown in succession. These holes should be arranged to suit the seams in the material.

Bench in material of this kind is usually taken out in two lifts, but the sub-bench is not as deep as the bench. Sub-bench is best drilled from 20 to 40 ft. in advance of the bench. From 4 to 6 holes in a row may be used with 6 to 10 ft. face. The bench is sometimes taken out in one lift. Centre holes are shot first, round and side holes later.

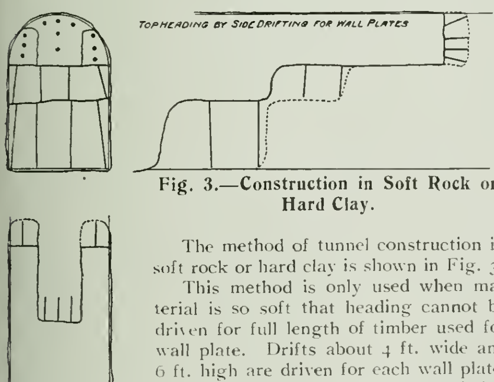

Fig. 3.—Construction in Soft Rock or Hard Clay.

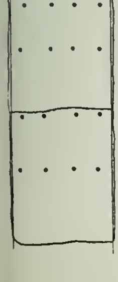

The method of tunnel construction in soft rock or hard clay is shown in Fig. 3.

This method is only used when material is so soft that heading cannot be driven for full length of timber used for wall plate. Drifts about 4 ft. wide and 6 ft. high are driven for each wall plate, and then core is taken out as timber rings are put in. Three or four holes may be used from 3 to 5 ft. deep in each drift. The amount of shooting necessary depends entirely upon the softness of the material. It can often be picked. The core may be soft enough to pick, or may be shot with from 4 to 8 holes, either drilled from face as shown or from sides of drifts.

Bench in this class of material is shot in one or two lifts. Very few holes are necessary.

Coast to Coast

Vancouver, B.C.—The new $300,000 immigration building is now under construction. Messrs. Snider Brothers and Brethour are the contractors.

South Vancouver, B.C.—A number of water mains will necessarily be lowered in the near future, owing to grading operations now being carried on by the city and adjoining municipalities.

Peterborough, Ont.—The new line of the Grand Trunk Railway between Belleville and Lindsay has progressed so rapidly that steel now extends over half way between Belleville and Peterborough. It is probable that this portion of the line will be completed before the end of the year.

Ottawa, Ont.—On the Hudson Bay Railway steel has now been laid on 180 miles of the total 420 miles to Port Nelson. Grading has been completed on 325 miles. Construction work this season has been handicapped by bad weather, but it is expected that the close of next year will see the steel laid completely to tide water.

Cobalt, Ont.—The new high-grade vein on the Savage property is estimated to average between 7,000 and 8,000 ounces to the ton over an average width of 4 inches. It was located at the 140-ft. level, and has been proven for a depth of 55 ft. This vein was encountered in the cross-cut driving through virgin territory from the 140-ft. level.

Chatham, Ont.—Civic improvements this year have been extensive. The programme in the matter of sidewalks was completed last week. Three reinforced concrete pavements and a bitulithic pavement have been laid in addition to numerous other pavement improvements. The sewerage programme will have been completed by the end of the week.

Montreal, Que.—To the Home Guard has recently been added a company of 250 men from the Canadian Pacific Railway Co., arms and equipment being supplied by the company. Half of the number is being enrolled from the Angus shops and the other half from the Windsor and Place Viger stations. It is intended that miniature rifle ranges will be established at Angus and Windsor station.

Toronto, Ont.—Good progress has been made by the city on the large trunk sewers in Ward 7. The work has been handicapped on both the Woodville Avenue and Humberside Avenue conduits by the intrusion of water, but steam pumps have been constantly in commission, and the work has proceeded without interruption. Both are rapidly nearing completion.

Regina, Sask.—The new Regina jail, a 3-story building of brick and reinforced concrete, has been completed. It is six miles from the city. Power is supplied by two semi-Deisel engines with direct-connected generators. This power is used for lighting, ventilating, water supply, laundry, while a motor is also used for operating the septic tanks at the sewage disposal works.

Fort George, B.C.—The Pacific Great Eastern Railway has now a force of nearly 7,000 men along its route between Squamish and this city, and it is expected that the entire route will be graded before the close of the year. Track will extend to Lillooet by the end of January, and it is hoped, to Clinton, by June. The entire line should be completed from tide water to Fort George by the close of next season.

Vancouver, B.C.—Traffic to the coast by way of the Kettle Valley Railway will likely be accommodated next summer. The Kootenay Central Railway is also well on the way to completion, the swing bridge over the Columbia River, near Lake Windermere, having recently been put into

position. Construction on this line has been carried on northwards from the Crow's Nest line and southwards from Golden, and the two sections will meet at the Columbia River bridge.

Toronto, Ont.—Owing to the present unsettled conditions, it is a question whether the next session of the Provincial Legislature will draft an extensive programme of construction in the matter of highway improvements in Ontario. During the past season much work has been done by the Public Roads and Highways Commission by way of investigation, compilation of statistics, traffic census, etc., and, under normal conditions, legislation should shortly be introduced, providing the necessary machinery for carrying the policy into effect.

Viking, Alta.—Natural gas has been struck near Viking, Alta., on the Grand Trunk Pacific Railway. The well has been bored for the city of Edmonton, and the gas will be piped to Alberta's capital, eighty-two miles distant. The well is 2,340 feet in depth, and is making 9,350,000 cubic feet per day. This well is only exceeded in size of flow on the continent by the one at Bow Island. It is stated that two wells of this capacity would supply all the power, light and heat required in the city of Edmonton.

THE ROYAL ASTRONOMICAL SOCIETY OF CANADA.

On December 1st a large attendance of the membership of the Society heard Mr. J. S. Plaskett, D.Sc., of the Dominion Observatory, who delivered an illustrated address descriptive of the new telescope now under construction for the observatory at Victoria, B.C.

At its next meeting, on December 15th, the Society will be addressed by Prof. L. B. Stewart, University of Toronto, on "Experiences on Surveying and Exploring Expeditions." The address will be illustrated. Mr. A. F. Miller is secretary of the Society, whose offices are at 189 College Street, Toronto.

PERSONAL.

R. S. BUCK, chief engineer of the Dominion Bridge Co., Montreal, has been appointed maintenance-of-way engineer for the New York Railway.

JAS. SHIELDS, consulting electrical contractor, has been chosen by the Toronto Hydro-Electric System as inspector of city wiring.

J. L. HARRINGTON, consulting bridge engineer of Kansas City, addressed the Victoria branch of the Canadian Society of Civil Engineers at its recent meeting on modern bridge construction.

GEO. GAUTHIER, assistant superintendent of the Montreal Light, Heat and Power Co., was seriously burned by a short circuit at one of the plants of the Shawinigan Water and Power Co. last week.

A. F. STEWART, chairman of the Toronto branch of the Canadian Society of Civil Engineers, delivered an illustrated address to the members of the Branch at a meeting on November 26th. His subject was "Bridges Destroyed during the South African War."

D. C. COLEMAN, of Calgary, general superintendent of the Alberta division of the C.P.R., will, it is reported, succeed Mr. Grant Hall as general manager of Western lines, the latter advancing to the vice-presidency vacated by Mr. George Bury, when Mr. Bury moves up to succeed Mr. McNicoll.

OBITUARY.

The death occurred last week of Mr. John H. Housser, secretary and one of the directors of the Massey-Harris Co., Toronto. Mr. Housser was connected with the firm for 42 years.

The death occurred in Montreal last week of Mr. R. C. Hadley, of the engineering staff of the George A. Fuller Contracting Co.

It has been announced that Mr. Fred. C. Robertson, inspector of C.P.R. Telegraphs for Ontario, died on November 29th at Port Hope.

The death occurred last week of Mr. A. E. Wilkinson, traffic superintendent of the Intercolonial Railway in Nova Scotia. Mr. Wilkinson was in his 45th year, and was a native of New Brunswick.

NEW G.T.R. BRIDGE AT PRINCE GEORGE, B.C.

The vertical lift-bridge over the Fraser River at Prince George, B.C., was opened last week to permit the passage of steamers. The lift-span is 100 ft. in length, and is electrically operated, assisted by concrete counter weights. When raised, it is 150 ft. above the river. The entire bridge is one of the longest steel bridges in the Dominion, being 2,654 ft. between abutments. There are twelve spans, excluding the lift portion. The structure rests on 14 concrete piers, and provides accommodation for two 12-ft. roadways and a 19-ft. railway right-of-way.

COMING MEETINGS.

ANNUAL MEETING, AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—The annual meeting of the American Society of Mechanical Engineers will be held in New York, December 1st to 4th, 1914. Secretary, Calvin W. Rice, 29 West 39th Street, New York.

AMERICAN ROAD BUILDERS ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

CANADIAN NATIONAL CLAY PRODUCTS ASSOCIATION.—Annual Convention to be held at the King Edward Hotel in Toronto, January 26, 27, and 28, 1915. Secretary, G. C. Keith, 32 Colborne Street, Toronto.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

AMERICAN WATERWORKS ASSOCIATION.—The 35th annual convention, to be held in Cincinnati, Ohio, May 10th to 14th, 1915. Secretary, J. M. Diven, 47 State Street, Troy, N.Y.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.—Annual meeting to be held at the Iowa State College, Ames, Iowa, June 22nd to 25th, 1915. Secretary, F. L. Bishop, University of Pittsburgh, Pittsburgh, Pa.

Officers of University of New Brunswick Engineering Society:—The Engineering Society at the University of New Brunswick elected their officers, recently, as follows:—Honorary president, Mr. Wallace Broad, St. Andrews; president, Prof. J. A. Stiles; first vice-president, Mr. E. McL. Balkam; second vice-president, Mr. J. P. Mooney; treasurer, Mr. J. D. Hickman; secretary, Mr. A. C. Edgecombe.

STORAGE DAM AT EUGENIA FALLS

PLANT AND METHODS EMPLOYED IN THE CONSTRUCTION OF THE CONCRETE-STEEL SECTION OF DAM ON BEAVER RIVER FOR THE HYDRO-ELECTRIC POWER COMMISSION OF ONTARIO.

By G. R. HECKLE,
Managing Director, Ambursen Hydraulic Construction Co. of Canada, Ltd.

IN estimating the cost of carrying out any construction project two factors of the greatest importance are the time in which the work must be completed and the plant to be employed. These two factors are practically analogous, as, of course, the capacity of the plant governs the time required. If the capacity of any unit is not as great as was estimated, moreover, there is a grave probability that the other units of plant may be delayed in employment, and while their capacity may be as large as estimated, they may be unable to carry the extra load occasioned by the delay of some one unit, and the whole schedule of operations may therefore be completely disorganized. As the "overhead" charges, such as superintendence, maintenance of plant, etc., are all based on the estimated duration of the work, they immediately start to increase as a relative percentage of the other work, and the contractor's estimate of profit is possibly absorbed in the process.

In the old days of contracting when manual labor was largely employed, there was less liability for an error in judgment with regard to the time and cost, as the forces employed were much less complex, and more laborers could be easily added or more work could be produced by better management from a given number of men. In modern contracting, however, when the plant is once installed the time and expense of replacing any units which may fall below their estimated capacity will in all probability eat up the profit and possibly more, so that it is of great importance that first calculations be on the safe side, and a considerable margin be allowed for contingencies.

With the above preamble, the writer begs to call attention to a contract for the construction of a concrete-steel dam of the Ambursen type for the Hydro-Electric Power Commission of Ontario, which is now nearing completion. The work is located at Eugenia Falls, Ontario, about eighty-five miles west of Toronto, and about thirty miles east of Owen Sound, the site of the dam being about seven miles from the railroad. The dam will furnish storage for a power development on the Beaver River, which is being constructed and will be operated by the Hydro-Electric Power Commission. The total length of the structure is approximately 1,900 feet, of which 1,260 feet is Ambursen section and 640 feet is earth embankment with concrete corewall about equally divided at both ends. The Ambursen section is approximately 51 feet high from bottom of cut-off to top of crest at the highest section; the total concrete required for the entire work being about 10,000 cu. yds., practically all of which is in comparatively thin reinforced sections, and distributed over a large area. The stripping of the site involved about 14,000 cu. yds. of earth excavation and about 2,500 cu. yds. of rock, principally in the cut-off trench, which is in a stratified and seamy limestone and which has an average depth of about ten feet.

The contract for the construction of this dam was closed with the Ambursen Hydraulic Construction Company of Canada, Limited, in the latter part of June of the present year, and the company guaranteed to complete the dam to within fifteen feet of the crest by December 25th of this year, so that water from the spring freshet of 1915 could be stored for power purposes, the entire dam to be completed by July 1st, 1915. The work was undertaken on a unit price basis with liquidated damages for non-completion to the elevation noted previously at the date specified. The latter stipulation required that the dam should be entirely completed with the exception of about 2,000 cu. yds. of concrete in the top lift in a period of about six months from the receipt of authority to proceed, and it was obvious that in order to accomplish this result it was very necessary not to overestimate the plant capacity.

In a general way the following plant and methods formed the basis of the estimate: A Bucyrus traction steam shovel of ⅞ cu. yd. dipper capacity for earth excavation, equipped with 1-yard capacity dump wagons; air drills of the Holman hand-hammer type for the rock excavation; a 1-yard capacity Smith mixer; a cableway of five tons capacity and about 1,325 ft. clear span of our own design, for distributing concrete and handling forms, and Dowd 1-yard capacity controllable bottom dump buckets for concrete. A guy derrick equipped with a three-drum 8-in. x 12-in. Beatty engine, with Dake swinger operating a 1-yard Hayward orange peel bucket, dredged gravel from a pit adjoining the dam, which was

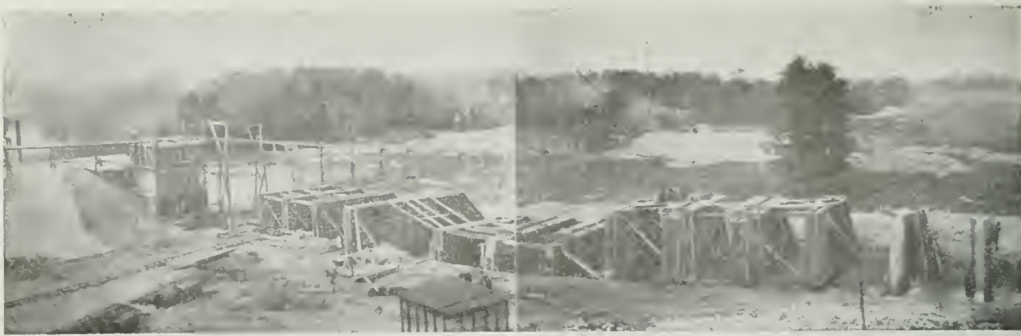

Fig. 1.—South Half of Dam at Eugenia Falls, as it Appeared on September 15th, 1914.

dumped into the hopper of a screening and washing plant, consisting of two revolving conical screens of ⅜-inch and 3-inch diameter holes respectively with automatic sand hopper of the Gilbert type. The product of this plant was hauled over the dam and gravel and sand bins on an inclined trestle by a small hoisting engine, and was either dumped directly into the bins or into storage piles immediately adjacent. By operating this plant day and night, the entire amount of sand and gravel required was furnished by about the last of October, and the derrick was then transferred to the storage piles for loading the bins, the difficulties due to operating a washing plant in freezing weather being thus avoided.

Steam power for operating the above plant, with the exception of the shovel and derrick, was furnished from two 40 and one 50-h.p. boilers of locomotive type, and the water for the sand and gravel washing was furnished by a 4-inch pulsometer assisted by a 2½-inch duplex boiler feed pump, another pulsometer also being used for unwatering the river section. For night work a small motor-generator driven by a steam engine furnished electric power for arc lights suspended from a cable attached to the cableway towers and spanning between them.

A small machine shop and carpenter shop were established immediately at the start of the work, the former being equipped with the usual blacksmith outfit, bolt machine, drill, pipe threader and cutter, and hand-lever shear for cutting reinforcing steel. The carpenter shop was equipped with band saw and air augers, driven by locomotive compressor of the Westinghouse type.

Fig. 1 shows the south half of the dam as it appeared on September 15th. At the left are seen the mixing plant bins and storage piles of gravel and sand. On the opposite side can be seen the screening and washing plant with derrick for loading. It will be noted that the mixing plant is approximately at the centre of the dam, thus cutting down the transportation of concrete by the cableway to a minimum.

With this general summary of the plant employed, it may be of interest to describe briefly its operation, and results obtained.

The shovel easily stripped ahead of the rock excavation and concrete work, and was afterwards employed in feeding the orange peel with gravel, thus saving the time and cost of moving this plant when the adjacent supply of gravel had been exhausted. It was also used for making the earth embankments at both ends of the dam.

The cut-off trench was carried on night and day, as it was much deeper than was anticipated, on account of the seamy nature of the rock, and the concrete plant was delayed somewhat in starting on this account. This trench had to be drilled and blasted with the greatest care to avoid disturbing the seamy rock as much as possible, and was the most difficult factor to contend with, with regard to both cost and time during the carrying out of the work. It was with great difficulty that rock excavation was kept from continually delaying the form and concrete work.

The form work was carried on in two shifts, one being of twelve hours, to take advantage of as much day-

Fig. 2.—Dam and Cableway on October

(Mixing Plant on Left; Screening and Washing Plant in Background.)

light as possible and the other of ten hours during the night, when the cableway was available for moving forms. In this way the required capacity from the concreting plant could be obtained by properly systematizing the gangs employed in form erection and stripping.

The progress of concrete was estimated as follows: Plant to be in operation about August 1st, figuring that this would insure approximately one hundred working days before December 25th, after deducting for Sundays and bad weather. To pour 8,000 yards in this time an average of 80 cu. yds. per day would be required. It was therefore apparent that one mixer would be more than sufficient, and that the form work was the governing factor. It was also apparent that the concrete plant had a large reserve capacity in case the estimated time of erection should be cut down, as turned out to be the case. It had been estimated that sufficient cut-off trench could be prepared by August 1st, while the plant was being erected, to allow form work and concreting to proceed at that date. On account of the much greater depth of cut-off required, however, and uncertainty at the start with regard to certain horizontal clay seams encountered, it was practically September 1st before the first concrete was poured. On account of this delay it was therefore necessary to exceed the estimated average progress of 80 cu. yds. daily, by at least 25 per cent., raising the rate to an average of 100 cu. yds. per day, and this condition was fully met by the concrete plant and form work, as shown in the following record.

During the month of September the average pouring was 99 cu. yds. of placed concrete per working day. In October the daily average was 140 cu. yds. In November the average for the month dropped to about 90 cu. yds. on account of stormy weather and the fact that most of the work was confined to the small sections at the top of the dam. This record, however, showed that the plant had placed in 78 working days about 9,000 cu. yds. of concrete, or an average of 112 yards per day, and that the "factor of safety" in its capacity was sufficient to make up for the unforeseen delays which had limited its working time. A large factor in the average attained was the high speed of the cableway, which easily reached a travelling speed of 1,500 feet per minute in operation.

Fig. 2 is a general view of the dam and cableway on October 20th, and in the direct foreground are two cars from the gravel plant starting up the incline to the mixer bins and storage piles. The top of the concrete at the left of the picture is about 15 feet below the crest of the completed dam.

Mr. F. A. Gaby is the chief engineer of the Hydro-Electric Power Commission, and the work has been directly under the department of Mr. H. G. Acres, hydraulic engineer. Mr. T. H. Hogg is responsible for matters pertaining to design and Mr. A. D. Watts is resident engineer for the Commission. Mr. A. J. Raymond is superintendent in charge for the Ambursen Hydraulic Construction Company, and Mr. G. A. Johnson is the company's engineer on the work.

20th, 1914. View from Central Point.

STEEL PASSENGER CAR FRAME CONSTRUCTION.

A PAPER presented at the December 3rd meeting of the Mechanical Section of the Canadian Society of Civil Engineers, by Mr. C. Brady, discussed in a very enlightening manner the differences existing in different types of frame construction designed for like loads and stresses. Mr. Brady emphasized the impossibility of drawing satisfactory conclusions as to the merit or weight of any particular type of framing when comparing cars built by different designers for different roads. This for the reason that variations in proportion and in size of plates and bars, together with different weights of other parts of the car and different general dimensions throughout, do not admit of close comparison. But the writer presents some interesting data respecting the four distinct types as they are actually built. These types are described as follows:

(1) Heavy centre sill construction, the centre sills acting as the main carrying member.

(2) Side carrying construction, the sides of the car acting as the main carrying member having their support at the bolster.

(3) Underframe construction, in which the load is carried by all the longitudinal members of the lower frame, the latter being interpreted to include the side girder below the windows.

(4) Combination construction, in which the side frames carry a part of the load, transferring it to the centre sills at points remote from the centre plates, so as to utilize the uniform centre sill area.

The writer does not submit particulars respecting the first type of construction, as it is quite unequal to the others in weight. Types 2, 3 and 4 are analyzed in detail with respect to the above considerations, and the reader is given a clear insight into what to look for in examining cars in service, or more especially, when the opportunity presents itself, to examine cars that have been in accident. The great importance of a minimum weight for a given standard strength is clearly emphasized. Ability to support its own weight and the usual maximum live load is brought out in the case of each, and each is proven entirely satisfactory in that regard. The same is said of end shocks in coupling and uncoupling, and in collisions, so long as the cars remain on the track in the same horizontal plane.

The condition that usually results in numerous injuries and loss of life is the telescoping of cars, as it is called, when the underframe of one car gets above the underframe of the next car and plows through the comparatively light superstructure. When this occurs it is impossible to express what happens in terms of a static load at a given location, but it has come to be generally accepted as inevitable that some damage must result to the vestibule and car end no matter what construction is used. The greatest protection to passengers is effected by making the end construction very strong, not necessarily to resist bending but rather to prevent tearing away at the fastenings. As a telescope contemplates conditions where the centre sills are not in line, some exponents of the comparatively light centre sill construction argue that the very large and powerful centre sills do not afford any additional protection but are actually objectionable because of the increased probability of their tearing away the end superstructure.

For resisting end shocks above the floor level, side swiping and bending, Type 2 is shown by the writer to be stronger than the others on account of the comparatively heavy top plate angle and the stronger post construction.

Advantages for the large heavy centre sills are not so easy to find, but there is one important condition where they would probably show up to advantage and that is in case of a collision where a locomotive strikes the car. A modern locomotive would not be at all likely to climb into the car, and if the speed was great even the heaviest car construction could not be expected to stand up against the massive castings and heavy steel plates used in locomotive construction; but it is quite reasonable to presume that the stronger the centre sill construction in the car the less the damage which would result.

From construction and operating standpoints the shallow centre sill car has the advantage of not interfering in any way with the locating of brake rigging and other equipment under the car, and it materially facilitates quick and thorough inspection in service.

ST. CATHARINES VIADUCT PLANS TO BE REVISED.

The proposed St. Paul Street bridge at St. Catharines, over the old Welland Canal, a description of which appeared in *The Canadian Engineer* for November 26th, 1914, is to undergo a slight change in plan to provide sufficient carrying capacity to accommodate the proposed Hydro-Electric railway between Windsor and the Niagara River. It has been decided to increase the strength of the bridge by approximately 20%, and the companies now tendering on the superstructure are being notified to that effect.

The bridge, as described in the article referred to, was designed to carry a 36-ton car, whereas, a 57-ton passenger car will probably be the requirement of the Hydro.

Although the Hydro-Electric Power Commission is probably not contemplating the early construction of this electric trunk railway line across the western peninsula, members of its engineering staff have conferred with the St. Catharines authorities in an advisory capacity with respect to the wisdom of providing for the future installation.

CANADIAN MANUFACTURE OF SHRAPNEL SHELLS.

As announced in these columns some weeks ago, the British War Office has awarded, through the Department of Militia at Ottawa, a number of contracts for the manufacture of shrapnel shells to different Canadian firms. It has just been announced that these contracts aggregate the sum of $2,500,000, and that practically all the material entering into their construction is being obtained in the Dominion. For instance, the Nova Scotia Coal and Steel Company supplies the steel, the Trail smelters in British Columbia supply the lead, and like materials come from various parts of the Dominion.

At present, about 200,000 shells have been contracted for, and they are being turned out at the rate of 30,000 a month. It is stated that there is capacity in Canada for the manufacture of 100,000 or more per month. The work is now going on at Montreal, Sherbrooke, New Glasgow, Amherst, St. John, Kingston, Toronto, Welland, St. Catharines, Hamilton, Dundas, Galt, Ingersoll, London, Lindsay and Smith's Falls.

IMPROVEMENT OF ORDINARY COUNTRY ROADS.*

By S. P. Hooker,
State Superintendent of Highways of New Hampshire.

IN a subject of this kind the first question to determine is the exact meaning of the title. What is light volume mixed traffic? How many vehicles are to pass over a given piece of highway and still be classed as light volume? What is their relative proportion as to motor-propelled and horse-drawn? The right interpretation of these terms is not clear. There are sections of the country where presumably the mixed traffic would consist almost entirely of horse-drawn vehicles, while in others a very large per cent. would be motor traffic.

The treatment of the surface of these two subdivisions would vary to a considerable extent. The writer is inclined to consider the subject as being the treatment of subsidiary roads which have only the horse-drawn traffic originating upon the road, together with motor traffic of the pleasure class and little or no freight traffic which is motor-driven.

With the immense mileage of roads, it would seem that a large proportion of the roads will never be improved under the types of construction which are now considered necessary for their improvement and that 90 per cent. of the entire mileage will be unimproved if it is necessary to improve them with the higher types of construction.

There must be a revulsion of feeling which will compel more mileage and lesser cost Given, then, a country highway as it now exists and the proposition that for 10 miles of this road there is only available the sum of $25,000, what can we do to render this really an improved road which, under proper maintenance, will take care of the traffic upon it? A preliminary survey may show that a portion of the road is in a low-lying level section without proper ditches where at present the natural tendency of the road is to act as a sort of drainage canal for lands adjacent to it. The soil itself consisting partially of leaf mold containing a large amount of humus and which if used as a cultivated field would produce good crops.

The next portion may consist of a sand and gravel formation, containing boulders and on a grade of from 5 to 8 per cent., rolling over elevations and into hollows and gullies and eventually working out into clear deep sand. Succeeding this may be a hollow from which you rise upon a side hill cut through a clay bank. Here you face the proposition that the clay is of such a nature as to practically absorb all the water and where your drainage condition is most difficult to handle. Your last section may be through ledge of native rock or large boulders, the soil slightly covered with either hard-pan or sand and upon grades which easily wash under the annual rainfalls.

On almost all country roads several of these conditions will ordinarily appear, while, of course, it is an exaggeration that they will all occur within the 10-mile stretch.

Confronted with these conditions, it seems to be absurd to attempt a standardization of such a highway in order to economically work out the problem. The material which is comparatively local must be used and the treatment of each section will be different.

The width of the present highway must first be taken up and, in general, standardized for the ordinary traffic, probably a width of 21 feet between ditches is the most satisfactory standard and considering that this should be accepted as the width of the road, you are next confronted with the alignment and drainage.

In all probability the alignment will be comparatively easy over the level, fertile section, but the drainage on this section will be a problem. Here, in general, you must first provide by deep ditching for reducing the water level of the surrounding land and by deep ditching is not meant the ordinary ditch from which the crown of the road rises, but in many instances a ditch which acts to a considerable extent as a drainage canal.

Culverts must be provided at all points where the drainage may be taken away from the road at every accessible point, and however level the plain or plateau may be as a whole, you will doubtless find a large number of places by which the water will be conveyed entirely away from the road.

In most instances the grading material obtained from the ditches, though seemingly of very inferior quality, may be used to raise the general grade of the road and, if kept dry by the side ditches, will compact and make a fair subgrade.

The next essential is to obtain upon such raised grade a sufficient quantity of metal of some kind to prevent the cutting through of the road surface from water which falls upon the road or in flood seasons cannot be entirely carried away by the ditches. This may be obtained either from fields, stone fences or even drawn from section two, which has an entirely different soil. In some places it would be necessary to practically lay this stone as telford. In other places it is enough to simply dump it in the road and only partially place it by hand labor. In many places where a roller is available this may be the method and the stone simply forced into the soft material excavated from the ditches and not as yet thoroughly dried out from the service rendered by the ditches.

As for surface material, in many places it will be found that along or adjacent to the road there are hills or hummocks which contain soil not properly either hardpan or clay, but in many places a combination of each containing considerable metal in the shape of either pebbles or fractured stone. Having obtained the bottom through drainage and the addition of stone so that the sub-base will be practically dry, you may apply 10 inches of the material containing a small amount of metal and by the use of road drags and road hones bring this first into section and next into a smooth, hard surfacing, which will prove satisfactory in all weather for traffic, provided it has constant attendance and is repeated after every rain dragged with the ordinary road drag. The drag removes every slight rut which may be started and does not allow the water to settle through the weak upper surfacing. The maintenance must be not intermittent, but constant. A somewhat slippery upper surface may still be found, in which case it will be necessary to add an inch or two of gravel or sand from section two. This may only require from 3 to 6 yards of gravel surfacing per 100 feet, and while it may be at a considerable distance from the improvement, it will not add materially to the cost.

The surfacing upon such a type of road will require practically 2,000 yards per mile, and if the material is from different banks along the roads the cost will not exceed 20 cents per yard. It is then perfectly feasible over this section to build such a highway, including the raising of the grade from 1 to 2 feet at a cost of not more than the estimated limit of $2,500 per mile.

---

*From a paper entitled "Surfaces for Light Volume Mixed Traffic," read at the Fourth American Road Congress, Atlanta, Ga., November 10-14, 1914.

On section two, as before described, there is a problem of grading, rather than of drainage. That is, the soil will readily dispose of water, but the grades must be reduced to a reasonable gradient and with a sandy material some method for compacting the road provided. The first to consider, then, is what shall be the maximum grade.

In this class of construction the writer proceeds backwards, rather than attempting to dictate an absolute gradient. That is, he takes the heaviest grade and sees to which per cent. he can reduce this with a reasonable amount of money, instead of saying arbitrarily that a 4 per cent. grade is the maximum, he figures how much it will cost for a 4 per cent., how much less for a 5 per cent. and what the saving would be, should even a 6 per cent. grade be allowed.

We will say that we may reasonable reduce the grade on this section to 5 per cent. This is established as a maximum and the other grades are brought to this maximum.

There will doubtless be considerable blasting on the large boulders to do on this section in order to properly widen the road, because the ordinary country road has no established width. In cutting the grades it will usually be found that a considerable portion of the material excavated in reducing the grade makes good surface material and almost the entire expense will be the shaping of the roadway and the drainage.

As we have imagined it, however, as the end of this section is approached you will have run through the gravel and into what is practically sand. Here the gravel on the other end will not properly compact or pack so as to make a suitable road surface and practically a sand-clay road must be built. The writer has not had good success with the sand-clay roads, unless he has practically telfordized the same by making the sub-base largely of metal.

In the treatment of this particular part of section two, we might endeavor, from the gravel pits used on the first part of it, to obtain the small boulders sufficient to build the entire bottom of the road to at least 6 inches in thickness of such pebbles. These might be filled with sand up to the top of the metal, then at least three alternating sections of clay and sand put on, repeating until the road is at least 10 inches thick, harrowing each section as it is built up, and seeing that the top surface is of sand rather than of clay. This portion of the section will doubtless cost much more than the sum per mile expended upon the gravel portion, but together they should leave the general average within the limit.

Section three, consisting largely of grade, is almost entirely a drainage proposition and it will be very necessary to practically tap the water coming from the side hill near the surface or originating within the road. It may be found necessary in many instances to run short drains for the express purpose of tapping the water holes, which come up in the road-bed proper, and it will doubtless be necessary on the inside of such a road to lay a side drain the entire length of every grade. A ditch should be dug on the upper side of the road to a depth of at least below frost line, a foot of sand being placed in the bottom and then an open drainage tile laid to as perfect a grade as possible, and the ditch filled in with sand, seems to be the most satisfactory way of cutting off this water.

Shaping the clay road is a comparatively easy matter, as such a road will retain its section and may be practically worked with a road machine and then covered with 2 inches or less of sand and gravel, harrowed in as thoroughly as possible. It is somewhat difficult upon a clay road to get the sand to work into it at first and the farther application during wet weather of at least 2 inches more will ordinarily give such a road a most desirable surface. The only caution is that the sand must not be applied in large quantities at a time, but this surface must be expected to require renewing frequently during the first two years.

We have assumed that we have now come to the ledge and boulder section and that all material must be drawn from a considerable distance to make a satisfactory road. Here, without question, the most feasible plan is to use a macadam roadway. The putting up of a local crusher and the macadam method of construction may facilitate building at a lower cost than would the use of the uncrushed material. Frequently, however, on such sections there is a great difficulty in getting sufficient water to properly flush a waterbound macadam road. The use of large quantities of water may be obviated by the use of bitumen, but this adds to the cost of your road.

Wherever macadam is used the same 21-foot section may be retained, though 15 feet should be the extreme width of the metalling. This will take 2,600 tons per mile of stone, and assuming the use of 2½ gallons of bitumen per square yard, the added cost will be something over $2,000 per mile. If water is fairly available, a waterbound road may be built and one-half gallon per square yard of bitumen applied as a cover coat at a cost of about $650 per mile, which will reduce the cost of the road for light traffic about $1,500 per mile. Unless there is considerable trouble about getting water, therefore, the use of waterbound macadam with the blanket coat is recommended.

The added cost of maintenance upon the macadam road, as compared with the cheaper forms, must also be considered, so that personally we should hesitate about using macadam whenever there is a possibility of using the cheaper surfacing.

Assuming a small apportionment available for the entire mileage needing improvement, the economic question is, what plan should be adopted for the treatment of such a highway? Will this 10 miles be practically completed with the money or will 3 miles of the higher type of roadway be built and the rest left unimproved? This seems to be the attitude adopted by most highway departments. They standardize their plans and specifications and are content with the small mileage of what they are willing to say is the best construction, and they dislike extremely to build for small cost what they term an inferior type of road.

The writer believes this to be a serious economic error and in most sections a road infinitely better than has previously existed may be built at a comparatively small cost to the great betterment of the roads in general and to the great help of the inhabitants of a community.

As far as automobile traffic is concerned, many of the inferior types of road are far more satisfactory to them in general than the highest type. The autoist cares little for a short section of the best possible road if at the end of it he plunges into what he is pleased to call an impassable road for three-quarters of the distance. The writer believes the development of roads in the future will be along the line of more mileage and less cost, and that this is the proper trend of development.

Cost of Maintenance.—Constant continuous maintenance is necessary upon all the types of roads that are built. It is indispensable, however, that upon the surfaces of the cheaper type of roadway the maintenance be both continuous and intelligent.

A road of what may be called natural surfacing, if left for even a week during the summer season without attention, loses all its features of a good road. It must be constantly patrolled, all holes in it which have worn must be filled, all weak spots which develop must be repaired within a few hours after discovery or the road will so rapidly degenerate that it is useless as an "improved."

The higher types of roadway may be left for varying periods of time without attention, and while this results in the end in being a more expensive method of treatment it is only a loss of money. You still have the road which may be repaired, but if you attempt this sort of treatment upon the cheap surface you eventually lose your highway entirely.

My experience is that a patrolman with a horse and cart, an efficient drag or hone, and the willingness to work, will keep in almost perfect condition from 5 to 7 miles of cheaply constructed roadway, at an approximate cost of from $175 to $200 per mile. Given the same mileage of the higher types of road, he will require a helper, a much larger equipment, and if working upon bituminous roads probably not less than $150 per mile for material in the way of bitumen, crushed stone, etc.

The average cost of maintenance upon the higher types of road including the use of a blanket treatment once in two years will not be less than $500 per mile, and in many instances it will greatly exceed this. On the expensive road also you are constantly facing the fact that within a reasonable number of years you must resurface at a cost approximating $6,000 a mile, while upon your cheaper road, if properly patrolled, you will find that the surface material is thicker than it was at the time the road was built, and has been in practically perfect condition during the entire period.

If the dust nuisance upon the cheaper road becomes intolerable it may be alleviated greatly and practically removed by the application of light bituminous oils or tars. The objection of this treatment, however, is the tendency on the part of a patrolman to allow the road to get out of section by neglecting to drag it after every rain, as he does not wish to destroy the skin coating on top, which is left after the treatment. The cost of this treatment adds about $150 per mile to the cost of maintenance and on the whole is not as satisfactory for light travel in its final results as adhering to the use of the natural soil and the regular treatment by dragging.

Road problems may be roughly divided into four subdivisions, and their order of importance is about as follows: Drainage, alignment, grade and surfacing. It is unfortunate that to most people the latter is more important, while relatively it is of far less importance than the other three. The surfacing material is frequently considered paramount and the settling of the question as to whether you have a bituminous road, penetration method or mixing, a concrete road, or a pavement type is the main subject of discussion, and with far more attention given to it than it rightly deserves.

The drainage, alignment and the change of grade are permanent features. The surfacing can never be permanent. I have sometimes wondered whether a bond issue to be paid for by posterity should ever be expended on any feature that is not permanent.

Concededly, surfacing of all kinds will require not only constant maintenance but rebuilding. With the essentials fully attended to, it is surprising how the surfacing may be maintained at a comparatively small cost. I believe that it is as necessary for us to turn our attention to the economic side of the road question as to the scientific. A highway must have an economic road rental, as well as a fixed road maintenance, and wherever the actual cost plus its maintenance exceeds its rental value we are wasting money in building too expensive a road. We must so adjust the scales that our costs are such as to provide a roadway for the traffic at the least possible expense.

PROGRESS ON THE PACIFIC GREAT EASTERN RAILWAY.

In the recent report of Mr. F. C. Gamble, chief engineer of the Department of Public Works, to Hon. Thomas Taylor, Minister of Railways, it is stated that track laying on the Pacific Great Eastern will likely reach the Fraser River at Lillooet, 120 miles from Squamish, early in January, unless work is impeded by exceptionally heavy snow falls. The rails are already laid from Squamish to the Lillooet River, in Pemberton Meadows, a distance of about 58 miles. Thence it will be continued over that river on a temporary bridge to Anderson Creek. This bridge is necessary while the Federal Government is deciding whether the Lillooet River shall be crossed by a movable or fixed span.

Between Lillooet River and Anderson Lake, a distance of about 28 miles, there will be two truss bridges, one over Owl Creek, with 100-foot span, and the other over Birkenhead River, with 125-foot span, besides small trestles. These two streams, however, may be crossed by temporary bridges to hasten the track to Anderson Lake, which it is expected will be reached this month.

The track having reached the latter point, timber for the trestles along the lake, which are for the most part small, will be put into the water and towed to the different sites, and erected ahead of the track. From the south end of Anderson Lake to the Fraser River there will be several small bridges.

Between Squamish and Pemberton Meadows there are 39,877 lineal feet of side tracks and sidings. These are laid in the Squamish yards and at various points up to Pemberton. The track, to within nine miles of Pemberton, is in excellent shape. There are steam shovels at work in the ballast pit near Squamish.

Of interest at this time is the completion, at the Canadian Locomotive Company's works, Kingston, Ont., of two oil-burning locomotives for the new line. Each locomotive, weighing 190,000 pounds without tender, has four driving axles, the driving wheels being 57 inches in diameter. The cylinders are 22 x 28 in. and are operated by Walshaert valve gearing. The steam will have a working pressure of 180 pounds per square inch, the locomotive being equipped with a Schmidt superheater adding about 250 degrees superheat. Other characteristic features of the locomotives are flexible boiler stay bolts, radial buffers between engines and tenders, and turbo-generator set supplying power for head-light and other lights.

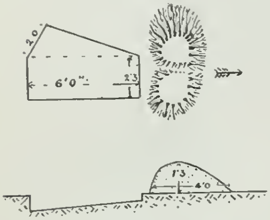
WELLAND CANAL CONSTRUCTION.

Expenditures totalling about $6,000,000 have been made on the Welland Canal work this season (described in *The Canadian Engineer* for November 5th, 1914). The contracts for sections 1, 2, 3 and 5 are reported about one-quarter completed. Together they total over $20,000,000. The sections still to be contracted for will not be let until the existing contracts have advanced considerably further. Nearly 3,000 men are at work.

ENTRENCHMENTS AND OBSTACLES.*

By G. Bertram Hartfree.

IN selecting a site for defensive purposes, natural features are the first consideration, and these will be supplemented by entrenchments; another factor is its advantages to the defenders for counter attacks and to allow a powerful rifle-fire from the position, and it is necessary that the defenders be well screened and protected from the enemy's fire. In deciding the type of entrenchment, time, of course is a great factor, and if this be unlimited, a substantial and well-screened type can be



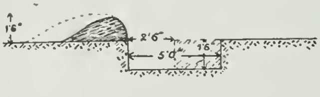


Fig. 1. Fig. 2.
Alternative Shelter Pits for One Man Kneeling.

adopted, but there is the possibility, however, that time will allow only of earthworks of a hasty character; these may be divided into three headings:—

1. Pits for sheltering skirmishers, sentries, etc.

2. Trenches for sheltering the main body of infantrymen and other reserve forces.

3. Pits to give cover for artillery.

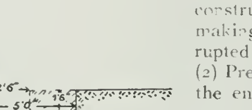
The simplest type is a pit to shelter one man, from which he would fire lying down; in such position the legs are usually inclined to the left. The length of the pit is about 6 feet, and the width 2 feet 3 inches, its depth about 9 inches. Two small adjoining mounds that leave a depression on which the rifle would rest, are constructed with the excavated earth to a height of 15 inches. When making the mounds, as the men's legs would incline to the left, as far as possible, shelter must be made in that direction. With a pick and shovel one man should construct such pit (Fig. 1) in 10 minutes. A better type of pit (Fig. 2) 2 feet 6 inches in width and 18 inches in depth, could be constructed in half an hour; in this a man can kneel when firing; should time allow, an hour's work would make a more comfortable and better protected pit, as shown by the dotted mound and hatching. By connecting adjoining pits, small shelter trenches may be formed, providing for groups of men. The usual allowance in width is 2 feet 6 inches per man. For a man to fire standing, a pit 3 feet in depth is required: this, with the excavated earth, gives a cover of 6 feet; the time taken in excavating and completing this by one man would be one and a half hours. For the foregoing, by commencing a shallower pit, as opportunity occurred, the greater depth could be reached. The ordinary earth mound necessitates a man firing over the top, which leads to an exposure of the head. For better protection loopholing is adopted, and is generally done by the use of sandbags, four of which are required per loophole, two being laid three inches apart as headers, and two resting on the top as stretchers. Fig. 4 shows how a kneeling pit may be developed, the original excavation "A" and embankment "a" may be increased as follows:—

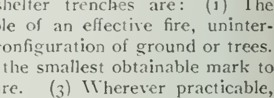
1. For men to stand close to bank, remove space marked "B"; by excavating part marked "C," a seat will be formed. Should a step or kneeling space be required, "B" would remain, and D, C and E would be moved. The breastwork shown on Fig. 5 is a development of the latter, the earth near the firing trench being pushed forward and an outer trench cut on the enemy's side.

The chief points to be considered when constructing shelter trenches are: (1) The making possible of an effective fire, uninterrupted by the configuration of ground or trees. (2) Presenting the smallest obtainable mark to the enemy's fire. (3) Wherever practicable, arrange for drainage. to avoid quagmires in rainy weather. (4) Sand and light earths are better defence than hard earths or plastic clays. (5) A trench should not be made in front of an elevation, particularly if not bullet-absorbing. In respect to the latter, a high sandbank of usual batter would be less disadvantageous to the defenders; but, given a hard rock or wall, on its being struck by a shrapnel shell, the contents would scatter at the rear of the trenches.

Infantry in the second line, either as supports or reserves, are, when possible, protected by natural depressions in the ground. In the absence of these, shrapnel-proof shelters may be requisitioned. These consist of excavations, roofed with timber and covered with earth dressed over to resist bullets and affording no mark to the enemy.

When cover is required for guns there are two





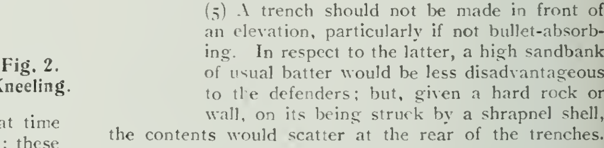


Fig. 3.—Standing Pit. Fig. 4.—The Development of a Kneeling to a Standing Pit. Fig. 5 (below)—Breastworks.

courses open: (1) Construction of an epaulment, or (2) sinking a gun pit. The choice depends on local conditions; given a soft soil with no natural shelter, the latter is preferable, as the excavated earth forms the embankment, and a reduced height above ground is required with less exposure to the enemy's fire. A roughly pitched base to take the wheels would be of advantage. Given a hard soil with natural banks, an epaulment would be preferable, the banks giving, in some part, natural shelter, and their existence requiring less soil for the completed earthwork. The advantage of the latter over the pit is the fact that it can be completed after the gun is in action.

*Read before the Institution of Municipal and County Engineers of Great Britain.

whilst, of necessity, the gun cannot be worked from the pit until its completion. Fig. 7 shows a gun pit which would take one man from 5 to 10 hours to construct, according to the nature of the soil; these pits rarely exceed fifteen inches in depth.

An epaulment is somewhat similar in plan, but varied according to local conditions.

Obstacles.—The strength of a post can be increased by the use of suitable obstacles. In selecting their position a site should be chosen where they can be well hidden from the assailants, but will allow an easy advance on the part of the defenders. No particular materials are specified for this purpose; the most suitable are those that cannot be removed by the ordinary weapons or tools that the attackers would carry. As an obstacle, that to the best of my knowledge is not mentioned in military manuals. I suggest broken bottles, etc., with bottoms set in concrete. Loose straw and leaves saturated with tar would be of advantage against a foe stalking on all fours. Orthodox obstacles include entanglements, pits and palisades; the former consist of wires: these, if set low, are about eighteen inches off the ground, fixed on stout stakes, well driven in and about six feet apart. The wires are twisted around the posts and carried horizontally and diagonally. An entanglement more difficult to negotiate is that with posts four feet above ground, with the wire from the base of one post taken to the top of another, and by crossing the wires a useful defence is made; barbed wire is, of course, preferable to plain.

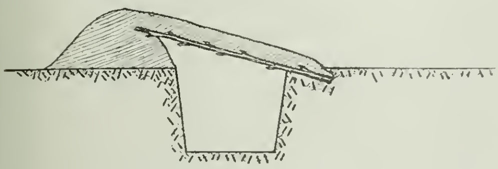

Fig. 6.—Cover for Reserves.

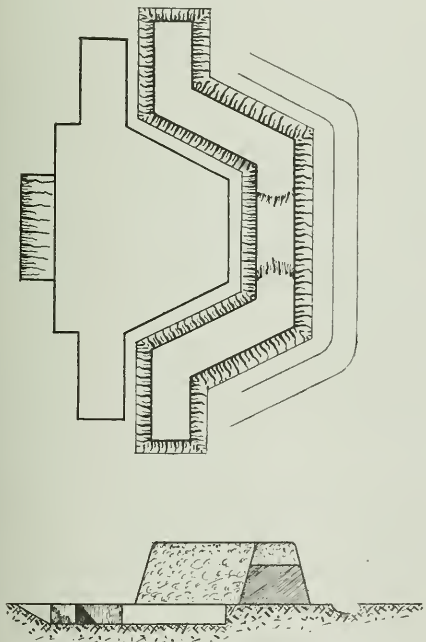

Fig. 7.—Plan and Section of a Gun Pit.

In the absence of wire, pickets with pointed tops, trees, or brushwood fastened with points in the direction of the enemy, will form difficult impediments.

Military pits are planned on lozenge pattern and consist of small holes containing pointed pickets: an entanglement of wire over the surface is of advantage, and further improvement is made by erecting on the enemy's side a glacis, formed of the excavated earth. This should be eighteen inches in height, as near vertical as practicable on the defenders' side, with an easy slope towards the attackers, to facilitate their progress and hide the obstacle until it is reached.

Palisades may be erected in ditches that are controlled by the defenders' fire. A useful material is the pointed form of galvanized iron fencing. In the absence of stock patterns, by the use of an axe on the top edge, the plain pattern can be made very effective.

STREET PAVING METHODS.

The repair of streets and roadways is one of the most important works that come under the direction of the municipal engineer. There are many causes for the defects that are constantly arising with ordinary paving, but perhaps the most prevalent is that the specification, in the first place, was not properly drawn up. Frequently pavements are laid with too weak a base, and cracks develop in all directions. Occasionally the lateral support is far from rigid. Where asphalt surface disintegrates in places it may be found that the decay is due to leakage from gas mains, in which case it is useless to try to patch the surface until things are properly adjusted underneath. The question is becoming pressing as to whether, in the course of the next few years, we shall not have to reconsider all our present methods of roadmaking. It is an open secret that many are investigating the behavior of materials under other methods of laying than those usually employed, under traffic conditions, and a number of interesting experiments have already been carried out. In connection with these it is interesting to recall the work done at Mankato, in Minnesota, a short time ago. First the driveway was narrowed to 30 ft., curbed and guttered, after which it was excavated to the depth of 6 in. and levelled. Five inches of dry crushed limestone, 1½ in. to 2 in. in diameter, was then put on and rolled down with a 10-ton roller. Ordinary tar, brought to the boiling point, was then applied until the whole surface was covered. Then a layer of broken stone of 1 in. to 1¼ in., mixed with coarse gravel, was applied on the surface, in the proportion of three parts of stone to one of gravel. This was first mixed dry on a platform and then thoroughly blended with hot tar, and applied on the surface to a depth of 2 in., and tamped into place to conform with the surface of the street. Dry domestic cement was then applied to the surface, and the street was again rolled, after which the road was heavily sanded and rolled for the last time. The road was allowed to stand for fourteen days before it was thrown open to traffic, and when hardened presented a very fine and somewhat resilient surface, which proved exceptionally durable.

FLOW REGULATION ON THE GRAND RIVER.

THE Grand River Valley, in Ontario, is well noted for its natural production and resources, its manufactures and trade, and its density of population. It is not the earliest settled part of the province, the eastern counties along Lake Ontario claiming that distinction. But with the advent of transportation facilities, the southwestern peninsula progressed and later surpassed the older settlement.

In line with its development, however, has been the partial sacrifice of one of the country's great natural resources—timber growth. Agriculture occasioned heavy invasions into magnificently wooded districts.

Another great natural resource is the perennial, never-failing, precipitation ensuring, with proper husbandry, the continuing productivity of the soil, and ensuring as well stream flow, ground water, water supply as required by large communities, and water power developments.

That the wasteful destruction of forest growth would have produced a marked effect on precipitation, is to be expected, from prevalent ideas of similar conditions elsewhere. That this is not the case, however, but that the effect has been rather on stream flow itself, is brought out in the following article. How the seriousness of the situation has aroused action to prevent damage by spring flood, and what steps are being contemplated to compensate for the axeman's intrusion upon Nature's mode of regulation was brought out in a most interesting manner before the Galt Board of Trade on November 27th, 1914, by W. H. Breithaupt, C.E., Mem. Can. Soc. C.E., Mem. Inst. C.E. Regarding the effect of land denudation, Mr. Breithaupt has this to say:

"Since the beginning of continuous observations, seventy and more years ago, in various parts of the peninsula, (at not many places but at enough to establish the fact), precipitation has remained practically constant, varying somewhat from period to period, but on the whole remaining about the same. Destruction of the great forests has not, as is sometimes erroneously held, diminished rainfall or snowfall. It has, however, caused great change in the flow of streams, the former characteristics of which, moderate floods on snow melting in the spring and well sustained flow throughout the year, having changed to destructive floods, and dwindling, almost disappearing, flow, in the low-water months of the year. The greatest factor of change in the run-off rate of a number of rivers in the Ontario Peninsula has been the drainage of the hundreds of square miles of swamps on the table land of the headwater area.

"With the destruction along the whole course of the river, particularly in the cities and towns along its banks, caused by the spring floods, now almost an annual occurrence, and the small flow of polluted river during the summer months, flood control, and regulation of flow, have become the most important conservation questions immediately concerning us in the Grand River Valley."

These matters were brought to the notice of the Provincial Government at various times. The result has been that for the past two seasons the engineering staff of the Hydro-Electric Power Commission of Ontario has been carrying on an investigation, by topographical survey and by precipitation and stream flow observations preliminary to the adoption of a plan of construction whereby future danger will be minimized. We abstract the following from Mr. Breithaupt's address, concerning the favorable results so far attained and concerning what, illustrated by existing cases of a similar nature, may be expected when the river has been subjected to a system of storage:

There are two main methods of preventing the overflow of a river channel: (1) By making such channel of sufficient cross-section and declivity, by means of walls or dykes on the banks, deepening and removal of obstructions in the channel, cutting off detours and otherwise straightening the channel so as to make it shorter and therefore its declivity greater. (2) By impounding water in excess of the capacity of the channel by means of reservoirs, or by retardation of flow on sufficiently large areas of the watershed by forestation.

When floods on a river are very large as compared to the normal flow the first method requires a relatively large channel, and has the further disadvantages that any improvements benefit only their immediate vicinity and may very detrimentally affect the country further down stream in that the velocity of delivery has been increased, and that the water which might have been held further upstream for sustained flow is wasted. The method of impounding excess waters, on the other hand, benefits the entire river below the reservoir, both in flood control and in sustained flow obtained by the gradual release of the impounded waters.

The St. Lawrence River, with its vast natural regulating basins, the Great Lakes, exemplifies on the largest scale the flow-regulating effect of large impounding reservoirs in the course of the river. On its largest tributary, the Ottawa, greatly increased storage is being obtained by raising the outlets of a number of lakes in the upper part of the watershed of the river.*

The work has been in progress since 1909 and material benefit has already resulted. When completed it will give an increase of low-water flow at the city of Ottawa of from 10,000 to 12,000 cu. ft. per second, bringing the flow for this period to a minimum of somewhat under 40,000 c.f.s. The great benefit of this conservation, in flood relief, equalization of flow and the raising of water level for navigation purposes, will, owing to very favorable natural conditions, be secured at an estimated total cost of less than one million dollars.

In general, the regulation of a river by means of storage reservoirs is more applicable on smaller rivers. On such rivers it has become a well recognized method, and has had numerous successful and highly beneficial applications. I shall here mention two, selected on account of their similarity in many respects to the Grand River regulation scheme, both of them in Germany.

The dam on the Eder River in the principality of Waldeck is 160 ft. high, above foundations, and makes a reservoir with storage capacity of 7,350,000,000 cu. ft., a little over 4½ sq. miles in area. The drainage area above the dam is 542 sq. miles, of which 40% is wooded. Average rainfall on the drainage area is 33 in. in the year. With only 10% of the capacity of the reservoir held as reserve the minimum flow is six times what it had been. The total cost of this undertaking was $4,902,380, of which $2,142,850 was for land and damages. Several small villages and many farms are flooded by the reservoir. One main purpose, beside flood prevention, was the development of water power. The large expenditure has already been found to be an excellent investment.

The largest dam in Europe is on the Bober River, a tributary of the Oder, and was completed in November, 1912. In keeping with its importance as an economic

*This storage on the Upper Ottawa was described in August 7, 1913, and December 4, 1913, issues of *The Canadian Engineer*.

work it was opened with great ceremony in presence of the Emperor. The contributary drainage area, mountainous and steep, with quick run-off, is 467 sq. miles, from which the maximum recorded discharge, in July, 1897, was 42,360 c.f.s., giving a very destructive flood which was the immediate cause of the building of the dam. In comparison to this discharge, that of the Grand River in Galt, from a contributary drainage area nearly three times as large, reached a maximum of between 30,000 and 35,000 c.f.s. on the evening of April 7th, 1912. The minimum flow of the Bober at the dam site is 53 c.f.s. The capacity of the reservoir is 1,765,000,000 cu. ft., large enough to impound the damaging part of the flood, the capacity of the lower river channel only being allowed to pass the dam. Owing to short duration of the flood flow, 60% of the capacity of the reservoir can be retained and used for water power development at the dam and for increase of flow downstream. The dam is 203 ft. high above foundations, and 918 ft. long and 23 ft. wide on the crest. It is a solid masonry structure. With the great depth of water in the reservoir its surface area is a little under one square mile when full. The cost of the dam was $1,416,000, and of land and land damages $576,000, total $1,992,000, of which the State of Prussia paid four-fifths and the province of Silesia one-fifth.

To make flow regulation of a river economically practicable by storage it is necessary that a natural storage basin, or basins, the fewer used for the required capacity the more economical, should exist in the course of the stream, with enough contributary drainage area to give the volume of water necessary to fulfil the requirements of regulation; enough that the impounding of the volume of water coming from it will materially lessen the volume further down stream, and enough that the water so impounded will, on being released at a fixed rate, give increase of flow down stream for a long enough period.

On the Grand River it has been sufficiently demonstrated that if the flood flow of the upper main river, extending to about the north line of the township of Waterloo, and the flood flow of the Conestogo tributary, can be held, in main part, the problem of prevention of destructive floods in the lower river will be solved. Let us see what this would imply. In the great flood of April 7th and 8th, 1912, the approximate maximum discharges, continuing at maximum only for short times and destructively high for two days at most at any place were: At Elora, being the bulk of the main upper river, 13,000 c.f.s.; at St. Jacobs, practically the whole of the Conestogo River, 12,300; at Bridgeport, 4 miles below the Conestogo outlet, 24,000; at Galt, 33,000; at Brantford, 51,000. It is clear that if 15,000 cu. ft. per second of flow of the upper discharge, including the Conestogo, could have been held back for two days the lower river would have remained within its normal channel.

The Hydro-Electric Power Commission began its work on the Grand River in the fall of 1912 with a reconnaissance survey extending from the outlet at Lake Erie to the headwaters of the river and also up all the main tributaries to their headwaters. This survey disclosed three sites on the main river practicable for reservoirs of considerable capacity, the largest one below Elora; two sites on the Conestogo River of fair capacity; two on the Speed River not large enough to be of material benefit; one on the Nith with fair capacity, and one on Whiteman's Creek. Levels were carried the length of the survey and bench marks established, mostly on bridge piers and abutments as far up as Belwood on the main river, and also on the Speed and on the Nith. Eighteen gauges were set, on the main river and tributaries. One in Galt is on the easterly pier of Concession St. bridge; its zero is 851 ft. above sea level. There is also one at Kerr St. bridge, Galt Creek.

Discharge observations began with July, 1913, and as the spring flood this year was an exceptionally light one no destructive flood discharge has yet been gauged by the Commission. Discharges are recorded for five stations on the main river, one on the Nith, two on the Speed, one on the Conestogo, one on Fairchild's Creek, one on Boston Creek, and one on Galt Creek at Kerr St. bridge.

Detailed topographical surveys of the larger reservoir sites have been the work of this year and it is here that important favorable conditions have been found. The largest practicable basin is on the main river in Pilkington Township, Wellington County, extending from about the southerly boundary line of the township, the northerly boundary of Waterloo County, into the gorge below Elora.

The general conformation along the river from the Canadian Pacific Railway bridge at West Montrose up shows a fairly straight, narrow valley, 2,500 to 3,000 ft. in width, with steep sides, about alike, for several miles, and then expanding into a wide basin, which again narrows toward Elora. Contours were established at 10-foot intervals and plotted on a large scale map. Two dam locations were considered, No. 1 dam some distance down the valley described, and No. 2 dam at its entrance at the neck of the wide basin. No. 1 dam gives considerably the larger capacity, 2,618,563,000 cu. ft., as compared to No. 2, 1,920,422,000 cu. ft. The elevation of the river bed at No. 1 dam is 1,065, and water level elevation for the capacity stated is 1,150 ft. Foundation investigations for the dam have not yet been made, but as limestone is exposed a little further upstream and is underlying at the site it is expected that a satisfactory foundation will be practicable. Allowing for depth to foundation and for height of crest above highest water the height of the dam will be 100 ft., or somewhat more, at centre. Its length will be approximately 2,800 ft. The area of the surface of the reservoir when filled to 1,150 ft. elevation will be almost exactly 2½ sq. miles; allowing for marginal land a total of about 2¾ sq. miles, 1,760 acres would be required. A large part of this land is stream bed or subject to overflow, the rest good farm land, including a number of farm steads with their buildings. Two roads and a bridge would have to be relocated. The mean depth of the reservoir when full would be 36.9 ft., maximum depth 85 ft. Assuming the water level not to fall below elevation 1,080 the dischargeable capacity of the reservoir would be 2,592,282,000 cu. ft., in round numbers 2,600,000,000.

The cost of this reservoir cannot yet be estimated with any close approximation. Assuming $75 per acre as an average for the total 1,760 acres we get for this item $132,000. The cost of the dam is as yet indefinite, but if the whole project can be carried out for $1,000,000, as now seems reasonable to expect, or even $1,500,000, it will well repay its cost.

The drainage area to this reservoir site is approximately 480 sq. miles. Assuming an annual precipitation of from 35 to 38 inches and a run-off of 1 ft., the annual run-off would suffice to fill the reservoir five times. The 1912 flood flow in Elora, 13,000 c.f.s., would take 55¼ hours to fill the capacity of 2,600,000,000 cu. ft. A considerable stream, the Irvin River, comes in just below Elora. This, with a smaller stream, gives over one-seventh of the drainage area of 480 sq. miles considered. Assuming the Elora discharge to be correspondingly in-

creased, to 15,000 c.f.s., we get exactly two days, 48 hours, of maximum flood flow containable in the reservoir, and this would be the maximum relief afforded for the length of the lower river from this one reservoir, a relief that would reduce the 1913 maximum two days' flow in Galt by more than half.

It is, however, very desirable to also control the flood flow coming from the Conestogo. On this tributary the results have not yet been so fully worked out as for the Pilkington basin. No such capacity as that is found practicable on the Conestogo, but there is one site, fairly upstream, with drainage area of not over 250 sq. miles (the drainage area to St. Jacobs is 312 sq. miles) where it is approximately estimated that a capacity of one billion cu. ft. can be obtained. This, together with the No. 2 Pilkington dam (smaller than No. 1) would give better flood control in the lower river, in that a much larger volume could be held back, even if for shorter time. In this manner a volume approximating 20,000 c.f.s., the combined flow of both main river and Conestogo tributary, could be held back for 24 hours.

As to maintenance of flow for the low-water months, 2.6 billion cu. ft. of water would give a continuous flow of 300 cu. ft. per second for three months and ten days. In that period rainfall at various times could be expected, making up not alone for evaporation in the reservoir but also contributing to flow. On the other hand, evaporation appears, as far as observations of stream flow have gone, to have large diminishing effect on run-off, in the Grand River watershed.

At Belwood the mean discharge for the months of August and September, 1913, was only 5 c.f.s.; at Conestogo, drainage area 538 sq. miles, 24½ c.f.s.; while at Eugenia Falls, on the Beaver River, on the steep slope to Georgian Bay on the north side of the table land, the main discharge for the same time, with only 74 sq. miles of drainage area, was 30½ c.f.s., a very remarkable difference, due to two main conditions, the much greater declivity of the Beaver drainage area, and the fact that it contains swamps and is otherwise still largely wooded.

A reservoir above Elora and Fergus is very desirable in the complete scheme. At Belwood the drainage area is 270 sq. miles and the valley deep and apparently well defined. Investigations so far have not given a sufficiently favorable reservoir site.

One feature greatly simplifying the problem on the Grand River is that there is only one large flood in the year, in the spring on snow melting. The great floods in Ohio and Indiana last year were also in the spring, in March, but were caused by rainfall, almost wholly.

There was rainfall of 5.31 in. in 47 hours, 3 in. in 20 hours after the first saturation. Three inches of run-off in the drainage area of Galt would produce 9,500,000,000 cu. ft. of water to pass which, even in 36 hours, would mean a continuous, uninterrupted flow of 40,000 cu. ft. per second, greater than any maximum that has occurred here. Waves lasting for hours only would much exceed even this discharge. There is no record of any such discharge in the Grand River valley. At the present day it would mean destruction of property on an unprecedented scale. Precipitation in the central parts of the United States and Canada is largely from the Gulf of Mexico, as this was. It spread over a large area in Ohio and Indiana. Why did it stop at Ohio? The cool belt of equable temperature over the Great Lakes, around the Ontario Peninsula is, no doubt, a barrier against extreme meteorological disturbances.

It may be accepted as now established that flow regulation on the Grand River, control of destructive floods and maintenance of flow in low-water period, by impounding surplus waters, whether in one or more reservoirs, is economically practicable.

SAFE LOADS FOR ROPES AND CHAINS.

The accompanying table shows the safe loads which can be carried by wire rope, crane chain and manila rope of various sizes, when used in different positions and combinations. This very useful information has been compiled by the National Founders' Association and published as a part of a safety bulletin recently issued. The following are from among the valuable pointers the bulletin contains:

Chain hooks and similar parts should slowly bend if overloaded and thus give warning of their unsafe condition. They should therefore be well annealed, and never tempered or hardened. A brittle part will snap outright and drop the load.

It is clear that hoisting appliances should be suitably designed and well made. It is yet more important that their use be carefully and intelligently supervised and their original strength maintained. There is evidently not so much danger when handling unusually heavy loads, for such operations are, as a rule, under the care of the most capable men, who anticipate the extra risk by careful preparation. Hoisting accidents more frequently occur when ordinary loads are being handled by ordinary men, and when the usual facilities are either too light, wrongly employed, or weakened by wear or use.

It is of first importance that men using hoisting accessories should know the strength of the same. It is not sufficient to know the size, unless the grade is also known. While 1,500 lb. may be a safe load for a single sling made of ⅜-in. plow steel wire rope, such a load would be excessive for an iron wire rope sling of the same diameter. This wide range of strength also occurs in different grades of chains and other accessories, but the difference is not readily apparent. It is therefore dangerous to provide several grades of slings and hooks in the same shop. Furthermore, a new workman, fresh from a shop in which only the strongest slings and hooks are employed, is liable to assume that the appliances in the new shop are equally strong. The safety of workmen, therefore, requires that all slings of equal size should be of equal strength, and of maximum strength, and that other details are proportionately strong.

While workmen who are accustomed to the use of slings acquire, by long experience, a valuable knowledge of the strength of chains and ropes under varying conditions, this should not be left to guesswork. It is advisable to post in conspicuous places in the shop, especially at the chain racks, and, where possible, at the point of operation of each crane, a chart showing the loads which can be safely supported by slings of various sizes, whether used normally or in a manner that decreases their lifting capacity. From a study of satisfactory crane practice in various large plants, a chart of safe loads has been compiled, which is published herewith. The loads recommended in this chart are more conservative than those usually specified, because it is intended to recognize the possible existence of slight, unobserved weaknesses in slings and the liability of excessive strains which may be applied to slings through misjudgment or accident.

It will be noted that the safe loads shown upon this chart are based upon the use of 6 by 19 or 6 by 37 plow steel wire rope; the best grade of wrought iron, handmade chain; and four-strand long fibre manila rope. Here

again the advantage of standardizing the grades of materials used for hoisting purposes is an advantage; otherwise the chart would be misleading.

Under no condition should hoisting appliances which are defective or unsafe be allowed to remain within the reach of the workmen. By carelessness or mistake, these may be used in place of perfect ones with serious results in the shape of an accident ensuing. A defective chain, hook, eyebolt, ring or other hoisting appliance should be removed from the shop on the instant of its discovery. In addition, they should be so damaged, if they are impossible of repair, that there is no possibility of a workman using them by mistake. One of the reasons which may tend to prevent enforcement of this rule, is an inadequate supply of slings and other accessories. Unless there are

SAFE LOADS FOR ROPES AND CHAINS
(IN POUNDS)
Prepared by National Founders' Association

CAUTION: When handling molten metal, wire ropes and chains should be 25% stronger than indicated in table.

NOTE. The safe loads in table are for each SINGLE rope or chain. When used double or in other multiples the loads may be increased proportionately.	Dia.	Cir.	When used straight	When used at 60° angle	When used at 45° angle	When used at 60° angle
PLOW STEEL WIRE ROPE	3/8"		1,500	1,275	1,050	750
	1/2		2,400	2,050	1,700	1,200
(6 strands of 19 or 37 wires.)	5/8		4,000	3,400	2,800	2,000

plenty of spare appliances, there may be hesitation in removing a sling from service for the purpose of repairs. It may be retained in use until a more convenient season, but during this interval it may become subjected to a greater strain than it can withstand in its weakened condition, and an accident with possible resultant loss of life may take place.

In the use of chain slings, the workman should be cautioned against striking heavy blows either upon the chain or the hooks to force them into position on the load. These blows are liable to injure the chain and cause a weakness, which will result in its eventual failure. Where multipart slings are used and it is necessary to equalize the length of each part, other material than cast iron should be used for insertion between the links of the chain. Cast iron pieces will break under load and the failure will cause a sudden shock on the chain links which may break or permanently injure it. In the use of wire rope slings, kinks must be avoided. These acutely bend the wires, which bends are suddenly straightened out under load. An excessive strain thereby comes upon the sling and breaks it.

INERTIA EFFECTS IN PIPE-LINES.*

By S. L. Berry,
Consulting Engineer, San Francisco, Cal.

An extended and detailed study of the conditions to be found in pipes conveying water, when the velocity of flow is changed, has led to the conclusion that there has not been an adequate recognition of the importance of considering the elasticity of both the water and the pipe walls. It has become clear that only by such consideration can correct results be obtained.

It is commonly admitted that the rapidly moving pressure waves set up, when a valve is opened or closed, are annoying and, when excessive, must be taken care of by relief valves, but it is claimed that they have no place in those greater and longer movements which accompany velocity changes. A formula which is often used to calculate these effects ignores the compressibility of the water and the elasticity of the pipe material. It is the purpose of this article to show clearly that this formula is absolutely and unequivocally wrong, has no foundation in fact, and must lead to erroneous results.

At the foundation of all these phenomena is gravity, the manifestation of nature which gives to bodies that quality called weight, which when opposed produces pressure and when unopposed produces movement. Should the opposition decrease, the pressure will decrease and the velocity increase, and vice versâ. This is universal and applies to all ponderable bodies. Such influences as friction, which cause a loss of energy, will modify the results in accordance with their magnitude.

Inertia is that quality of bodies which tends to keep them in a given state of rest or motion unless acted on by some force. A body in motion has energy in proportion to its weight and to the square of its velocity. It is evident, therefore, that to increase the velocity of a body it is necessary to put energy into it, and to decrease it, energy must be taken from it. This act is called overcoming the inertia of a body. It is furthermore true that with a given change of velocity, the amount of energy put in when accelerating will be the same as that taken out when retarding. In other words, acceleration and retardation differ only in direction, the energy change being the same with any given velocity change.

The above remarks are elementary in nature and are introduced solely for the purpose of laying a foundation for what follows.

Consider a pipe-line filled with water under pressure and provided with a valve at the lower end. When the valve is in a closed position the water is compressed and the pipe distended in proportion to the pressure. In this case gravity, being opposed, produces pressure. On

*From Western Engineering, August, 1914.

opening the valve the opposition to gravity decreases and movement results. This commences at once, and the velocity at a point behind the valve will be in proportion to the fall in pressure at that point. Whether a gauge located there will correctly indicate the fall in pressure will depend upon its accuracy and sensitiveness and upon the manner in which it is attached to the pipe. In this case the energy which must be put into the water to increase its velocity comes from the water itself and from the pipe walls, which are now under less stress, and which have given up a portion of the energy stored in them. This involves a change from potential to kinetic energy.

On the other hand, when the valve is moved in a closing direction, the opposition to gravity is increased, the velocity decreases and the pressure increases; the energy given up by the water as a moving body is stored in the water and pipe walls, the one being compressed and the other distended.

In both instances an unstable condition is set up, as in the first case the pressure is much below that due to the head, and in the latter much higher. The former persists until the energy taken can be restored, which occurs on the return of the wave from the reservoir, and the latter until the excess stored can be dissipated. Equal velocity changes are accompanied by equal pressure changes whether the water be accelerated or retarded.

The changes which commence at the valve are followed by changes along the pipe-line, pressure waves traversing the pipe at velocities dependent upon the material of the pipe walls and the ratio of wall thickness to diameter.

In a previous article formulæ and diagrams were given to determine the velocity of wave propagation and the maximum ram pressure attained under any given set of conditions, and reference is made thereto for these particulars.

It is to be noted that if, in a given case, a decrease in velocity of flow of 1 ft. per second is accompanied by a ram pressure of 50 lb., a like increase in velocity will be accompanied by a fall in pressure of 50 pounds.

The formula commonly used for calculating the inertia effects of velocity changes is

$$Ha = \frac{L\,v}{g\,t} \text{ in which}$$

Ha = accelerating or retarding head in feet.
L = length of pipe in feet.
v = velocity change, feet per second.
t = time of change, in seconds.
g = 32.2 feet per second.

This considers that the pipe is rigid and the water incompressible. It necessarily includes, as a condition, that, in a uniform pipe, all the water shall have the same velocity at the same time; that any change in velocity at the lower end shall be accompanied simultaneously by the same changes throughout. This is indicated by the inclusion of L, the length of the pipe. As a matter of fact such a condition has been shown, theoretically and experimentally, to be impossible.

The most extensive and thorough experiments along these lines were made in 1897 and 1898, in Moscow, Russia, by three engineers, working under the directions of N. Simin, manager of the city waterworks. The results were worked up by N. Joukowsky, in 1898 and published in 1900.

These show conclusively that changes initiated at the valve produce changes along the pipe after a time interval dependent upon the distance and the velocity of wave propagation, and they prove, in a very satisfactory manner, the formulæ which have been developed by theoretical means.

To bring out clearly the difference in results between the correct elastic theory and the incorrect rigid formula, the following table has been prepared. It applies to a steel pipe, 24 in. diameter, ¼-in. wall, and having lengths as listed. The velocity of wave propagation is 3,370 ft. per second.

Pipe = 1,000 ft. long.

Time of gate closing, sec.	0.00	0.02	0.04	0.10	0.30	0.45	0.60
Pressure, rigid formula	00	675	337	135	45	30	22
Pounds, elastic formula	45	45	45	45	45	45	45

Pipe = 10,000 feet long.

Time of gate closing, seconds	0.00	0.02	0.10	0.30	1.00	3.00	4.00	5.00	6.00
Pressure, rigid formula	00	6750	1350	450	135	45	34	27	22
Lb., elastic formula	45	45	45	45	45	45	45	45	45

There are several interesting facts brought out in the table. In the rigid formula the pipe length has a decided influence on the calculated result, while in the elastic, it has none whatever as far as the amount of pressure is concerned, but it does control the duration of this pressure. This has been amply proved by experiment. In the rigid formula the time of gate movement has an inverse proportionate effect upon the calculated pressure, while in the elastic, within certain limits, it has no effect. There is this fact to be noted in this connection, that the rigid formula requires that the pressure shall instantly rise to the figure given and remain there during the entire closing movement of the gate, and that the elastic indicates that the rise will be gradual and in proportion to the decrease of velocity. Experiments have shown that the former is not true and that the latter is true.

The pressures agree for a closing time equal to the time required for the wave to reach the reservoir, but with the non-elastic formula, this pressure must be considered to have existed during the entire time, while in the elastic, the maximum is reached only at the end of the period. To obtain this pressure throughout the entire period, using the elastic formulæ, the gate would have to be closed instantly. With less closing time than that mentioned above the non-elastic formula gives results which are excessive, and with greater results which are too low.

There is nothing in the non-elastic formula to account for that lagging effect which is so well known and which causes recurring waves. These are perfectly accounted for by the elastic theory, and, under proper conditions, can be predetermined.

At the limits given in the table the pressures given by the elastic formulæ commence to fall off, decreasing with increase of closing time. It is readily seen that with long conduits a great variance in results will be found, and as the elastic formulæ are based on actual conditions fixed by natural laws, a choice should not be difficult to make.

The table is based on a velocity of only 1 ft. per second. For changes of 5 to 10 ft. per second the differences would be much increased, as the ram pressures in both cases increase in proportion to the velocity change.

It is evident that the non-elastic formula is based on certain assumptions, namely, that water is incompressible and that the pipe walls are rigid, which are not true; therefore the results obtained by its use cannot be correct. How great the variation will be will depend, as shown in the table, upon the time taken for the velocity change.

COMPUTING CROSS-SECTION AREAS.

THE co-ordinate method of determining areas is not well understood, probably because of its simplicity. Were it to involve the use of higher mathematics every engineer would likely be more or less familiar with it.

Distances measured parallel to $X X$ are usually called abscissas, and those parallel to $Y Y$, ordinates. (See Fig. 1.)

The co-ordinates of any known point are usually computed from the co-ordinates of some other point to which the unknown point is tied by an angle and distance. The difference in co-ordinates between the known and unknown points will be obtained thus:

Difference in X = distance × sin. azimuth angle.

Difference in Y = distance × cos. azimuth angle.

Sometimes the unknown point is located by angles from two other points, in which case the distance between the two points whose co-ordinates are known can be computed and then the distance from one of the known points to the unknown point.

To Determine the Area of by Rectangular Co-ordinates.—The area of the figure 1, 2, 3, 4 (Fig. 1) is equal to the trapezoids:

$(a, 1, 2, b)$ + $(b, 2, 3, c)$ — $(a, 1, 4, d)$ — $(d, 4, 3, c)$.

Expressed as an equation in terms of the co-ordinates the area is:

$$1, 2, 3, 4 = (y_1 - y_2)\frac{x_1 + x_2}{2} + (y_2 - y_3)\frac{x_2 + x_3}{2}$$

$$- (y_4 - y_3)\frac{x_4 + x_3}{2} - (y_1 - y_4)\frac{x_1 + x_4}{2} \quad - \quad - \quad (1)$$

$$= \tfrac{1}{2}\left[y_1(x_2 - x_4) + y_2(x_3 - x_1) + y_3(x_4 - x_2) + y_4(x_1 - x_3)\right] \quad (2)$$

From this equation is derived the following rule for obtaining the area from the co-ordinates of its corners:

(1) Number the corners consecutively.

(2) Multiply each abscissa (or ordinate) by the difference between the following and the preceding ordinates (or abscissas), always subtracting the following from the preceding (or always subtracting the preceding from the following), and take half the sum of the products.

The adoption of this method of computing railway cross-sections or other earth bodies is quite simple. A cross-section is considered merely as an area, the co-ordinates of all corners of which are known—the cuts or fills being looked upon as ordinates, and expressed in terms of Y, the distance out from the centre being looked upon as abscissæ and expressed in terms of X, and the area being A. The general formula for any conceivable shape of section (Fig. 2) would be:

$$A = \tfrac{1}{2}\, y_0 \left[(x_1 - x_n) + y_1(x_2 - x_0) + y_2(x_3 - x_1) + y_3(x_4 - x_2) + y_4(x_5 - x_3) + y_5(x_6 - x_4) + y_6(x_7 - x_5) + y_7(x_n - x_6) + y_n(x_0 - x_7)\right].$$

The application of this formula is by no means so difficult as the formidable appearance of the algebraic or word statement would indicate. In making use of this formula (which is adopted to the computation of any conceivable shape of area) it may be necessary for one in figuring the first few sections to draw rough sketches of the sections in order to make sure he is not confusing the order of the points, but a very little experience soon enables him to compute the areas from the cross-section notes directly without this help. The formula may be taught in a few minutes to men with scarcely a grammar school education, while well educated engineers are frequently obliged to plot each section, and then laboriously either break it up into triangles or run the planimeters over it to find in the end only an approximate area.

The formula is not an approximation, as slope and other formulas are. It is mathematically exact as shown in Fig. 1, and is absolutely general. Its application to the

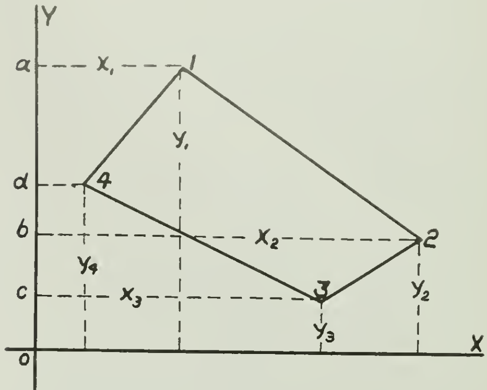

Fig. 1.

simpler sections shows up, as well as the more difficult "three-level" section. The following concrete directions should be followed:—

Begin at any point on the section and proceed in either direction (clockwise or counter-clockwise), multiplying each cut (or fill) in its order by the horizontal distance between the point just preceding and the point just succeeding. In cases where one passes to the right in measuring the horizontal distance from the preceding to the succeeding point the product obtained by multiplying this distance by the cut (or fill) at the intermediate point is of one sign and in cases where one passes to the left the product is of the opposite sign. Take one-half the difference between the sums of the products of opposite signs and the result is the area of the section.

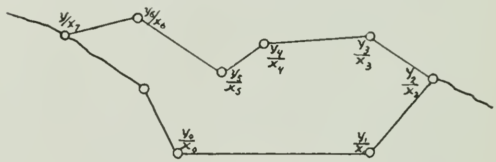

Fig. 2.

A peculiarity of this formula is that while it is absolutely general, its application to the simpler sections shows immediately the shortest possible way of computing the areas. Thus, in a side cut where only the slope stake reading and the intersection of the earth surface with the grade line are taken, the area is a simple triangle and application of the formula to the computation of the area would seem to require three multiplications. But one factor in each of two of these multiplications is zero because the points are on the grade line and the cut (or fill) equal to zero, and it is therefore necessary to perform only one multiplication and take half the product. Also in the case of the so-called "three-point section," or "three-level section," which is really a five-point section,

two multiplications are similarly eliminated and two more (the outside slope points) can be worked together by first taking the sum of these cuts (or fills) and then multiplying by one-half the roadbed widths. This fact is apparent at once, because inspection shows that in every section each of the outside cuts (or fills) will be multiplied by half the roadbed width. Many more useful and interesting features of the application of the formula appear as one extends its use.

The data obtained from field notes are usually in the form of cross-sections which are taken at right angles to some general line of the construction, thereby dividing the earthwork into prismoidal solids with their bases parallel and their sides either plane or warped surfaces. The

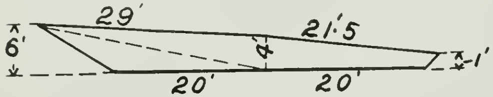

Fig. 3.

bases of the solids are the cross-sections which are obtained by taking sections of trench excavation or of road construction.

End Area Formula.—The simplest method of computing the volume of a prismoidal solid is to average the areas of the two bases and multiply by the distance between them, which, expressed as a formula, is

$$v = \frac{A_1 + A_2}{2} \times l \quad \text{(End area formula).}$$

in which A_1 and A_2 are the areas of the two end bases and l is the distance between them. This method is used to a very great extent throughout the country, although it does not give sufficiently accurate results for certain classes of work.

Prismoidal Formula. — The correct volume of a prismoid is expressed by

$$\text{Volume} = \frac{l}{6}(A_1 + 4A_m + A_2)$$

in which l is the distance between the two bases, A_1 and A_2; and A_m is the "middle area"; i.e., the area half-way between the two bases, which is obtained by averaging the corresponding dimensions of the two end areas, A_1 and A_2; it should not be taken as the mean of A_1 and A_2.

The end areas can easily be computed by dividing them into triangles, as shown in Fig. 3, the area of which can be found readily from the dimensions given in the field notes.

$$\text{Notes of section:} \quad \frac{29.0}{+6.0} \quad +4.0 \quad \frac{21.5}{+1.0}$$

$$\text{Area} = \frac{4 \times (21.5 + 29)}{2} \quad \frac{20 \times (1 + 6)}{2}$$

$$= 2 \times 50.5 + 10 \times 7 = 171.$$

It is also the custom with some surveyors to plot each section carefully to scale and to obtain its area by use of the planimeter. This is probably the most practical method when the sections are very irregular since the field work does not warrant the use of very accurate methods.

There are several other methods employed in computing earthwork but the above are by far the most common.

Rough Estimates.—Rough estimates of the quantity of earthwork are often required for preliminary estimates of the cost of construction or for monthly estimates of the amount of work done. For preliminary estimates of road construction, very frequently the notes of alignment and the profile of the centre line are the only information at hand. From this profile the centre cuts or fills can be obtained, and the cross-sections can be assumed to be level sections and computed by the end area method. The slight errors resulting will be corrected in the final estimate.

In obtaining the required data from which to make an approximate estimate of the quantity of earthwork, the engineer has an opportunity to exercise his judgment extensively. Rough estimates do not, as a rule, call for a large amount of field work. It is important that as few measurements as possible should be taken and that these should also be at the proper places to give complete data and to allow simple computations. Too often engineers, as soon as they arrive on the work and before making a study of their problems, begin to take measurements, consequently they return to the office after hours of hard work with a mass of figures from which it will take several more hours to compute the quantities. A few moments' thought given to the choosing of the proper measurements to be taken in the field would give data which could be computed in a few minutes by use of the slide rule, affording results sufficiently accurate for rough estimates.

FAILURE OF TEMPORARY DAM.

The new power plant of the Ottawa and Hull Power and Manufacturing Company, which is being constructed at the Chaudiere Falls, has received a setback owing to the breaking of a temporary dam while excavation work was in progress. Foundation work includes a large amount of rock excavation. The lumber mills of J. R. Booth & Company are close by, and a temporary dam, which had been constructed of earth and cinders, was built on the edge of the power site nearest the mills. It is thought that owing to a sudden rising of water in the river and a simultaneous starting of the mills, a strong eddy was produced near the temporary structure. It was of such duration that before the water had subsided the cinder embankment had been worn away and the excavation flooded.

A cofferdam will be constructed without delay and the flooded portion pumped out.

YORK COUNTY (ONT.) ROAD WORK IN 1914.

At the November session of the York County Council, just closed, Mr. E. A. James, chief engineer of the York Highway Commission, presented the commission's report.

The commission was organized in 1911, with instructions to build 110 miles of road in the southern part of York County. During 1914 they constructed some 20 miles of roads, including bridges, at a cost of about $90,000. This makes completed to date some 80 miles of road at an expenditure, including bridges, of $500,000. The type of road includes gravel, water-bound macadam, tar-bound macadam, concrete and brick.

A new $300,000 post office was opened last week at Lethbridge, Alta.

Editorial

ONTARIO WORKMEN'S COMPENSATION ACT

The new Workmen's Compensation Act, passed at the last session of the Ontario Government, comes into effect on January 1st, 1915. Those who have given the matter serious consideration have not reasonable grounds to find fault with this advanced legislation.

It has taken a long time for the province to make proper provision for workmen injured by industrial accidents and their dependants. Under the old law the employer of labor had many defences which enabled him to resist, if desired, claims for compensation made by injured employees. This was the fault of the laws on the statute books relating to the liability of an employer for accidents to his employees. Under the new law, these defences are abolished. The fact of the injury alone will entitle an injured workman or his dependants to certain compensation provided by the act. The Ontario government, therefore, has shown a progressive spirit in enacting a new law to take the place of the obsolete one that has been in operation in that province since 1885.

But *The Canadian Engineer* cannot see eye to eye with the government regarding the plans they have adopted for the administration of the new act. Based on the German system, the new act has taken away the liberty of the employer in schedule known as number 1, preventing him buying his protection, or insuring, in the cheapest market. He is compelled under the grouping system to subscribe to an accident fund and is assessed with other employers of labor in the same group, according to the requirements of the case, in respect to current payments as well as deferred payments, as called for under the act. Great powers are given the commissioners in the matter of making assessments and transferring employers from one group to another as they may deem advisable. Indeed, the commissioners have the power at any time to take the employer out of Schedule I. and transfer him to Schedule II. or to put him beyond the scope of the act altogether. Schedule II. deals with industries, the employers in connection with which are individually liable to pay the compensation.

When an employer is taken out of Schedule I., which schedule subscribes to the accident fund, and is placed in Schedule II., the individual liability obtains. That is to say, he still comes under the provisions of the act, but is compelled either to carry his own risk or to insure with a casualty insurance company. This individual liability concession has been made, amongst others, to the big steam railway companies as well as to electric railway companies. It is obvious, therefore, that by putting these industries into Schedule II. a material concession has been made that does not apply to the employers grouped in Schedule I. In other words, the employers grouped in Schedule II. are permitted to buy their insurance in the cheapest market. The question arises whether these special concessions should be made only to big corporations, such as the railway companies, etc., while other industries are forced to pay into an accident fund on an assessment basis, thereby making it absolutely impossible for them to know what their insurance will cost. The weakness of this accident fund scheme, or grouping system, has already been demonstrated. The commissioners, according to the official Ontario Gazette dated November 28, have made numerous changes in the groups in Schedule I. and have read a number of industries out of the act altogether. Those that have been read out of the act are liable to common law actions. These changes cannot have been made by reason of any experience on the part of the commissioners in their administration of the act, because the act has not yet come into force.

The government evidently appreciate the weakness of their experiment and fortunately made provision in the new act for the transfer of any industry coming under Schedule I. to Schedule II., so that it is in the power of the commissioners to transfer any one or the whole of those in Schedule I. to Schedule II. In the latter event, the individual liability would apply to every case, just as it now applies only to the big corporations cited above. The present conditions brought about by the war are bound to have a telling effect on the assessment plan scheme, and it is questionable whether it is wise for the government to run the risk of seeing this new legislation fall to pieces.

The appointment of the commissioners is a most commendable feature of the new act. They are a final tribunal in adjudicating upon accident claims in dispute. Litigation should therefore be a thing of the past, as the commissioners' decision will be final. It is not too late for the government to remedy the mistake which seems to have been made. *The Canadian Engineer* does not advise deferring the effective operation of the act, but the commissioners will be conserving the best interests of employers and employees alike if they forthwith transfer to Schedule II. many or all of Schedule I. The workman has nothing to lose by the change. The employer is bound to do one of two things. He must take out insurance covering all the provisions of the new act or put up substantial security with the government to provide for any accidents for which he may be called upon to pay compensation.

THE EXPANSIVE FORCE OF ICE.

In the transactions of the Royal Society of Canada appears a paper by Messrs. H. T. Barnes, J. W. Hayward, and Norman M. McLeod, which contains some very useful information on the expansive force of ice, a matter of very great importance in engineering work in Canada. Allowance for the frost of the ice sheet has been the subject of considerable diversity of opinion, and the conclusions which these gentlemen have reached as a result of their studies, as yet of a preliminary nature, of ice expansion, will be found interesting:

(1) The crushing strength of ice is most probably 400 pounds per square inch.

(2) An ice block will yield under pressure at approximately 200 pounds per square inch, probably due to the slipping of the crystals.

(3) An ice sheet will form cracks on the upper and under surface due to unequal strain.

(4) A permanent expansion may result if the cracks become filled and frozen.

(5) According to the most trustworthy results of other observers, the ice frozen to concrete develops its full crushing strength, and the tensile strength of ice is under 200 pounds per square inch.

INITIAL OPERATION OF CEDARS RAPIDS PLANT.

The extensive power plant which the Cedars Rapids Manufacturing and Power Company has under construction on the St. Lawrence River, about 30 miles west of Montreal, has reached the stage of near-completion. At the present time the company is developing power to a limited extent and utilizing it for lighting the village of Cedars and for power for construction equipment. The work at present is largely of a cleaning-up nature, preparatory to actual commencement of operations next month. It will be remembered that the initial development of 80,000 h.p. has been contracted for, 60,000 of it by the Aluminum Company, for use at Messina Falls, N.Y., and the remaining 20,000 by the Montreal Light, Heat and Power Company. The design calls for an ultimate development of 160,000 h.p.

An incident of particular interest occurred on October 29th, when a berm acting as a cofferdam during the construction of the 2-mile head-race, prematurely gave way, filling the head-race and putting one of the large units into operation. Some small damage was caused as the unit was without oil in its thrust bearing.

The design and construction of this large power plant has been described and illustrated in previous issues of *The Canadian Engineer*. For the bulk of details respecting it, the reader is referred to issues of January 1st, 1914, and July 9th, 1914. The 2-mile earth bank forming the south wall of the canal and extending to the power house was joined to the shore at the head of the canal by an earth bank which acted as a cofferdam and shut off the water from the entire canal and power house site. The bank was of quite sufficient mass, but the company, anxious to make progress, set about to have as much as possible of it removed by steam shovels, so as to enable a speedy completion of the job, when the power house had been completed and ready for operation. The steam shovels had only excavated one cut along its bank when the water broke through, filling the entire canal in a few hours, submerging the shovels and breaking through one of the power house intakes, starting up a 10,800 h.p. unit.

It had been the intention of the contractors to remove the berm after the canal had been filled with water at a gradual rate extending over several days, so as to subject the dike forming the south bank of the head race to as gradual an increase of pressure as possible. The dike resisted the speedy application of hydrostatic pressure thrust upon it, however, and sustained no damage. The accident was undoubtedly a severe test for the dike, the specifications for which called for a concrete core-wall over 8,000 ft. in length.

As for the power unit, the only damage done to it was in the Kingsbury thrust bearing on the top of the generator. It is 5 ft. in diameter and supports a load of over 5½ million pounds. Although in operation for only a short period, before the intake was closed, the heat generated between the bearing surfaces, in the absence of oil, soon burned the babbit out.

According to statistics compiled by the American Iron and Steel Institute in 1913, about seven times as much steel pipe as iron pipe was made in the United States. In 1905 the amount of steel pipe was only a little more than double the amount of iron pipe. The amount of iron pipe produced year by year, however, remains about stationary or slowly declines, while steel pipe production has rapidly increased. The use of steel in making welded pipe was not successful commercially until about the close of the '80's, but has had a very rapid growth in the quarter century since it began, the output in 1913 having been 2,189,000 tons.

SPEEDY CONSTRUCTION AT ROGER'S PASS, B.C.

The following has been announced by Messrs. Foley Bros., Welch & Stewart as the record for November in the construction of the Roger's Pass Tunnel, 26,400 ft. in length through Mount Macdonald of the Selkirk Range:

East end centre heading, 588 ft. schist with some quartzite.

East end pioneer heading, 529 ft. quartzite with some schist.

West end pioneer heading, 817 ft., slate with small quartzite bands.

West end centre heading, 654 ft. slate with small quartzite bands.

The west end pioneer heading footage of 817 ft. in thirty days is believed to be the record for the American continent. It was driven down grade through rock that could not be broken over 6 ft. per round. The greatest footage in a single day was 37 ft.

In our issue of June 12th, 1913, we commented upon the record established by the Mount Royal Tunnel and Terminal Co. in driving 810 ft. in 31 days. In this instance the daily progress averaged 22 to 28 ft. for the greater part of the time.

It is very interesting to note that these two examples of speedy engineering construction are Canadian. While both typify the use to best advantage of the most modern plant and methods of construction, it is all the more interesting in that the tunneling methods differ materially. In the Roger's Pass enterprise the use of a pioneer heading is being tried out for the first time on such a gigantic scale, it being felt that considerable time could be saved by this method. Time was also a vital factor in connection with the choice of methods for the Canadian Northern tunnel, and a bottom centre heading method was adopted with this in mind.

At the present time the pioneer bore of the Roger's Pass tunnel is about two-fifths completed. It is anticipated that the entire work will be finished many months before the specified time. Mr. Joseph Murphy is assistant superintendent east end, and Mr. Joseph Fowler is assistant superintendent at west end.

SOUTH AFRICAN IRON INDUSTRY.

According to a consular report the manufacture of steel from steel and iron scrap has been started at Vereeniging by the Union Steel Corporation of South Africa, Limited. Rolling was commenced at the works of the corporation on August 1, 1913, and a Siemen's steel melting furnace was started on September 1, 1913, upon which date the first ingot of steel produced in South Africa was cast. The full equipment of the works consists of a 10 to 12-ton Siemen's open-hearth melting furnace, a 600-ton press, two Siemen's reheating furnaces and a 12-inch rolling mill. The whole plant is covered in by buildings of galvanized corrugated iron. The scrap yards now contain roughly 20,000 tons of scrap of which about 16,000 tons had been removed by the corporation from the Pretoria depot of the railway administration. The material produced consists of bar iron and steel of all sections, fencing standards, light colliery rails, and so forth.

The number of men employed at the works of the corporation is about 100 Europeans and 90 natives. Most of the skilled operatives have been brought out from England under contract.

THE CRUSHING STRENGTH OF ICE.

VARIOUS values, ranging from 325 to 1,000 pounds per square inch, as determined by a standard United States testing machine, have been presented for the crushing strength of ice. The importance of this, when calculating the expansive force of an ice sheet (referred to editorially on another page of this issue), makes it very desirable for hydraulic engineers to have more accurate knowledge. In 1871 a value of 208 pounds per square inch was given by Czowski for ice below the freezing point. Ludlow estimated it to vary from 100 to 1,000 pounds with an average of 575 pounds, from a study of ice on Delaware Bay. C. A. Mees arrives at a value of 400 pounds per square inch in the following way: He concludes that the crushing strength may attain a value of 800 pounds in a short column, but adds that wherever the effects of ice expansion have been carefully observed, it has been noted that bending takes place and this may be expected because we have, in an ice sheet, a long column effect. On this account, assuming one-half the crushing strength may be developed before bending, the maximum thrust may equal 400 pounds per square inch.

Table I.

Results of Compression Tests (Bell).

No. of test.	Size of cube.	Crushing strength.	Lbs. per sq. inch.	Temp.'s Ice.	Temp.'s Air.	Remarks.
1	2 x 2	1,926 lbs.	481.5	18	27	1 23/32 height after crushing.

" 26	17	7 x 6½ x 6	Parallel	....	224 "
" 26	18	6⅛ x 6 x 5⅞	"	248 "	557 "

Mean 370 lbs. per sq. inch, axis parallel.
" 356 " " axis perpendicular.

Mean of both 363 lbs. per sq. inch.

Table I. gives the results of a valuable series of experiments by George G. Bell, who used small cubes of approximately 2 inches.

This information is introductory to a paper on the subject presented last May to the Royal Society of Canada by Professor H. T. Barnes, of McGill University,

Montreal. Dr. Barnes is inclined to neglect Mr. Bell's highest result, thereby securing more consistent values, ranging from 358 to 783 pounds per square inch. Mr. Bell himself states that he considers 400 pounds a fair estimate of the crushing strength of ice from all his tests.

Dr. Barnes describes experiments performed by himself to determine the crushing strength of perfectly clear ice on somewhat larger blocks. The ice was cut from the river and tested in a hydraulic press. One large piece 6 in. x 28 in. x 40 in., furnished the largest number of individual blocks. The direction of the crystalline axis was determined by knowing the plane of freezing, and the various blocks were cut by a hand-saw accordingly. The ends of the blocks were melted smooth on a hot plate to fit the plates of the press. When the pressure was applied, considerable melting resulted on the ends. The blocks were kept outside at a temperature ranging from —8° C. to 0° C. and were brought into the laboratory for the tests. One interesting fact was noted, that the blocks were heard to crack at a pressure, approximately one-half the ultimate crushing force. It was repeatedly observed that as soon as the pressure was increased sufficiently to cause the first audible crack, the block appeared to stiffen, and the pressure ran up much quicker, with much less melting. In some cases the melting appeared to cease altogether. Dr. Barnes concluded that the giving way of the ice under pressure allowed the melted ice to run into cracks, where it must have frozen and cemented the block more firmly, being unable to see any of the cracks which could be distinctly heard at half the crushing pressure.

The only effect of varying the position of the axis of the ice with respect to the direction of the pressure, appeared to be the way the block burst. When the axis was parallel to the applied pressure, the ice burst sideways into innumerable long needles, resembling a cake of ice which has all but fallen to pieces in the sun. The cake fell to pieces on being removed from the press. When the axis was at right angles to the applied force, the block cracked lengthwise and transversely without shattering.

Table II. gives the results of the tests performed by Dr. Barnes. It will be seen that the mean value for all the tests for parallel axis is a little higher than the mean for perpendicular axis, but the difference is too small to make it possible to draw any definite conclusions. The results show considerable variation, which may be purely accidental or may have some bearing on the character of the initial distribution of the pressure.

The relation between the first cracking of the ice and the final crushing force is one which, the experimenter states, must be further investigated.

In closing he remarks: "The question of the relation of temperature to the crushing strength is one of importance. It has been assumed that ice becomes stronger at low temperature. The hardness of ice increases considerably as the temperature falls to 0° F. but I am inclined to think that the ice also becomes more brittle. In the neighborhood of the freezing point, ice is much more plastic than it is at lower temperatures. The plastic effect is, however, masked by the regulation effect, and it is a question whether the ice mass is not really firmer near the freezing point than when cooled much below. This can, however, only be settled by further experiment."

A number of samples of radium-bearing ore from British Columbia have been received by the mines branch, Department of Mines, Ottawa, for investigation.

THE SUCCESSFUL BURNING OF LIGNITE.

In *The Canadian Engineer* for December 3rd, 1914, the investigations of the Saskatchewan government into the coal resources of the province were referred to, and an analysis was given to illustrate its serviceability as fuel for power and domestic purposes.

Following it we present herewith some notes respecting the burning of lignite in the State of Texas, in which state there is an estimated area of over 60,000 square miles, containing what is roughly concluded to be 30 billion tons of lignite. In many centres its use in manufacturing plants has been extensively adopted. The lignite resources of the state have been recently investigated by Professor Wm. B. Philips, of the University of Texas, who has made a study of its commercial use. In a recent report he alludes to the introduction of a grate specially adapted to burn lignite screenings, a grade that is sold at from 50 to 60 cents per ton. This grate is similar to the ordinary grate, being rectangular in cross-section, but slightly wider at the top than at the base. On its top face are marginal and transverse ribs or partitions, forming fuel pockets adapted to retain fine fuel. On its bottom face are recesses forming air pockets. These fuel pockets are from one-half to five-eighths of an inch deep and are connected with the air pockets by tapered ventilating holes, largest at their lower ends, being about three-eighths of an inch in diameter at the top and 50% larger at the bottom. The tapering form of the ventilating holes tends to cause a discharge of the air in jets into the fuel.

In ordinary grates, especially where a forced or induced draft is used, the air rushes through the weakest places in the fire. With this grate the individual air pockets underneath prevent the air from rushing past some of the ventilating holes and overcharging others. These air pockets form sources of supply to the separate groups of ventilating holes and cause an even distribution of the air to the fuel pockets in the top of the bar throughout the grate surface. A steam blower is used with these grates.

Much lignite is now fired by hand, and while this method unquestionably gives good results when proper care is taken, the stoker seems to be necessary for large establishments. There are no difficult obstacles to be overcome. The main points to consider are that lignite is a fuel which parts with its volatile combustible matter more quickly than does ordinary bituminous coal and that the fixed carbon is not of a coking nature. This means that a large quantity of air must be supplied within a short time after the fuel begins to part with its volatile combustible matter and is supplied at the requisite points. The smoke must be prevented from forming, for it is difficult to handle it afterwards. The fixed carbon will take care of itself, if prevented from falling through the interstices of the grate; it is the volatile combustible matter that has to be cared for.

It does not appear that there are greater variations in the composition of lignites than in the coals with which they are to compete, so that a stoker installation successful with one lignite should be capable of burning any other under comparable conditions.

It has been stated in Ottawa that the value of minerals produced in Canada this year will be considerably less than that of 1913, because of the scarcity of capital for mining development and also because of the low prices which have existed for silver and other minerals.

TIDEWATER ACTIVITIES AT HALIFAX.

CONSIDERING the effect which the war and the anteceding depression has had upon engineering work in general, the progress that has been made during the past several months on the Intercolonial Railway ocean terminals under construction at Halifax, is inspiring and more or less remarkable. The work on the superstructure of pier No. 2 has made material advancement, as has also the railway cuttings and other phases of the whole scheme. The general details of the terminal plans were given in *The Canadian Engineer* for July 30th, 1914. Briefly, the terminals will extend for 1 ¼ miles southward from Fawson Street along the western shore of Halifax Harbor. They provide for a bulkhead passenger landing quay 2,000 ft. long, and four new piers from 650 to 800 ft. long and 235 ft. broad, the whole protected at the southern end by a rubber mound breakwater a quarter of a mile long. Ample railway tracks and connections, sheds and equipment, grain elevator, etc., will be provided for the handling of passengers and cargo, and a special feature of the terminals will be the exceptionally good facilities for the handling of passengers, mails and express freight. Extensive immigration quarters will be provided at the passenger landing quay. The quays will provide for depths ranging up to 45 ft., and will therefore be ample for the largest transatlantic liners afloat.

View, Looking South, of No. 2 Shed, While Under Construction.

Entrance to Reinforced Concrete Freight Shed, Pier No. 2.

A part of the scheme is the Halifax Ocean Terminals Railway, a double track line from Rockingham, four miles from North Street station, Halifax, to the site of the new terminals. Thus the existing line of the Intercolonial will be connected with the quay. The line includes the formation of a freight terminal yard and a diversion of the I.C.R. at Bedford Basin and at Fairview. It passes under the Halifax and South Western Railway and follows the North West Arm to Young Avenue. This portion of the line includes a cutting, mostly through rock, and of sufficient depth to pass under all existing roads and streets with very slight alterations. Grade crossings have been entirely eliminated and the location of the railway along the North West Arm and the south end of the peninsula was decided upon with a special view toward the preservation of the natural beauty of these suburban and residential parts of the city. Railway construction work has included a large amount of filling along the west shore of Halifax harbor for the proposed bulkhead, quays and piers.

The contract for the grading of the railway was awarded a year ago last June to the Cook Construction Company and Wheaton Bros., and work commenced early last fall. Grading included earth cuts 22 ft. wide for single track with an additional 13 ft. for each extra track. In rock the widths were 20 ft. and 13 ft. respectively with slopes of ¼ to 1. Embankments were to have a grade width of 16 ft. or 18 ft. when under or over 16 ft. in height, respectively. The earth slopes were to be 1½ to 1. The maximum grade is 6/10%, compensated for curvature and the sharpest curve, 4%. This contract included the construction of the freight terminal yard and breakwater. Materials for both were provided by the excavations from the railway cuttings. The breakwater embankment consists of rock protected on the sides and seaward extremity by rubble rip-rap and paved on the top with large angular pieces of rock.

Specifications call for a core embankment 40 ft. in width at low-water level of ordinary spring tides. Side slopes 1 : 1 extend from the bottom of the harbor to low-water level. From its base to 30 ft. below water level the embankment consists of varying sized rocks. In the upper portion these rocks are not to weigh less than 1 ton each. The sides have large angular blocks for protection to 30 ft. below water level, these blocks weighing from ½ ton to 2 tons each. On the seaward slope the rip-rap is to be composed of blocks weighing from 2 to 8 tons. This is also the required weight of blocks from the top of the embankment at low-water level to the top of the breakwater. The breakwater will measure 30 ft. in width across the top, and is to be evenly surfaced with all interstices tightly packed.

The buildings for the new terminal include a passenger station, the plans for which have recently been prepared by Ross & Macdonald, Montreal. Plans for other buildings to be constructed upon the piers are now being prepared. The contemplated arrangement includes a power house to furnish light, heat and power, a grain elevator and the large freight shed with abundant trackage facilities for the rapid handling of freight.

The pier, which is the widest in Canada, and which has a floor area of 258,000 sq. ft., is one which, owing to its piling problems, difficulties of concrete construction, length from bulkhead, spacious yard room, etc., has occasioned much admiration from the maritime provinces. At the present time concreting has been practically completed on the freight shed structure, and the building glazed. Accommodation is being provided in it for 2,000 passengers. This accommodation is but temporary and will be removed when the new passenger station has been built.

Four tracks along the south, two in the centre of the building and one on the north side of it, are being installed, the latter three running the full length of the shed. The present immigration building will be removed to permit the laying of the north tracks which will also require, for support, an extension of the bulkhead. This work will be held over until spring.

TELESCOPE FOR VICTORIA OBSERVATORY.

THE Dominion Government contemplates the erection next year of new observatory buildings on Saanich Hill, in the vicinity of Victoria, B.C. The telescope to be installed there during the year was the chief subject in an illustrated address delivered by Dr. J. S. Plaskett, of the Dominion Observatory, Ottawa, at a meeting on December 1st, of the Royal Astronomical Society of Canada, Toronto. The construction of the telescope has been under way for some time. The disc for the main mirror is being ground at the works of the John A. Brashear Co., Pittsburgh. It is 73⅝ inches in diameter and 13⅛ inches thick, and weighs 4,960 pounds. The aperture in the centre of the disc is 9 inches in diameter. The disc itself was made at the Belgian factory of the St. Gobain Glass Works, and shipped from there three days before the outbreak of the war. Dr. Plaskett describes the construction of the mirror as follows:

The mirror-disc is ground and polished on the back surface only approximately, not optically, flat. The front surface, however, the one facing the sky, is carefully and most accurately ground, polished and figured to the correct curve, which is a parabola of revolution. Then this surface is carefully silvered with a thin bright coat of silver, highly polished, reflecting back the light, which hence does not enter the glass at all. As long as the front surface of the glass is perfect, and the rest of the material is sufficiently homogeneous and rigid to hold this surface perfect and unchanged, it does not matter about its transparency or freedom from bubbles or minor defects.

After reflection at the concave surface of the big disc the light from the star proceeds back up the tube in a converging cone towards the focus of the upper mirror. It may be observed in three ways: (1) It may be received on a bent telescope, one with a right-angled prism in it, and the enlarged images may be viewed at the side of the tube. This is the prime focus arrangement. (2) A plane mirror at an angle of 5 degrees may intercept the cone of light about three and a half feet below the focus, thus forming the images at the side of the tube, where they may be viewed by the eyepiece. This is the Newtonian arrangement. (3) The light may be intercepted about seven feet below the focus by a convex mirror, which reflects the light back through the hole in the centre of the big mirror-disc, forming the images anywhere desired along the optical axis generally, of course, a foot or so below the big disc. Here they can be viewed by eye-pieces. This is the Cassegrain method.

The Cassegrain and Newtonian attachments intercept between six and seven per cent. of the light incident upon the big mirror, but when the images are viewed at the focus the quality is not affected at all; the quantity of light only is slightly diminished. Exactly the same effect would be produced by sticking a circular disc of paper one inch in diameter centrally over a four-inch objective. The image would not seem to be affected.

The construction of the telescope mountings has been under way for some time. The heavy steel castings are being made for the Warner & Swasey Company in Pittsburg and Cleveland and are to be delivered in about four months' time. All the mechanism and smaller parts are being made at the Warner and Swasey works, and it is expected that the entire mounting will be ready for shipment next October.

The plans for the dome and the building for the telescope are practically completed. The walls are to be about 35 ft. high, and the dome about 35 ft., making the total height over 70 ft.

The plan for the office building provide for a large library, which will also be used as a lecture room, with seating for 200 people.

The plans for the other buildings required are well under way. The contracts for the buildings first needed will be let as soon as possible in the New Year, so that construction may begin on April 1. There is every prospect, therefore, that the telescope will be installed during 1915.

AMERICAN ROAD BUILDERS' ASSOCIATION.

The eleventh annual convention of the American Road Builders' Association, to be held in Chicago, December 14th to 18th, inclusive, has attracted the attention of many Canadian highway engineers, and a more than usually representative attendance from this country will likely be in evidence. Among those who have signified their intention of being present are Hon. F. G. MacDiarmid, Minister of Public Works for Ontario; Hon. E. H. Armstrong, Minister of Public Works for Nova Scotia; Mr. John Stock, Deputy Minister of Public Works for Alberta; W. A. McLean, Provinical Highway Engineer for Ontario; W. G. Yorston, Provincial Highway Engineer for Nova Scotia; S. T. Robinson, chairman of the Highway Board of Saskâtchewan; A. McGillivray, engineer to the Manitoba Highway Commission. Representatives of various Canadian cities, of the Toronto Harbor Commission, and similar bodies throughout the Dominion, will also be in attendance.

SOME INTERESTING MOTOR-TESTING EQUIPMENT.

There is an interesting installation in New York where investigations of various kinds on steam engines, particularly of the turbine and rotary type, are carried out. The equipment includes high-speed indicators of the "manograph" type by means of which diagrams can be obtained at speeds as high as 2,000 revolutions per minute, as well as at ordinary low, piston speeds. Another notable feature is the apparatus for making brake tests. This includes an 80 h.p. electric dynamometer with rocking fields, built by the Sprague Electric Works, and also a Heenan and Froude hydraulic dynamometer of the model used by the British Admiralty, having a maximum capacity of 600 h.p. at 5,000 revolutions per minute. Steam is available at 480 pounds per square inch. These facilities have recently been installed in the laboratories of Mr. Joseph Tracy, 1790 Broadway, New York.

The suggestion has been made, and it has been stated that the Government will likely act upon it, that aliens of enemy nationality, who have been placed in charge of the military authorities, be set to work cutting roads and clearing tracts for settlement in the clay belts of Ontario and Quebec.

Coast to Coast

Haileybury, Ont.—Messrs. P. H. Secord and Sons, contractors, have just turned over the newly-completed drill hall to the Department of Militia.

Porcupine, Ont.—The output of the Dome Lake mines has been increased by some 15 tons daily by the addition of extra tables and equipment, put into operation last week. This brings the capacity of the mill up to 50 tons per day.

Cranbrook, B.C.—The branch of the Kootenay Central from Cranbrook to Golden was formally open last week, connecting the Crow's Nest with the main lines of the C.P.R. and traversing one of the most fertile parts of the province.

Princeton, B.C.—Southern British Columbia is looking forward with great interest to the linking up of the boundary valleys with adequate railway facilities, and the good progress that is being made on the Kettle Valley Railway is an assurance that the advent of better transportation will not be long delayed.

Galt, Ont.—The Lake Erie and Northern Railway is ready for business. Work has been rushed along during recent months, ballasting has been proceeded with briskly, and the bridge across Mill Creek, paralleling that of the Grand Trunk Railway, was completed last week.

Portage la Prairie, Man.—The electric railway line into Stonewall is practically completed, there only remaining a little overhead work to be done. Regular service between Winnipeg and Stonewall will likely be in operation before the middle of the month.

Vancouver, B.C.—The greater part of $10,000 a month will be spent, to provide employment during the winter, in the grading of boulevards and streets. Mr. F. L. Fellowes, the supervising city engineer, has closely inspected the entire city, and has made a number of recommendations for extensive improvements in this respect.

Hamilton, Ont.—Engineers of the Department of Public Works, Ottawa, were in Hamilton last week inspecting a revetment wall on the Bay front, which for a distance of about 40 ft., has bulged 31 inches out of alignment as the result of pressure from back-fill. It is estimated that the expenditure connected with the straightening of the wall will be about $25,000.

Toronto, Ont.—Some difficult excavation work has been encountered by the sewers department in connection with the driving of the large trunk sewer tunnel under the C.P.R. tracks near Woodville Ave. At this point the sewer is about 40 feet below the tracks. Compressed air has been used on the job for preventing the intrusion of water, the seepage of which is overabundant.

Winnipeg, Man.—The W.S. and L.W. Ry. have completed the construction of their electric car line from Winnipeg to Stonewall and a service will be in operation about December 15th. Besides 17 miles of 13,200 volt line and track, this work included a subway beneath the C.P.R. Beach line at Middle Church, a sub-station and station house at Stony Mountain, and a station house at Stonewall.

Edmonton, Alta.—As announced in another column of this issue, a contract has been let to D. F. McArthur and Co., for the construction of a line 186 miles in length from Lac la Biche to Fort McMurray. The announcement was made last week by Mr. J. D. McArthur, president of the E.D. and B.C. Railway. It is expected that the new line will be finished by November of next year. It will involve an expenditure of about $2,000,000.

PERSONAL.

A. C. McKENZIE has been appointed town engineer of Preston, Ont.

H. M. PASSMORE has been appointed secretary to the Minister of Public Works of Ontario.

J. W. PUGSLEY has been appointed secretary of the Department of Railways and Canals, Ottawa.

LAWFORD GRANT, sales manager of the Eugene Phillips Co., Montreal, is at present in England on a business trip.

LIEUT. A. L. MIEVILLE is in command of the Toronto section of Canadian engineers now in training at Ottawa.

GEORGE A. JANIN, chief city engineer of Montreal, is to receive a commission enabling him to proceed with the company organized by himself, with the second contingent.

E. W. BEATTY has been appointed vice-president and general counsel of the Canadian Pacific Railway Co. Mr. Beatty has been associated with the legal department of the company since 1901.

H. O. FISKE, until recently connected with the Peterborough (Ontario) Light and Power Co., succeeds Mr. C. B. Howse as manager of the Utilities Commission of that city.

C. BRENNAN, one of the construction engineers of the Edmonton, Dunvegan and British Columbia Railway, is superintending the cutting of the right-of-way of a 60-mile section of the line beyond Smoky River.

Dr. C. J. HASTINGS, Medical Officer of Health for Toronto, was elected first vice-president of the American Public Health Association at the closing session of its annual convention in Jacksonville, Fla., last week.

GEO. W. CRAIG, city engineer of Calgary, had the misfortune to meet with a painful accident while in Omaha, Neb., last week. We are informed that Mr. Craig is improving and will return to Calgary in a few days.

W. A. McLEAN, Provincial Highway Engineer of Ontario, is president of the American Road Builders' Association, and will spend next week in Chicago, where he will preside over the sessions of the eleventh annual convention.

C. L. HERVEY, C.E., chief engineer of the new Glengarry and Stormont Railway, which connects Cornwall with the C.P.R. at St. Polycarpe, Que., was tendered a complimentary luncheon upon the occasion of the completion of the laying of steel last week.

FRED. D. NIMS, electrical engineer and general superintendent of the Western Canada Power Co., Limited, is leaving the service of that company to accept a position with the Olympic Power Co., of Port Angeles, Wash. Mr. Nims deserves special mention for his successful efforts to form a section in Vancouver of the American Institute of Electrical Engineers. Mr. Nims is a member of several of the standing committees of the Institute.

OBITUARY.

The death occurred at Ashtville, North Carolina, of J. T. M. Burnside, B.A.Sc., in his 40th year. Mr. Burnside was a graduate in engineering of the University of Toronto, graduating in 1899, and engaging in mining for several years. He then turned to military affairs, and held a commission in the 48th Highlanders Regiment. Later he transferred to the British army and for some time was stationed on the Gold Coast. A few years ago Mr. Burnside engaged in rail-

way building in China, afterwards returning to Canada and devoting his attention to mining in the Cobalt region. Impaired health induced him to go South, where death overtook him.

Death came suddenly last week to Mr. Frank Rankin, of Haileybury, a member of the engineering staff of the Transcontinental Railway.

CANADIAN SOCIETY OF CIVIL ENGINEERS.

The meeting of the Mechanical Section of the Canadian Society of Civil Engineers, held in Montreal on the evening of December 3rd, was addressed by Mr. C. Brady, his subject being "Steel Passenger Car Frame Construction." Mr. Brady's paper was a neat and masterly treatment of the subject, and was well received by the members. An abstract of it appears on another page of this issue.

Following it an address was given by Lieut. Shirley T. Layton, A.M.Can.Soc.C.E., a graduate of R.M.C. and of McGill University. The speaker dwelt upon the primary object of artillery in modern warfare, explaining it to be for the protection of the advancement of infantry and assistance to its movements. The secondary object was the destruction of the enemy's war equipment. Such interesting points as the uses of different classes of artillery, including horse artillery armed with 13-pound guns, field artillery with 18-pounders, and others of larger order, made Lieut- Layton's paper a most instructive one for the members. He observed that in Montreal there were two heavy artillery batteries, armed with 60-pound guns, one having gone with the first contingent. The remaining battery was now armed with 4.7-inch guns, throwing shells weighing 45 pounds. This gun was well described by the speaker. Its mechanism and ammunition were illustrated by slides. The gun weighs about 4½ tons and the maximum range given on the sight drum is 9,600 yards. It has great power and is remarkably accurate at long ranges. The speaker emphasized its usefulness in bringing cross-fire to bear upon the enemy and also against buildings and fortifications. The recoil of the gun, method of loading and timing of shell explosion were explained in detail. The construction of different kinds of shells and the devices to prevent premature explosion were described.

It may be said of Lieut. Layton that some time ago he left the engineering staff of Walter J. Francis and Co., to accept a commission, and since that time he has recruited the whole number for the Montreal part of the Heavy Brigade, which will go with the next contingent. It is interesting to note in this connection that the Heavy Brigade in Montreal has been in charge of Lieut.-Col. Lacey R. Johnson, also a member of the Society. About 120 members of the Society are participating in active service.

NOMINATIONS, CANADIAN SOCIETY OF CIVIL ENGINEERS.

The following is a list of members who have been nominated for the various offices of the Canadian Society of Civil Engineers for the year 1915:—

For President, F. C. Gamble, Chief Engineer, Public Works Department, Victoria, B.C.; for Vice-President for 3 years, A. E. Doucet, District Engineer, National Transcontinental Ry., Quebec; A. St. Laurent, Public Works Department, Ottawa. For Vice-President for 1 year, E. E. Brydone-Jack, Professor of Civil Engineering, Manitoba University; Gordon Grant, Chief Engineer, National Transcontinental Ry., Ottawa.

For councillors, District 1, S. P. Brown, Chief Engineer, Montreal Tunnel, etc., Canadian Northern Ry.; H. R. Safford, Chief Engineer, G.T.R.; A. Surveyer, Montreal; R. M. Wilson, Montreal. District 2, C. B. Brown, Chief Engineer, Canadian Government Railways, Moncton, N.B.; F. W. W. Doane, City Engineer, Halifax, N.S. District 3, A. Amos, Quebec; T. A. J. Forrester, Quebec. District 4, G. J. Desbarats, Deputy Minister Naval Service, Ottawa; A. J. Grant, Superintending Engineer, Trent Canal, Peterborough, Peterborough, Ont. District 5, S. B. Clement, Chief Engineer, T. and N.O. Ry., North Bay, Ont.; J. L. Weller, Engineer in Charge, Welland Ship Canal, St. Catharines, Ont. District 6, W. G. Chace, Winnipeg; F. H. Peters, Calgary, Alta. District 7, N. J. Ker, Vancouver; D. O. Lewis, District Engineer, Canadian Northern Pacific Ry., Victoria, B.C.

CANADIAN NATIONAL CLAY PRODUCTS ASSOCIATION.

The following speakers are among those who have arranged to prepare papers for presentation at the coming convention of the Association in Toronto, January 26th, 27th and 28th, 1915:—A. C. McKay, Principal of Toronto Technical Schools, "Toronto Technical Schools and their Relation to the Manufacture of Clay Products"; W. W. Smith, Shallow Lake, Ont., "The Making and Burning of Drain Tile"; A. F. Greaves-Walker, Manager, Sun Brick Co., Toronto, " Kiln Kinks"; E. W. Knapp, "Possibility of Manufacturing High-Class Paving Bricks in Ontario"; Andrew Kruson, "Cheap Glazes for Use on Ontario Clays and Shales"; and Philip W. Green, B.A.S.C., A.M.Can.S.C.E., "Standardization of Clay Products from an Architect's Point of View."

TORONTO BRANCH CANADIAN SOCIETY OF CIVIL ENGINEERS.

A meeting of the Toronto Branch of the Canadian Society of Civil Engineers is being held this evening (December 10th), and is being addressed by J. E. Noulan Cauchon. The subject of his address will be the town planning problem, with special reference to the railway features.

COMING MEETINGS.

AMERICAN ROAD BUILDERS ASSOCIATION.—Eleventh Annual Convention; fifth American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau Street, New York, N.Y.

CANADIAN NATIONAL CLAY PRODUCTS ASSOCIATION.—Annual Convention to be held at the King Edward Hotel in Toronto, January 26, 27, and 28, 1915. Secretary, G. C. Keith, 32 Colborne Street, Toronto.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

AMERICAN WATERWORKS ASSOCIATION. — The 35th annual convention, to be held in Cincinnati, Ohio, May 10th to 14th, 1915. Secretary, J. M. Diven, 47 State Street, Troy, N.Y.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.—Annual meeting to be held at the Iowa State College, Ames, Iowa, June 22nd to 25th, 1915. Secretary, F. L. Bishop, University of Pittsburgh, Pittsburgh, Pa.

A weekly paper for engineers and engineering-contractors

ROSEDALE SECTION, BLOOR STREET VIADUCT

PORTION No. 2 OF THE PROPOSED $2,500,000 STRUCTURE TO BRIDGE THE DON AND ROSEDALE VALLEYS IN NORTHEAST TORONTO.

IN *The Canadian Engineer* for October 29th, 1914, a description was given of the larger section of the proposed viaduct to connect Danforth Avenue (east of the Don River) with Bloor Street, thereby linking it and the surrounding district with the older business thoroughfares of the city. While the article dealt chiefly with the design, executed by the Department of Works, for a 1,618-ft. section of the proposed development, it included an interesting summary of preliminary investigations of site and foundation tests. That portion, known as the Don section, was opened to tendering of both steel and concrete interests last July, and the tenders that have been under consideration have included five for steel and five for concrete. The concrete tenders were all based upon designs submitted by the contractors themselves, while the steel tenders were based upon the design of the Department of Works, described in the article referred to above. On Friday, December 11th, the city council awarded the contract for this section to Messrs. Quinlan & Robertson, Montreal, the price being $996,564.81, it being the lowest steel tender, although it was about $147,500 higher than the low tender for a concrete viaduct.

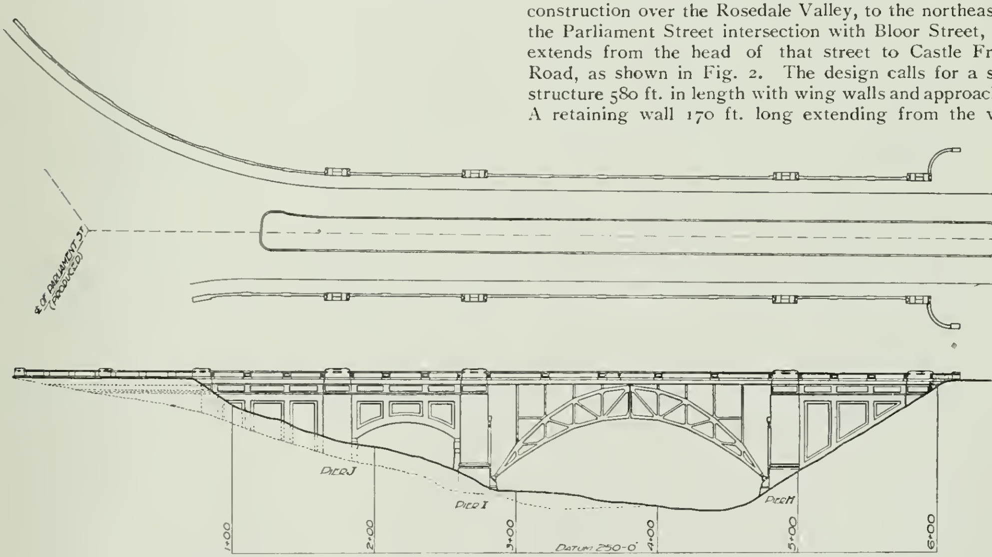

Fig. 1.—Plan and Elevation of the Proposed Rosedale Section of the Bloor Street Viaduct, Toronto.

The Rosedale section of the project provides for the construction over the Rosedale Valley, to the northeast of the Parliament Street intersection with Bloor Street, and extends from the head of that street to Castle Frank Road, as shown in Fig. 2. The design calls for a steel structure 580 ft. in length with wing walls and approaches. A retaining wall 170 ft. long extending from the west abutment of the bridge toward Sherbourne Street, and on the north side, forms an interesting part of the design. The bridge itself includes a 190-ft., 3-hinged steel arch span with steel spandrels and with a 64-ft. rise. This arch is of the same type as the arches on the Don section, previously described. Similarly, there will be an 80-ft. span corresponding in design to that of the Don structure. The cross-section of the bridge is similar to that of the other section, having a total width of 86 ft. from the outer edge of the railing. The centre 22 ft. will be devoted to two street railway tracks. On either side the

design provides for a 20-ft. roadway, bordered on the outside by cantilevered sidewalks $10\frac{3}{4}$ ft. wide. The height of the roadway above the Rosedale Valley drive will be 94 ft. In many respects the general design of the Rosedale section corresponds to the design for the Don section. The specifications also are practically the same for the former as those for the latter. The loading diagrams as well as the clearance diagram for the lower deck, are the same in both cases, and are as illustrated in Figs. 3 and 4, respectively. In Fig. 3, A gives the loading on the upper deck for a 50-ton electric car; the loading diagram, C, is for a 20-ton motor truck, while B denotes the loading for a train of cars on the lower deck. It is to be noted that provision is made here for the future development of a lower deck, as in the case of the other section.

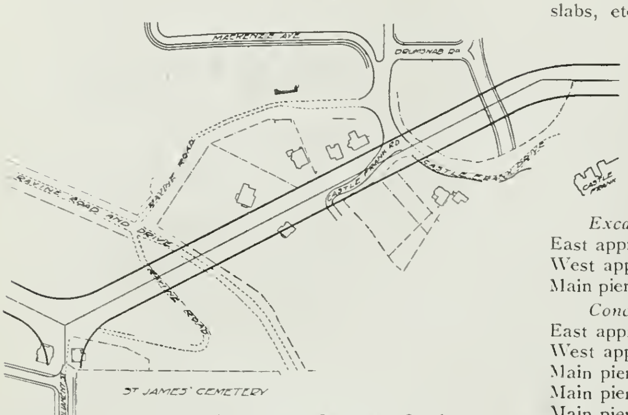

Fig. 2.—Location of Rosedale Section.

The retaining wall is of interesting design, calling for a wall of counterfort type for 69 ft., with a maximum height of 24 ft., the buttresses being spaced 15 ft. c. to c. The remaining portion of the wall will be of cantilever type.

The work and materials required in the construction of the Rosedale section involve about 31,100 cubic yards of excavation for the east and west approaches and for the piers. There will be about 16,900 cubic yards of concrete work in piers, approaches, retaining wall, floor slabs, etc. Reinforcing steel to the extent of about 486,000 pounds will be required, and the structural steel will have a weight of about 3,063,000 pounds. Provision for the lower deck of the Rosedale section (identical in cross-section to that proposed for the Don section) will require about 352,000 pounds of structural steel and 320 cubic yards of concrete. The engineer's estimate of quantities, in brief detail, is as follows:—

Excavation:	
East approach, cu. yds.	21,207
West approach, cu. yds.	1,819
Main piers, cu. yds.	8,082
Concrete:	
East approach, cu. yds.	[1]2,252
West approach, cu. yds.	[2]2,267
Main pier H, foundations, cu. yds.	1,847
Main pier H, body, cu. yds.	3,038
Main pier I, footing, cu. yds.	829
Main pier I, body, cu. yds.	2,610
Main pier I, top, cu. yds.	305
Main pier J, footing, cu. yds.	610
Main pier J, body, cu. yds.	1,540
Main pier J, body, cu. yds.	1,540
In floor, cu. yds.	[3]1,450
Concrete parapet and railing, lin. ft.	1,080
Reinforcing Steel:	
East approach, lbs.	38,100
West approach, lbs.	35,060
Retaining walls, lbs.	19,430
Floor, lbs.	193,260
Pier H, lbs.	46,090
Pier I, lbs.	64,890
Pier J, lbs.	39,970
80-ft. span, lbs.	16,310
Steel Work:	
West approach, lbs.	306,600
80-ft. span, lbs.	451,770
190-ft. span, lbs.	1,501,040
Upper parts piers H and I, lbs.	143,300
Metal in expansion joints, lbs.	7,300
Cast iron pedestals, lbs.	7,600
Cast iron gullies and catch-basins, lbs.	32,300

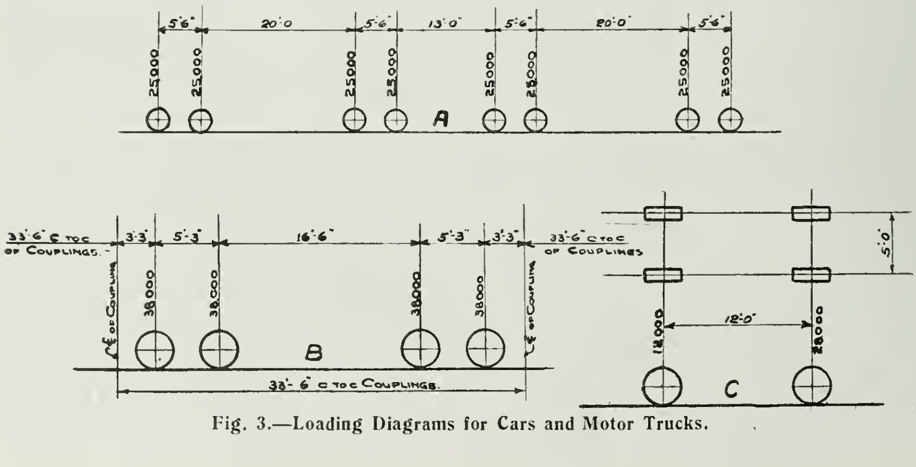

Fig. 3.—Loading Diagrams for Cars and Motor Trucks.

Waterproofing:

Track allowance, membrane and mastic, sq. yds.	1,306
Roadway, felt and waterproofing compound, sq. yds.	2,578
Back of retaining wall, sq. yds.	460
Granite bearings for 190-ft. span, cu. ft.	455

[1]Of this total 228 cu. yds. is in footings for east abutment, 970 cu. yds. is in body of abutment and wing walls, 221 cu. yds. is in north longitudinal walls and 324 cu. yds. in a cross-wall above footings. [2]This includes 620 cu. yds. in body of west abutment, 320 cu. yds. in longitudinal walls, 190 cu. yds. in soffit of 80-ft. span and 284 cu. yds. in side walls of 80-ft. span. [3]Of this 1,257 cu. yds. is floor slab.

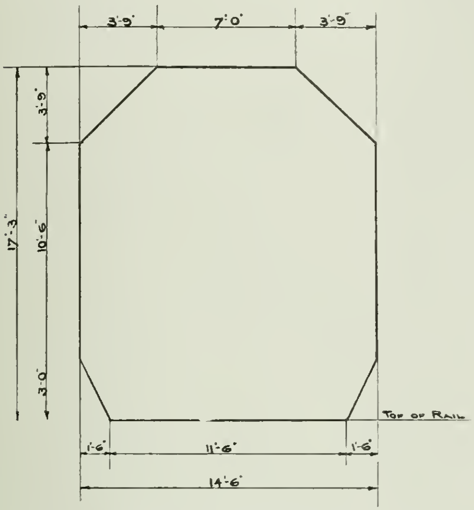

Fig. 4.—Clearance Diagram for Lower Deck (contemplated for the future).

The material required for the lower deck includes the following:—

Steel in stringers, floor-beam stiffeners and anchor bolts, lbs.	352,000
Concrete in slabs, cu. yds.	316
Steel reinforcement in slabs, lbs.	32,300
Hook bolts in slabs, lbs.	550
Cast iron gullies and shoes, lbs.	11,800
Waterproofing, membrane and mastic, sq. yds.	510

Tenders for the Rosedale section were advertised for early in November and will be received up to December 21st, 1914. As in the case of the Don section, bids for steel will be accepted on the plan of the Department of Works, as described herein, and also on a reinforced concrete structure, in which case the tenderer will submit his own plans and specifications.

Among the latest incorporations is that of the Walkerville Roofing Mfg. Co., Limited, capitalized at $60,000. Messrs. J. T. Sullivan, L. H. and C. J. Cheesement are associated with the new concern.

FLOW OF STEAM THROUGH PIPES.

There is perhaps no phase of power-plant design in which the rule-of-thumb methods are still adhered to so commonly as in the determination of the proper size of steam pipes.

Several reasons are attributed by "Power" to this: The commonly accepted formulas are complex, are not any too well substantiated by experimental data nor based on sound theory; the tables given by various writers are incomplete and inconvenient. The engineer who installs pipes which are too large will seldom be criticized, for the mistake shows but slightly in the first cost of the entire plant and the large radiation losses remain unnoticed. Many designers overestimate the importance of keeping the pressure drop in the lines low. Loss of pressure in a pipe line carrying any fluid is due to friction, and results in the transformation of energy of motion of the fluid as a whole into molecular energy or heat. In a water line this heat is usually a total loss, but with steam flowing in well covered pipes most of this heat is carried on with the steam, raising its temperature or its quality. Thus, instead of being able to figure the percentage loss of power as being equal to the percentage of pressure, as is usually true for water or electricity, the loss is materially reduced by the return of the heat to the steam. Or, the total energy of each pound of steam just after entering the pipe is, heat energy + pressure × volume energy + energy of velocity along the pipe.

Before leaving the pipe the heat energy has been drawn upon to increase the volume and also to increase the velocity of the steam, while at the same time the friction has been absorbing a part of the energy of velocity and returning it in the form of heat energy. So, if the pipe could be perfectly insulated all the energy entering the pipe would be delivered at the other end.

CANADIAN PATENTS OWNED BY GERMAN AND AUSTRIAN SUBJECTS.

The following is a list of Canadian patents issued to German and Austrian subjects during August, 1914. For the import of this information our readers are referred to *The Canadian Engineer* for October 29, 1914, page 589. In connection with the following list it is essential to note that the Commissioner of Patents will not void any of these patents, but will grant licenses under the same when the applicant can show that he is willing and intends to manufacture the invention in Canada, and that it is in the interest of Canada, part of Canada, or a particular trade that a license be granted. The applicant will also be required to pay a royalty to the government of probably about 5 per cent. of the selling price of the article.

157216, Aug. 4, 1914—Friction coupling. (Hungary.)

157219, Aug. 4, 1914—Fuse.

157221, Aug. 4, 1914—Type setting and distributing machine.

157236, Aug. 4, 1914—Iron manufacture.

157246, Aug. 4, 1914—Bicycle alarm.

157396, Aug. 18, 1914—Acid converting process.

157402, Aug. 18, 1914—Method of producing chemical reactions in gases.

We are indebted to Ridout and Maybee, Toronto, for the above list.

CAUSES OF BREAKS IN WATER MAINS.

THE annual report of the City of Chicago for 1913 contains the results of an investigation made by Mr. Claude E. Fitch, assistant mechanical engineer, into the causes of breaks in the city's water mains. Many breaks have occurred during past years, but no attempt had been made, until 1912, to discover the cause. Mr. Fitch's findings are very interesting, and are abstracted below. The causes of breaks were ascribed to improper design, poor material, improper handling and installation, soil movements, jarring from traffic, frost, temperature changes, electrolysis, corrosion, excessive static pressure, excessive momentary pressure, periodic pressure waves and extraordinary causes. Explanations of these causes are given as follows:

Improper Design.—For the design of pipe there are numerous formulas giving very nearly the same results, as much the result of experience as theory, and generally considered satisfactory. For the design of valves and special fittings, theory and practice are not so far advanced, but there is not much danger of breaking and such as there may be is more likely to occur at the time the first test is made.

Poor Material.—All reputable builders and nearly all large users employ inspectors who may be reasonably depended on as conscientious in their work. Measurement, superficial inspection, pressure test, hammer test and the breaking of a test bar are the methods usually employed. Chemical tests have their value, but are not so universally used.

Improper Handling and Installation.—A pipe otherwise good may be badly damaged by mishandling in transit or in laying, and thus weakened so as to be unserviceable; or it may be improperly caulked.

Subsidence or Rise of Soil.—Assuming that the pipe has been properly laid, then the soil might be disturbed in one of several ways. Parallel trenches, heavy buildings nearby or the construction of tunnels and subways may so displace soil as to cause leaks or breaks.

Jarring from Traffic.—Where pipes pass through railroad embankments or under street railways or in streets subject to heavy traffic, there is not only displacement of soil from the weights above, but also jars are transmitted to the pipe. Where the displacement is considerable, the danger to the pipes is the same as described in the previous paragraph. The jarring may break a brittle pipe, but the more probable trouble is at the caulking, where the lead is continually deformed by the slight motion, until no longer tight. The resulting leakage causes softening of the soil, making further displacement probable.

Frost.—Under ordinary conditions, this is little to be feared in large mains, as the depth to which the ground freezes in severe winters has been determined by observations extending over many years. Further, the water is scarcely ever below 39 degrees F. in temperature, and if flowing will ordinarily not freeze solid. Troubles from frost are ordinarily confined to smaller mains and service pipes.

Temperature Changes.—The range of temperature of water in mains is not very great, probably 25 degrees, but this is enough to cause a measurable amount of expansion. Expansion or contraction of metals is exerted with great force; almost invariably enough to cause endwise motion of the pipe against the friction of the surrounding soil. This motion is undoubtedly taken up in the more loosely caulked joints, causing them to become more loose and to leak a little. This ability to move slightly at the joints is the reason for the use of the bell and spigot joints, rather than bolted joints.

A more serious phase of this condition may occur at a tightly caulked joint where the cast iron of the bell is first severely strained by the excessive caulking. Should this caulking be done in cold weather, the later expansion of the lead, being several times as great as that of cast iron, may cause sufficient additional strain to rupture the bell.

Electrolysis.—The evidences of damage by electrolysis are generally plain and are likely to be confused only with chemical action due to seepage of corrosive liquids through the soil.

Corrosion.—Pipes are made thicker than is necessary for resisting the physical strains imposed, in order to allow for rusting, and are painted within and without to protect the metal. So far as simple rusting is concerned, a pipe otherwise strong would outlive its usefulness several times in a country of rapid changes. Lead and iron in contact with water or moist earth will cause an electrolytic action on the iron, but experience has shown that this is not a serious matter.

Excessive Static Pressure.—In a small system, relatively new and tight, this might be a source of danger, but in a large system with numerous pumps, engines and mains, much cross connected and with some pipes old and leaky, the danger is not great.

Excessive Momentary Pressure.—Shock, or momentary pressure in the shape of a blow, is one of the most serious troubles to which water mains are subject. Its intensity cannot be calculated with any degree of certainty and therefore it cannot be provided for even approximately in the design. The blow is of the most searching character and is very severe.

Pulsation from pumps is one cause to be considered and may be classed under the head of water hammer. Under this name the effect has been extensively studied.

Periodic Pressure Waves.—Injury from this cause is comparatively infrequent, but may be quite serious, and its way of action is not so easily discovered. Should a pipe receive a set of pressure waves in tune with its natural period of vibration, it will vibrate with increasing force, possibly until it is ruptured, unless stopped by friction.

Extraordinary Causes.—These include explosions and blasting, earthquakes, lightning, intentional injury and possibly the breakdown of a heavy truck above.

An analysis of the list of breaks in Chicago during 1912 showed 42 joint leaks, 3 broken valves and 2 burst pipes. The valves were all three of an ancient type of poor design. No cause was discovered for the bursting of the pipes, although irregular cooling strains were indicated in one case. Of the joint leaks, one was under a railroad embankment and was probably due to the jar of trains and subsidence of the soil. Four were under street tracks where heavier cars have recently been run than previously. A large number were discovered in the spring and early summer after a very severe winter, and temperature changes may have been partly responsible.

But the majority of these leaks were within a mile or so of the Fourteenth street pumping station. This station differs from the Harrison street one only in one pump—the other pumps are exactly similar in the two stations. This pump has twice the rated capacity of the others, a relatively lighter flywheel, and only one air chamber, which is on the pipe line, while the other pumps have a

large air chamber for each plunger. Moreover, the check-valve is placed between the air chamber and the water main. It was therefore concluded that the greater part of the joint leaks were caused by some derangement of the action of this pump, which transmitted pulsations to the mains, possibly assisted by temperature changes and soil movements.

PROPOSED STANDARD SPECIFICATIONS FOR ONE-COURSE CONCRETE HIGHWAY.

THE following specifications have been submitted to the members of the American Concrete Institute to be given their consideration prior to the coming Convention of the Institute to be held in Chicago in February. Many interesting and useful points are contained therein, as indicated below:

Materials.—1. The cement shall meet the requirements of the Standard Specifications for Portland Cement, adopted by the American Society for Testing Materials, August 16, 1909, with all subsequent amendments and additions thereto adopted by said Society, and adopted by this Institute (Standard No. 1).

When the cement is not inspected at the place of manufacture it shall be stored a sufficient length of time to permit of inspecting and testing. The engineer shall be notified of the receipt of each shipment of cement.

2. Fine aggregate shall consist of sand or screenings from clean, hard, durable, crushed rock or gravel consisting of quartzite grains or other equally hard material graded from fine to coarse, with the coarse particles predominating and passing, when dry, a screen having ¼-inch openings. It shall be clean, hard, free from dust, loam, vegetable, or other deleterious matter. Not more than twenty (20) per cent. shall pass a sieve having fifty (50) meshes per linear inch, and not more than five (5) per cent. shall pass a sieve having one hundred (100) meshes per linear inch.

Fine aggregate containing more than three (3) per cent. of clay or loam shall be washed before using.

Fine aggregate shall be of such quality that the mortar composed of one (1) part Portland cement and three (3) parts fine aggregate by weight, when made into briquettes, shall show a tensile strength at least equal to the strength of 1 to 3 mortar of the same consistency made with the same cement and Standard Ottawa sand.

In no case shall fine aggregate containing frost or lumps of frozen material be used.

3. Coarse aggregate shall consist of clean, hard, durable, crushed rock or gravel, graded in size, free from dust, loam, vegetable, or other deleterious matter, and shall contain no soft, flat or elongated particles. The size of the coarse aggregate shall be such as to pass a one and one-half (1½- inch round opening and be retained on a screen having one-quarter (¼) inch openings. In no case shall coarse aggregate containing frost or lumps of frozen material be used.

4. Natural mixed aggregate shall not be used as it comes from deposits, but shall be screened and used as specified.

5. Water shall be clean, free from oil, acid, alkali, or vegetable matter.

6. Reinforcement.—Concrete pavements twenty (20) feet or more in width shall be reinforced with metal fabric. All reinforcement shall be free from excessive rust, scale, paint, or coatings of any character which will tend to destroy the bond. All reinforcement shall develop an ultimate tensile strength of not less than 70,000 pounds per square inch and bend 180 deg. around one diameter and straighten without fracture.

7. Joint filler shall consist of prepared felt or similar material of approved quality having a thickness of not less than ⅛ nor more than ¼ in.

8. Joint Protection Plates.—Soft steel plates for the protection of the edges of the concrete at transverse joints shall be not less than 2½ in. in depth and not less than ⅛ in. at any point nor more than ¼ in. in average thickness. The plates shall be of such form as to provide for rigid anchorage to the concrete. The type and method of installation of joint protection plates shall be approved by the engineer.

9. Shoulders.—Materials for the construction of shoulders shall be approved by the engineer.

Grading.—10. The term "grading" shall include all cuts, fills, ditches, borrow pits, approaches and all earth moving for whatever purpose, where such work is an essential part of or necessary to the prosecution of the contract. When to bring the surface to grade, a fill of one (1) foot or less is required, the area shall be thoroughly grubbed. All soft, spongy or yielding spots and

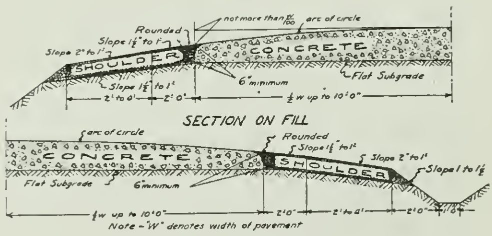

Fig. 1.—One-course Concrete Highway—Sections on Fill and in Cut.

all vegetable or other objectionable matter shall be removed and the space refilled with suitable material.

11. Stakes will be set by the engineer for centre line, side of slopes, finished grade and other necessary points properly marked for the cut or fill.

12. Excess material shall be disposed of as directed by the engineer, the free haul not to exceed.........feet.

13. Over-haul.—Materials hauled a greater distance than the free haul from the place of excavation shall be paid for at the rate of................cents per cubic yard for each additional................feet.

14. Fills.—Embankments shall be formed of earth or other approved materials and shall be constructed in successive layers, the first of which shall extend entirely across from the toe of the slope on one side to the toe of the slope on the other side, and successive layers shall extend entirely across the embankments from slope to slope. Each layer, which shall not exceed one (1) foot in depth, shall be thoroughly rolled with a roller weighing not less than five (5) tons nor more than ten (10) tons before the succeeding layer is placed. The roller shall pass over the entire area of the fill at least twice.

The sides of the embankment shall be kept lower than the centre during all stages of the work, and the surface maintained in condition for adequate drainage. The use of muck, quicksand, soft clay or spongy material which will not consolidate under the roller, is prohibited.

When the material excavated from cuts is not sufficient to make the fills shown on the plans, the con-

tractor shall furnish the necessary extra material to bring the fills to the proper width and grade. When the earth work is completed the cross-section of the road shall conform to the cross-sectional drawings and profile shown in Fig. 1.

15. All slopes shall be properly dressed to lines given by the engineer.

16. Finished Grade.—When grade line is approached, the final grade stakes will be set, for which sufficient notice must be given to the engineer. (In excavating cuts, it is considered advisable, when the line of the sub-grade is approached, to compact the remaining material by rolling. The depth of material left in the cut to be compressed to the finished grade by rolling will depend upon the character of the material.)

17. Drainage.—The contractor shall construct such drainage ditches as will insure perfect sub- and surface-drainage during construction and such work shall be completed to the satisfaction of the engineer, prior to the preparation of the roadbed as herein specified.

Tile drains shall be placed as shown in the drawings attached hereto. Tile to be laid in the trench at least ....(........) inches wide and .... (........) feet deep below the established grade of the finished pavement. Such trench shall be back filled with crushed stone or pit run gravel, with sand removed, which after light tamping shall be ....(........) inches in depth.

Open ditches must be constructed along the concrete road as shown in Fig. 1, the dimensions, side slopes and grade of said ditches being as shown on the cross-section and profile.

At the time of the acceptance of the road, the ditches must be in perfect condition, with clean slopes and bottom, containing no obstructions to the flow of water.

Sub-grade.—18. Construction.—The bottom of the excavation or top of the fill, when completed, shall be known as the sub-grade, and shall be at all places true to the elevation as shown on the plans attached hereto.

The roadway shall be graded to the proper sub-grade to permit of the specified thickness of paving materials being laid to bring the finished surface of the pavement to the lines and grades as shown on the plans.

The sub-grade shall be brought to a firm, unyielding surface by rolling the entire area with a self-propelled roller weighing not less than ten (10) tons, and all portions of the surface of the sub-grade which are inaccessible to the roller shall be thoroughly tamped with a hand tamp weighing not less than fifty (50) pounds, the face of which shall not exceed 100 square inches in area. All soft, spongy or yielding spots and all vegetable or other objectionable matter shall be entirely removed and the space refilled with suitable material.

Where considered necessary or of assistance in producing a compact, solid surface, the sub-grade before being rolled shall be well sprinkled with water.

When the concrete pavement is to be constructed over an old roadbed composed of gravel or macadam, and the concrete is to be wider than the old gravel or macadam road, the latter shall be entirely loosened and the material spread for the full width of the roadbed and rolled. All interstices shall be filled with fine material, and rolled to make a dense, tight surface of the roadbed.

19. Acceptance.—No concrete shall be deposited upon the sub-grade until it is checked and accepted by the engineer.

20. Completion.—Upon the sub-grade thus formed shall be laid the concrete pavement as shown in Fig. 1.

Forms.—21. Materials.—The forms shall be free from warp, of sufficient strength to resist springing out of shape, and shall be equal in width to the thickness of the pavement at the edges. Wooden forms shall be of not less than two (2) inch stock and shall be capped with two (2) inch angle iron.

22. Setting.—The forms shall be well staked or otherwise held to the established line and grades, and the upper edges shall conform to the established grade of the road.

23. Treatment.—All mortar and dirt shall be removed from the forms that have previously been used.

Pavement Section.—24. Width, Thickness of Concrete and Crown.—The concrete pavement shall be...... ......feet wide,............(......) inches in depth at centre, and............(........) inches in depth at the sides. The finished surface shall conform to the arc of a circle, as shown on Fig. 1.

NOTE.—Crown shall be not more than one-one-hundredth (1/100) of the width. The thickness of the concrete at the edges shall not be less than six (6) inches.

Joints.—25. Width and Location.—Transverse joints shall be not less than one-quarter (¼) inch nor more than three-eighths (⅜) inch in width and shall be placed across the pavement perpendicular to the centre line, not more than 35 feet apart. When a curb is specified or where pavement abuts a building a joint not less than one-quarter (¼) inch wide shall be placed between it and the pavement. All joints shall extend through the entire thickness of the pavement and shall be perpendicular to its surface.

26. Protection of Joints.—The concrete at transverse joints shall be protected with soft steel joint protection plates which shall be rigidly anchored to the concrete. The installation of the metal protection plates shall meet with the approval of the engineer. The surface edges of the metal plates shall conform to the finished surface of the concrete, as shown in Fig. 1.

All joints over one-quarter (¼) inch high or one-half (½) inch low shall be removed.

27. Joint Filler.—All joints shall be formed by inserting during construction and leaving in place the required thickness of joint filler which shall extend through the entire thickness of the pavement.

Measuring Materials and Mixing Concrete.—28. Measuring.—The method of measuring the materials for the concrete, including water, shall be one which will insure separate and uniform proportions of each of the materials at all times. A bag of Portland cement (94 lbs. net) shall be considered one (1) cubic foot.

29. Mixing.—The materials shall be mixed to the desired consistency in a batch mixer of approved type, and mixing shall continue for at least forty-five (45) seconds after all materials are in the drum. The drum shall be completely emptied before mixing successive batches. The drum of the mixer used shall revolve at a speed not less than the minimum nor more than the maximum number of revolutions shown in the following table:

Rated capacity, cu. ft. unmixed material.	Capacity, bags of cement in 1 : 2 : 3 mix.	Revolutions per minute of drum. Min.	Max.
7 to 11	1	15	21
12 to 17	2	12	20
18 to 23	3	12	20
24 to 29	4	11	17
30 to 33	5	10	15

30. Retempering of mortar or concrete which has partially hardened, that is, mixing with additional materials or water, shall not be permitted.

31. Proportions.—The concrete shall be mixed in the proportions of one (1) bag of Portland cement to not more than two (2) cubic feet of fine aggregate and not more than three (3) cubic feet of coarse aggregate, and in no case shall the volume of the fine aggregate be less than one-half (½) the volume of the coarse aggregate.

A cubic yard of concrete in place between neat lines shall contain not less than one and seven-tenths (1.7) barrels of cement.

The engineer shall compare the calculated amount of cement required according to these specifications and plans attached hereto with the amounts actually used in each section of concrete between successive transverse joints, as determined by actual count of the number of bags of cement used in each section. If the amount of cement used in any three adjacent sections (between transverse joints) is less by two (2) per cent., or if the amount of cement used in any one section is less by five (5) per cent., than the amount hereinbefore specified, the contractor agrees to remove all such sections and to rebuild the same according to these specifications at his expense.

32. Consistency.—The materials shall be mixed with sufficient water to produce a concrete which when deposited will settle to a flattened mass, but shall not be so wet as to cause a separation of the mortar from the coarse aggregate in handling.

Reinforcing.—33. Concrete pavements twenty (20) feet or more in width shall be reinforced. The cross-sectional area of the reinforcing metal running parallel to the centre line of the pavement shall amount to at least 0.038 square inch per foot of pavement width and the cross-sectional area of reinforcing metal, which is perpendicular to the centre line of the pavement, shall amount to at least 0.049 square inch per foot of pavement length.

Reinforcing metal shall not be placed less than two (2) inches from the finished surface of the pavement and otherwise shall be placed as shown on the drawings. The reinforcing metal shall extend to within two (2) inches of all joints, but shall not cross them. Adjacent widths of fabric shall be lapped not less than four (4) inches.

Placing Concrete.—34. Immediately prior to placing the concrete, the sub-grade shall be brought to an even surface. The surface of the sub-grade shall be thoroughly wet when the concrete is placed.

After mixing, the concrete shall be deposited rapidly in successive batches upon the sub-grade prepared as hereinbefore specified. The concrete shall be deposited to the required depth and for the entire width of the pavement, in a continuous operation, between transverse joints without the use of intermediate forms or bulkheads.

In case of a breakdown concrete shall be mixed by hand to complete the section or an intermediate transverse joint placed as hereinbefore specified at the point of stopping work. Any concrete in excess of that needed to complete a section at the stopping of work shall not be used in the work.

35. Finishing.—The surface of the concrete shall be struck off by means of a template or strike board which shall be moved with a combined longitudinal and crosswise motion. When the strike board is within three (3) feet of a transverse joint it shall be lifted to the joint and the pavement struck by moving the strike board away from the joint; any excess concrete shall be removed. Concrete adjoining the metal protection plates at transverse joints shall be dense in character and any holes left by removing any device used in installing the metal protection plates shall be immediately filled with concrete.

After being brought to the established grade with the template or strike board, the concrete shall be finished from a suitable bridge, no part of which shall come in contact with the concrete. The concrete shall be finished with a wood float in a manner to thoroughly compact it and produce a surface free from depressions or inequalities of any kind. The finished surface of the pavement shall not vary more than one-quarter (¼) inch from the true shape.

The edges of the pavement shall be rounded as shown in Fig. 1.

Curing and Protection.—36. Excepting as hereinafter specified, the surface of the pavement shall be sprayed with water as soon as the concrete is sufficiently hardened to prevent pitting, and shall be kept wet until an earth covering is placed. As soon as it can be done without damaging the concrete, the surface of the pavement shall be covered with not less than two inches of earth or other material which will afford equally good protection, which cover shall be kept moist for at least ten (10) days. When deemed necessary or advisable by the engineer, freshly laid concrete shall be protected by a canvas covering until the earth covering can be placed.

It at the time the pavement is laid or during the period of curing the temperature during the daytime drops below 50 degrees Fahrenheit, sprinkling and covering of the pavement shall be omitted at the direction of the engineer.

Under the most favorable conditions for hardening, in hot weather, the pavement shall be closed to traffic for at least fourteen (14) days, and in cool weather for an additional time, to be determined by the engineer.

The contractor shall erect and maintain suitable barriers to protect the concrete from traffic, and any part of the pavement damaged from traffic or other causes occurring prior to its official acceptance, shall be repaired or replaced by the contractor at his expense in a manner satisfactory to the engineer.

Before the pavement is thrown open to traffic the covering shall be removed and disposed of as directed by the engineer.

37. Temperature Below 35 Degrees Fahrenheit.—Concrete shall not be mixed or deposited when the temperature is below freezing.

If at any time during the progress of the work the temperature is, or in the opinion of the engineer will within twenty-four (24) hours drop to 35 degrees Fahrenheit, the water and aggregates shall be heated and precautions taken to protect the work from freezing for at least ten (10) days. In no case shall concrete be deposited upon a frozen sub-grade.

Shoulders.—38. Construction.—Where shoulders are required they shall be built upon the properly prepared sub-grade, as shown on the cross-sectional drawing, Fig. 1. The work shall be done to the entire satisfaction of the engineer.

ADDITIONAL POWER FOR KINGSTON, ONT.

The Public Utilities Commission is considering an offer from the Gananoque Electric Light and Power Company for the supply of a large block of power, presumably from the development at Kingston Mills on the Rideau. Mr. F. A. Gaby, chief engineer of the Hydro-Electric Power Commission of Ontario has been consulted regarding the technical features of the proposition. At present the Kingston Street Railway Company consumes 51 per cent. of the city's existing output, which it obtains at a rate of 1 2-5 per k.w. hr.

USES FOR POWER FROM IRRIGATION DAMS.*

THE question may be asked, What is the best use to make of electric power which is developed by water for irrigation? Irrigation dams are usuolly situated at considerable distances from cities and other centres where electric current is wanted for lighting, tramways, and motive power. Although electric transmission of power is efficient, a long distance transmission line is expensive to construct and maintain, and even in countries where there is no trouble with ice and snow, there are the risks of stoppage due to wind and dust storms, bush fires, etc.

When estimating the supply available from a given source for domestic purposes, only the minimum flow can be reckoned upon, if risk of shortage is to be obviated. Therefore, for a domestic supply of electricity all surplus between the minimum and the maximum flow is wasted, so far as power is concerned, and expensive spill-weirs and channels have to be provided.

Clearly, it is wise to make use of the electric power as near to where it is generated as possible, also for operations which use the same power right through the 24 hours, but which can be temporarily suspended if need be.

When the Assuan dam comes to be harnessed a part of the power is to be transmitted about 30 miles and used for pumping. Assuan presents considerable difficulties, because, in the first place, it is not easy to select an industry to be pursued which could utilize power that varies between 100,000 h.p. and 10,000 h.p.; also during the greater part of the year the climate at Assuan is extremely hot, and it is, therefore, difficult to develop large manufacturing industries in such a climate.

When the Trawool dam scheme was being considered a suitable use for the power appeared to be to transmit it to the cities of Ballarat, Bendigo, and Melbourne for a domestic supply. The great advances of the last few years of electro-chemistry and metallurgy have, however, changed the situation considerably. During this period of eight years many new industries which utilize large quantities of cheap electrical power have safely passed the experimental stage, and a single factory making fertilizers could now easily utilize the entire output of the water power, and with an absolute certainty of selling the product without disturbing prices. The tendency is now to establish electro-chemical and metallurgical factories close to the power, and to dispense with transmission lines; also to work the water power and the factory together, arranging the output of the one to meet the demand of the other so that the utmost use can be made of the water available. When that is done surplus water need not be wasted, and under certain conditions the whole mean annual rainfall may be reckoned upon after allowing for evaporation.

The following are some of the new electrical industries which require large quantities of electrical power at low cost: (1) Manufacture of nitric acid from atmospheric nitrogen in electric furnace by the direct method. (2) Making nitrogenous and phosphate nitrogenous fertilizers by the direct process. (3) Manufacture of calcium carbide for acetylene lighting. (4) Manufacture of calcium cyanamide fertilizer from calcium carbide. (5) Electric reduction of iron and steel. (6) Making alkali from salt by the electrolysis. (7) Making aluminum from bauxite. (8) Making carborundum for use as an abrasive. (9) Making graphite in the electric furnace. (10) Melting concentrates. (11) Treating refractory zinc ores, etc.

Some of these industries have to be carried on continuously, as, for example, the manufacture of calcium carbide and calcium cyanamide, the reduction of iron and steel, and the making of aluminum, etc. The cost of stoppage and restarting is excessive in all smelting and allied operations. On the other hand, some of the industries, such as fixation of atmospheric nitrogen by the direct process, can be worked intermittently. The manufacture of graphite can also be carried on intermittently.

Where the water can only be used for a portion of the year, the problem is to fix upon some particular industry which can utilize power intermittently, and will permit of changes in the amount of labor employed, without undue additional expense. Also, the product must be such that it has a widespread market, so that when it is turned out in considerable quantities it does not upset prices. At the same time it should be capable of being conveniently stored at times when the output may temporarily exceed the demand. The manufacture of fertilizers from atmospheric nitrogen by the direct furnace process meets all these conditions, and is, therefore, ideal. Not only can the process be carried out intermittently, but the demand is practically unlimited, for to be continuously productive all soil requires plant foods. The most direct and simple method to make fertilizer is to blow air through an electric arc flame so as to form nitric oxide gas. In the presence of oxygen this changes to nitrogen peroxide, which, when brought into contact with water, produces nitric acid. If lime is acted on by this dilute nitric acid a nitrogenous fertilizer called calcium nitrate, containing 12¾ per cent. of nitrogen, is produced. Large quantities of this fertilizer are made in Norway, and it is finding its way to the fruit lands of California and to other parts of the Pacific in competition with sodium nitrate and sulphate of ammonia.

A valuable fertilizer can be made by grinding up phosphate rock and mixing it with water to the consistency of cream. When the gas from the furnace is passed through this it changes the phosphate into the citric soluble state, so making it valuable as phosphate fertilizer. At the same time the lime is acted upon and takes up nitrogen, so that the fertilizer contains two out of the three principal plant foods. The phosphate of basic Bessemer slag is in the soluble condition, and is very largely used as a phosphate fertilizer, but the slag from some open-hearth steel furnaces is largely insoluble, and so the phosphate is not in a form in which it is immediately available for agriculture. This waste basic slag is being produced in Middlesborough alone at the rate of 150,000 tons a year. With the aid of the electric furnace it may be possible in the future to turn it to good account. The direct method of making fertilizers has reached enormous proportions in Norway. One factory utilizes 140,000 h.p., which is generated by a water-power at Rjukan, while another factory to utilize 120,000 h.p. is being equipped. About $40,000,000 is invested in the business in Norway alone.

* Abstracted from a paper by E. Kilburn Scott before the British Association, Australian meeting, August, 1914.

Mayor H. C. Hocken, of Toronto, and several of the officials of the works department will represent the city at the fifth American Good Roads Congress in Chicago this week.

The MacArthur Concrete Pile and Foundation Company has appointed the Douglas Milligan Company as their sales agents for Eastern Canada, with main office in the New Birks Building, Montreal, and branch office at 95 King Street East, Toronto.

NEW ASPHALT PLANT AT MONTREAL.

By Daniel J. Hauer, C.E.

THE need of the proper kind of a modern asphalt plant in many Canadian cities has been made very evident to the writer in his visits to the eastern part of the Dominion during the past few years. The newest municipal asphalt plant recently put in use in Montreal is therefore of interest, and admits of the following description:

Tenders were submitted to the city upon plans and a general arrangement specifying size and capacity, together with a set of specifications showing the quality of materials, etc., gotten up by the chief engineer of Road Department of Montreal. The contractors had to design the building and plant, also provide a set of specifications for the building and machinery, all of which were to be approved by the city. The successful bidders for the job were Warren Bros. Company, of Boston, Mass.

The Building.—The plant is located in the Road Dept. yard in the north end of the city. The building, as shown in Fig. 1, is built of structural steel with corrugated sides and roof. The main part of the structure is of two stories with a tower on each end of an additional story for the hot storage bins for sand and stone. In the rear, in a 1-story addition, is the boiler and engine room. The windows in this room are ordinary in type, while in the rest of the building they are of corrugated steel, each opening as a shutter.

The lower floor has a concrete pavement in it. The second story has a reinforced concrete floor designed to carry a dead load of 400 lbs. per sq. ft. with a factor of safety of 4. This floor is intended for storage of limestone dust and asphalt. The third floor is of similar construction, but the dead load figured for it with the same factor of safety is 200 lbs. per sq. ft. The roof is designed to carry a snow load of 40 lbs. per sq. ft., with a safety factor of 4. The corrugated iron used on the sides of the building is No. 24 gauge and on the roof No. 22. The entire lower story is open, allowing easy transit for men and teams.

Arrangement of Ground Floor.—In the centre of the first story is located 5 asphalt melting tanks or kettles, provided with air agitation, each of a working capacity of 2,000 Imp. gal. Two of these tanks are of the enclosed pressure type and three are open, all being connected at the bottom with a 3-inch pipe line, by means of which the contents of any of the open tanks may be drawn by suction into either of the pressure tanks, with suitable connections in the air compressor so that it may be operated as a vacuum pump to accomplish this purpose. On the second floor a 3-inch pipe runs from the pressure tanks to the asphalt weighing buckets at both mixers, thus feeding the asphalt by air.

The melting tanks are encased in brick and each has an independent fire-box for heating purposes, the bottom of the tanks being protected from burning by fire brick. The fire-boxes are constructed for coal consumption. There is an independent smoke stack for these tanks.

Fig. 2 is a view of the lower floor and shows these melting kettles. In the foreground is the driveway under the binder mixer and at the other end of the building is a similar driveway under the topping course mixer. These two driveways can be seen better in Fig. 1. To the rear of the melting tanks are located the drying units, consisting of 2 Warren standard 40-inch sand dryers and a single binder dryer. Each sand dryer has independent settings, but are coupled together with the same driving gear. Each dryer is fed by an independent bucket elevator. The stone and sand are brought to the plant in cars or wagons and dumped near the building, where it is picked up by the elevators and fed directly into the drying units. The revolving cylinders are 19 ft. 8 in. long and the dryers are so constructed that the material passes through them by gravity instead of being forced through by spirals. These dryers are so arranged with induced draft, so that the flames and hot gases pass the full length of the dryer on the outside of the revolving cylinder and return through the inside before being taken out by the fan. In the cylinders longitudinal vanes are provided that lift the materials being dried to the top of the cylinder, dropping it as the latter revolves, through the hot gases being drawn through it by the exhaust fan.

This induced draft is supplied by a 50-inch steel plate exhauster, provided with a Cyclone dust collector to separate from the exhaust the fine particles of sand, thus preventing the sand from being discharged into the air. Each dryer has a fire-box 3 ft. 8 in. wide and 10 ft. 6 in. long, giving an extremely large grate surface, providing a low rate of combustion of fuel and obtaining the full capacity of the dryers, without unduly forcing the fires.

The revolving cylinders are supported at either end by heavy 6-in. x 12-in. Universal bearings, the rear bearings being fitted with thrust collars to take care of the expansion and contraction of the cylinders.

Fig. 1.—Exterior of New Municipal Asphalt Plant of Montreal.

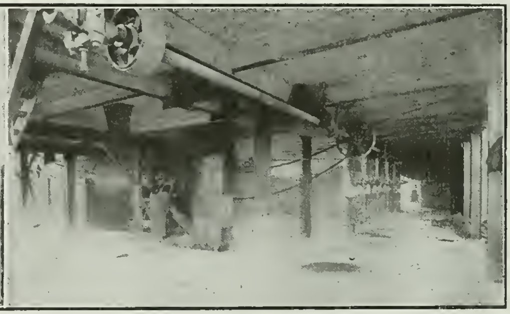

Fig. 2.—View of Ground Floor.

The binder dryer is of similar type and size but using only a 40-inch steel plate exhaust. The exhaust gases from the dryers are carried off in stack from the dust collector.

The dryers discharge their contents by gravity into boots below the level of the floor, from which the hot material is carried by enclosed elevators to the hot bins on the third floor in the towers. The elevator shown in Fig. 2 is that for the binder, while beyond the melting tanks is located the one for the hot sand. The spout projecting through the concrete floor in the illustration is the bottom of the rejection bin, which serves as a storage reservoir for the rejection, when running topping, so that they may be hauled away without creating a nuisance around the plant.

The screens for the materials are located over the hot bins in the towers. All the shafting for operating the plant is on the ground floor.

Power Plant.—The power plant (see Fig. 1) consists of a horizontal tubular boiler 66 ins. by 14 ft. in a brick setting, and has a stack 40 ft. high. The boiler is equipped with an injector and a boiler feed pipe, also a 100-h.p. open feed water heater for heating the boiler feed water. The engine is built by the Goldie & McCulloch, Company,

Fig. 3.—View of Second Floor.

Limited, of Galt, Ont. It is an enclosed engine of the automatic cut-off type, 13 x 12 in. stroke and equipped with the splash oiling system.

A 6 x 10 x 8 in. Clayton fly-wheel compressor, capable of compressing 80 cu. ft. per min., makes up the equipment in the engine room. The piping of the air system is so arranged as to be able to run the pump as a compressor or as a vacuum pump, as the requirements dictate.

Hot Bins and Towers.—The hot bins, as already stated, are located in the towers. These bins are of steel and have a capacity, level full, of 10 cu. yds. These bins serve the mixers. Each bin is provided with a rotary sand screen 30 in. in diameter, having an effective screening surface of at least 3 lin. ft. of 8-mesh iron wire cloth made of No. 20 gauge wire. Each screen is so arranged that when it is desired to run binder from either of the mixers the stone may be discharged directly into the bin without passing through the screen. The top of each bin is covered with light steel casing to retain the heat in the material and to confine the dust to the bins.

Arrangement of Second Floor.—The interior of this floor is shown in Fig. 3, as standing alongside of the topping mixer and looking towards the binder mixer. Ample room is provided for storing the bags of limestone dust and barrels of asphalt. The plant is equipped with two elevators for carrying these materials to this floor. These can be seen in Fig. 1, the continuous bag elevator on the right and the continuous barrel elevator on the left.

In the centre of Fig. 3 can be seen the tops of the 5 melting tanks and the asphalt feed pipe running towards the two mixers.

The two mixers are of Warren 9 cu. ft. type, capable of mixing economically batches of 1,000 lbs. of topping mixture and 1,100 lbs. of binder mixture. The drive of this type of mixer is furnished with a jaw clutch, so as to throw it out quickly in case of an accident. The bottom of the mixer is fitted with sectional reinforcing lines made 3/8 in. thick to take the wear and tear off the mixers. One mixer is equipped with topping teeth and the other with regular binder teeth. The mixers discharge by means of a sliding gate through the floor into wagons beneath.

A limestone dust bin of 2 cu. yd. capacity is provided with each hot material bin so that topping may be run from either mixer as desired. The dust is fed into the hot sand weigh-box by means of a screw conveyer operated by a friction clutch controlled by the weigh-box attendant. A separate elevator is used for placing the dust in the bins.

Each mixer has an asphalt weighing-bucket mounted on a carriage running on an overhead track with scales that automatically weigh the bucket full and empty.

The weigh-box at each mixer has a capacity of 12 cu. ft. This box is filled from the hot bins by an orifice with a swinging cut-off gate. The weigh-box rests on platform scales and discharges its contents through a gate in the front, by gravity, into the mixer. A by-pass in the tray allows of rejected material being dumped into a reservoir, as previously stated. The scales used for weighing are of such a type that each batch of material is weighed without the necessity of calculation, and so that the proper charge of limestone can be weighed with the sand.

A flux-weighing tank having a capacity of 300 gal. is also provided, resting upon a 3,000-lb. platform scales, constructed to balance the tare and give the weight of the oil by direct reading.

The main drive from the engine is an oak-tanned triple extra leather belt. The drives from the main shaft to the elevator countershaft are of double extra leather. The drives from the main shaft to the mixer driving shafts are silent chains. Those to the dryers are of steel bush roller chains, while the rest of the drives are detachable link belting. The entire plant is interchangeable and can be used for binder and topping, or can be used for topping alone. When the two classes of materials are run the capacity of the plant is 2,000 sq. yd. of finished pavement per day, while if the plant is run on topping alone it will produce 3,000 sq. yd. 2 inches thick.

This plant is, in consequence of this output, the largest asphalt plant in the Dominion, and is one of the largest municipal asphalt plants in use anywhere.

This is the third plant built by these contractors for the city of Montreal. The first plant built was in the east end, the second in the west end of the city. Both of these plants are still in operation, the first one being built in 1903 and the second one in 1907.

The north end plant is a modern and economical one. Similar plants with smaller capacity can be built by decreasing the units and their size. It is economy to have a well-designed plant rather than a makeshift, and the money so expended will earn a handsome dividend over using a poorly designed and constructed plant in the cost of operation alone, not considering the quality of the pavement laid.

COPPER AND THE WAR.

THE world's production and consumption of copper have been seriously interfered with by the war, and prices are very unreliable, as no one can foresee, at the moment, the probable demand during the immediate future, nor the length of the war. The world's production of copper during recent years has been as follows:—

	Tons.		Tons.
1913	1,005,900	1911	893,800
1912	1,018,600	1910	891,000

More than 50 per cent. of the total is produced in the United States. It is noteworthy that although the United States output largely exceeds the United States consumption, copper is, nevertheless, imported. Thus, during October 475 tons of slabs were imported from Japan and 690 tons of pig copper from Peru.

Copper was produced last year in the following countries: Mexico, 90,000 tons; Japan, 77,200 tons; and Australia, 41,800 tons. As regards Europe, German and Austrian output was the largest, the quantity being 52,100 tons, out of a total European output of 186,500 tons. Great Britain is second, with 41,100 tons; then Russia, 34,300 tons; and Spain with 23,600 tons. European consumption during 1913 reached 643,100 tons; after allowing for the European output, 456,600 tons had to be imported, obviously mainly from America. The European consumption was as follows: Germany, 259,300 tons; Great Britain, 140,300 tons; France, 103,600 tons; Russia, 40,200 tons; Austria, 37,200 tons; Italy, 31,200 tons. The United States consumption reached the enormous quantity of 351,000 tons.

Reduced consumption has necessarily resulted in reduced production; the world's copper output, now that curtailment has become effective, has dropped, according to very competent expert opinion, to a basis of about 500,000 tons per annum.

The world's consumption of copper over a term of years has been as follows, in tons:

	1913.	1912.	1911.	1910.
England	140,300	148,877	159,736	148,187
France	103,600	106,753	106,408	92,838
Russia	40,200	38,818	31,830	28,237
Germany	259,300	253,429	234,985	208,826
Austria	37,200	51,574	41,101	37,150
Italy	31,200	34,378	40,949	32,487
United States	351,000	365,922	316,791	334,565

The copper exported from America, practically all to Europe, during the nine months of the year and the corresponding months in the preceding four years has been as follows:

	1914.	1913.	1912.	1911.	1910.
January	35,566	24,659	30,967	29,357	26,699
February ...	34,384	26,767	35,418	18,992	25,238
March	46,504	42,428	27,074	23,200	19,963
April	34,787	33,024	23,341	27,466	31,062
May	31,948	38,251	32,984	26,655	20,832
June	35,182	27,808	26,547	30,074	23,430
July	34,145	29,096	25,445	34,955	22,875
August	19,676	34,722	29,526	27,893	27,876
September ..	16,838	34,314	25,572	25,745	31,733

These figures distinctly indicate the effect of the war during August and September on the world's copper markets.

Towards the end of September, a noteworthy feature of the copper market was the action of the British Government in acquiring all the stocks of copper carried in Dutch warehouses, as this metal almost always is destined for Germany. Three cargoes of copper afloat for Holland were also taken by the British Government. It is reported that the German Government has followed the lead of the British Government in the compulsory acquirement, and paying at prices fixed by the British Government, of all stocks of copper stored in Rotterdam warehouses, and captured afloat in neutral vessels, belonging to American companies. Considerable stocks of copper are stored in Germany belonging to American owners; the German Government has confiscated them, and is paying for them in precisely the same terms as those fixed by the British Government.

We are indebted to Engineering (London) for the information.

GOVERNMENT GRAIN ELEVATOR AT VANCOUVER, B.C.

The contract for the new Government grain elevator at Vancouver has been awarded to Barnett & McQueen, whose headquarters are in Minneapolis, Minn., with a branch office at Fort William, Ont. The construction of this elevator, the contract price for which is $690,000, will practically complete the government's chain of interior and terminal elevators extending across Canada between Port Arthur and the Pacific Coast. The elevators included in this system are: One at Port Arthur for eastbound grain, the proposed elevator at Vancouver for Pacific trade, and three interior elevators at Moose Jaw, Saskatoon and Calgary. In this connection might also be mentioned the elevators of the Montreal Harbor Commission, which are now under the control of the Western Grain Commission in many respects. It is also likely that an elevator, for terminal purposes, will eventually be constructed at Port Nelson for the Hudson Bay route.

The Vancouver elevator is to be of reinforced concrete. It is to have a storage capacity of 1,250,000 bushels, 300,000 of which will constitute the capacity of the working house, and 950,000 of the storage building proper. The design shows 52 circular storage bins in the latter, and 32 in the former. The storage building is further equipped with 32 interspace bins. It is to be 232 x 71 ft. The working house will be 126 x 62 ft. and, in addition to the 32 circular bins, there will be 21 interspace and 15 outerspace bins. The elevator buildings will also include a sacking plant and transformer house. These will be housed in one building 62 x 25 ft. The adjoining track shed is to be 150 ft. 8 in. long x 52 ft. wide. The wharf on Burrard Inlet will accommodate seven lines of tracks, and there will be also five tracks between the wharf and the Canadian Pacific Railway line. Three car ways will lead to receiving hoppers, each hopper with a capacity of 2,000 bushels. In all, there will be nine of these hoppers. Outgoing grain will be loaded on vessels by two-belt galleries, one on either side of the wharf. The sacking plant will include two sets of automatic sacking scales, each scale with a hopper capacity of from 2 to 6 bushels, and capable of weighing 1,500 bushels an hour. The power equipment will consist of forty 60-cycle, 3-phase, alternating current motors, aggregating 1,520 horse-power.

It will be noticed that the above elevator will resemble in many particulars those now in operation at Port Arthur, Saskatoon, Calgary and Moose Jaw. It is expected that the structure will be completed in November of next year.

HYDRAULIC PLANT, JOLIETTE, QUE.

A VERY interesting pumping plant is now in the process of construction in the town of Joliette, on the Assumption River. Fig. 1 shows the general layout. This includes a solid concrete overflow dam about 230 ft. in length, and varying in depth from 5 to 7½ ft., tapering from a width of 2 ft.

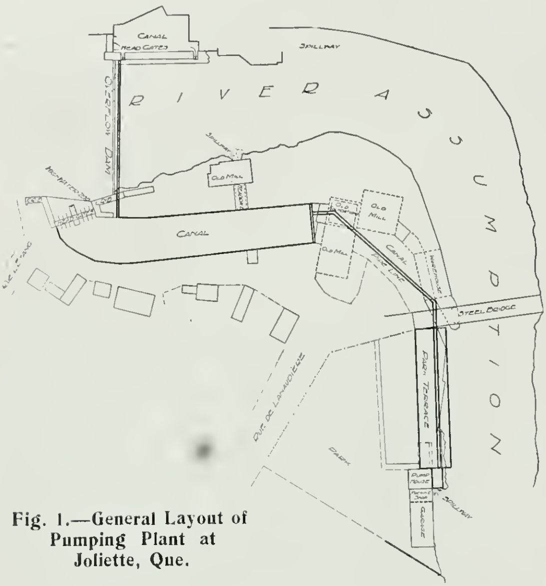

Fig. 1.—General Layout of Pumping Plant at Joliette, Que.

at the top to 11 ft. at the base. West of this structure the head gates admit water into a canal, the sides of which are of concrete retaining construction, and are terminated by a solid concrete head wall with an entrance to a stave flume 6 ft. in diameter and about 400 ft. long. The power house, also of reinforced concrete construction, contains a double Francis turbine of 200 h.p., carrying a horizontal shaft to which are belt-connected two centrifugal pumps, each with a capacity of 1,500 Imperial gallons per minute when working in parallel, and providing water at 65 pounds per square inch pressure. The drawing also shows a reinforced concrete platform 210 ft. long and 40 ft. in width, running parallel to the river, and to be used for pleasure purposes. Buildings indicated by dotted lines on Fig. 1 show the position of buildings, the demolishment of which is being necessitated by the new development.

Fig. 2 shows a section of the dam. It shows anchor bars 1¼ in. in diameter, which are staggered the entire length of the dam in planes 4 ft. 9 in. apart, the rods having a longitudinal spacing of 12 ft.

The wood stave pipe 6 ft. in diameter, is joined with steel sections. Two pronounced angles are encountered in the alignment of the conduit. The pipe is supported on concrete pedestals placed 8 ft. c. to c. and resting on rock foundations. These supports are to be 12 in. in thickness, and 6½ ft. in length at the top with a gentle taper. The lower end connection of the pipe is shown in plan and elevation in Fig. 3.

The terrace has been designed in reinforced concrete supported by pillars 17 ft. c. to c., resting on rock foundation. An artistic arch construction will be accompanied by reinforced concrete railings and ornamental lighting standards. The park side of the terrace provides three approaches by concrete

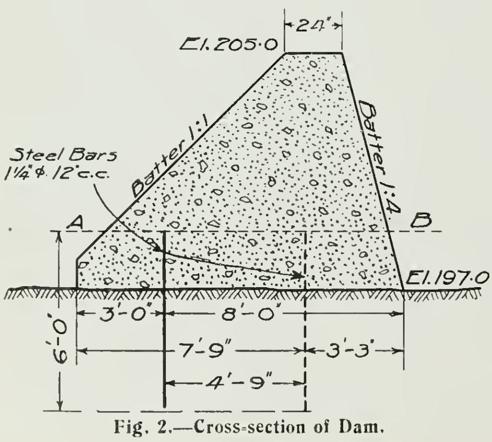

Fig. 2.—Cross-section of Dam.

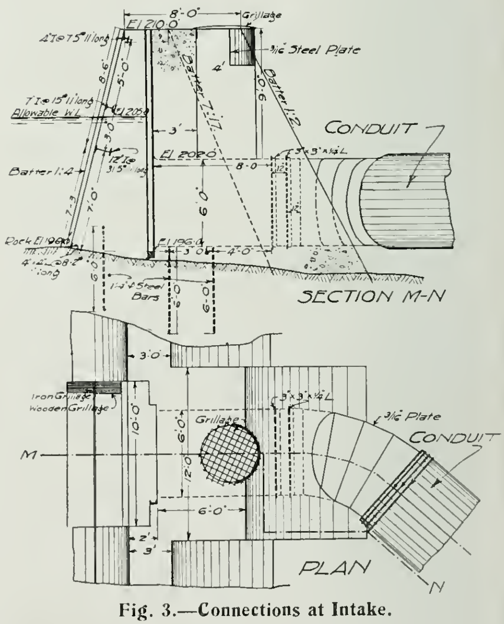

Fig. 3.—Connections at Intake.

steps. A section of the supporting piers, showing also the location of the conduit, is given in Fig. 4. The terrace provides 39 columns 14 in. x 14 in. in section reinforced by ¾-in. steel rods placed longitudinally and varying in length from 8 to 11 ft. The floor slab is 6 inches thick and the beams and girders are 20 and 28 inches deep, reinforced longitudinally with Kahn bars.

At the south end of the terrace will be situated the pumping plant, of reinforced concrete construction on

rock foundation. The turbine chamber into which the water enters from the conduit is 12 ft. x 9½ ft. The water leaves the turbine through an 8-ft. vertical draft tube tapering from 4 ft. 5 in. in diameter at the turbine end to 5 ft. The tail race projects beneath the floor of the building directly to the river bank. This flume is also of reinforced concrete construction.

To the turbine shaft is direct connected a fly wheel 8 ft. in diameter with belt drive to the floor above, where the two 1,500-gal. centrifugal pumps are installed. The general arrangement of this is shown in elevation in Fig. 5.

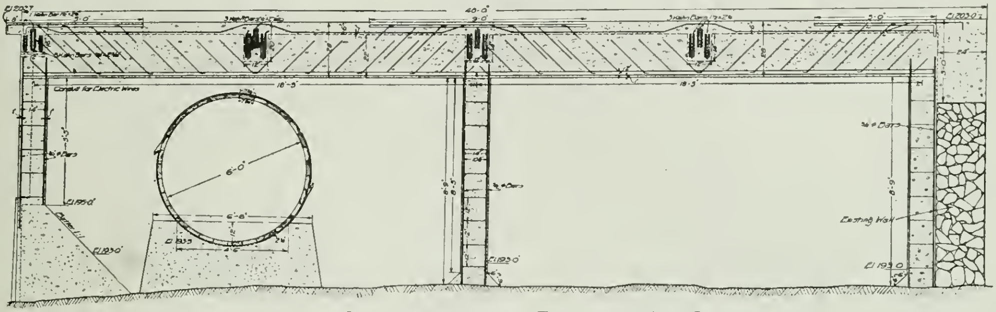

Fig. 4.—Cross-section of Park Terrace and Pipe Line.

The general contract for the development was let to Messrs. Arsenault and Planondon, engineers and contractors, Montreal, for $32,516. Escher Wyss & Company are supplying the machinery, the price being $5,155. Surveyer and Frigon, civil engineers, Montreal, have charge of the development.

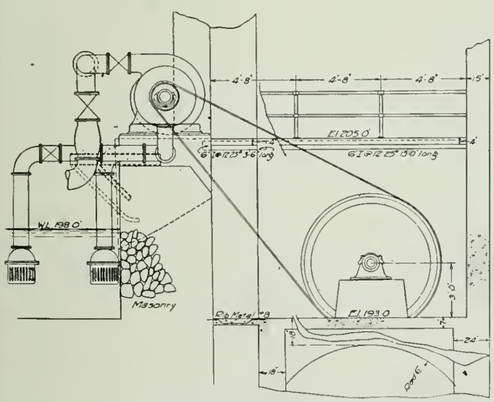

Fig. 5.—Pumping Arrangement.

Wood paving block is specified as one of five kinds of paving that may be laid in Honolulu streets. Approximately 100,000 Douglas fir blocks have been laid in the city. The size of block that is thought best adapted is 3 by 4 by 4-in. A bid submitted by a contractor during the middle of October, 1914, named $1.962 per square yard for Douglas fir blocks, furnished and placed, including foundation. The price bid was lower than in some previous tenders. Ohia also has been used for paving block and, being a native wood, has probably been favored. No large amount of wood-block paving remains to be done in Honolulu, but much will be done in the future in the next largest city, Hilo.

NOTES ON MINING ACTIVITIES.

In commenting upon the effects of the war upon mining, a contemporary states that they are not all harmful. The lack of employment in the copper fields has induced copper miners to invade gold and silver-producing districts to lease and to begin operating. Prospecting, too, has received quite a boost.

"This," states the writer, "must result in much good to the mining industry. The work of prospectors will result in new mines and the opening up of new opportunities for investors. The working of leases means greater development and more extensive mining operations. The man who takes a lease and succeeds—that is, makes good money for himself—is pretty sure to continue in independent mining. The more independent successful miners there are in a camp the livelier and more prosperous the camp." There has been a serious lack of prospecting during recent years and if the war will have the effect outlined above it will be a benefit, no doubt, to mining. When general business and industrial conditions recover from the effects of the disturbance caused by the breaking out of the war mining should find itself in a better position than it would have been had the war not occurred. There should be an increased demand for the products of the mines, not only to supply the needs of Europe, but to meet increased demands of domestic industries, and mining should prosper.

According to the Labor Gazette, the mining industry, however, is fairly active in this country. In November the collieries at Sydney Mines were running full time. The Dominion collieries were reported as not quite so busy, though they had a fair amount of work. Other collieries in coal mining districts in Nova Scotia were fairly active. In some of the western mines the delay in the advent of cold weather rendered conditions somewhat inactive. At Nanaimo the mines were working to full capacity, though some of the mines in the adjacent districts were not working full time.

In metal mining, operations in the Cobalt district came back to normal, and at the month's close very few men in the camp were out of work. At Porcupine the Hollinger mines increased their force and had about 1,000 men employed. Some reductions were reported in the staff in the iron mines at Michipicoten.

Heavy shipments of ore were reported from the Rossland mines to the Trail smelter, and the larger output of the mines in the district and the increased numbers at work were having the effect of renewing activity in business at Rossland.

EFFICIENCY OF HIGHWAY ORGANIZATION.*

By Col. E. A. Stevens,
State Highway Commissioner of New Jersey.

THE very size and the commercial importance of the highway problem make efficiency necessary to a fully successful solution. To-day we can state the problem in general terms only. Even the total mileage of roads and what portion of them have already been improved are only approximately known facts. There is to-day no need of arguing the necessity of good roads. The questions to be answered are: Where will the roads to be built be located? What will they cost? How are we to insure that, once built, they will give us the service for which they were built, and for which the people are paying? In all of this how are we to insure that the man who pays the bill is not to be taxed more than need be, that he gets value received for every dollar expended?

It would be a foolish man who would undertake to dig the cellar and lay the foundation for his house without first deciding how much room he needed to house his family; how much he could afford to spend therefor; how he is to meet the cost of housekeeping, repairs, insurance, and taxes; and finally how all this is to be done without waste.

In such a case, it is easy to see the need of some forethought. In the much larger problem of providing good roads, the very immensity of the quantities and costs, and the difficulty of gathering the data necessary to state them with approximate accuracy, or the failure to realize the importance of this knowledge, seems to have prevented preliminary study. We have in general tackled the problem with a view limited to a solution over a very narrow field. Since we took up the subject, the problem of administration, design, and construction, have been changed by motor traffic. This traffic has made the road a matter of general and not of local interest; has shown us that hitherto approved methods of construction are no longer generally available, and that systematically organized methods of caring for our roads and of raising our road funds are at least worthy of our most careful thought.

Let us, therefore, look at our problem for a moment without worrying about what others have done. The best way of doing the job is still an unsettled question. On whom shall we place the burden of arriving at the best method? Taking John Fritz's quip that "an engineer is the man who can do with one dollar what any fool can do with two," it is clear that that sort of an engineer is the man we want. Without a force properly drilled in the work, and properly organized to do it, efficiency, the getting for one dollar what with waste will cost us two, is impossible. With such a force, money and time spent in careful preliminary study, in being sure we are right before we go ahead, will not be wasted.

We need, first, a force that can lay out a well-thought-out plan with a fair chance to do so without political meddling. The cost can then be forecast. Changes in traffic may lead to changes in general design and detail without making efficiency impossible. The same happens so often with even so simple a task as building a house, that the wise man always allows some margin on the first detailed estimate of cost. With the cost known, plans for raising money can be made for meeting it, and a program of construction arranged with a view of giving the earliest and greatest return for the money spent.

Bond issues and the "pay-as-you-go" plan must be considered. It is evident that over any period for which bonds are issued, the tax levy must include interest and amortization charges on the bonds, as well as the cost of caring for the roads built, and to meet depreciation. If the same amount be raised each year by taxation and used to meet road-building, repair and depreciation charges, it is clear that the amount raised for interest and amortization, and, in the first part of the period, some of the amount raised for repair, etc., can be used for new work. The net result over the whole period is a reduced cost for a given mileage. Against this we have the use of the roads built for a longer average time. This benefit will, in many cases, be cheap at the increased price, but only on the assumption that bonds are issued on some definite and business-like plan, and the proceeds wisely invested. This has not always been the case.

Any satisfactory road administration must provide for proper design. The data for this is not readily at hand. Traffic figures over an unimproved road bear no relation to the traffic to be expected after improvement. Even were satisfactory traffic data readily available, the economic values of different types of construction are unknown. Motor traffic for not over ten years has been a serious destroyer of road surfaces. It is increasing yearly in intensity. The surfaces specially designed to carry this troublesome and valuable load have not been in use long enough to determine their probable lives and cost of upkeep under the conditions of to-day. The cost of the road is a yearly one, and must include depreciation, if the waste of road material is not made good every year. Therefore, it may well be cheaper to spend money in the repair of a cheap type, such as macadam or gravel, rather than to resurface with an expensive pavement pavement whose life is at the best uncertain.

For example, a macadam road under heavy traffic may be maintained at about the following cost per square yard:—

	Cents.
Stone, say, ½ in. or 42 lbs. at \$3 a ton rolled in place	6.3
Bituminous binder, say, ⅜ gal. at 15 cents, spread and covered	5.6
Ditches and drains, say	1.0
	12.9

If an improved type of surface is laid on the old macadam at a cost of, say, \$1.25 a yard, the annual charge to be seen in the tax levy will for some years be merely the cost of ditch and drain work and a small amount to care for imperfections. The community might, however, have used the \$1.25 for new work, or might have left it with the taxpayer; in either case, it is costing the interest which, at 4 per cent., is 5 cents. We have, then, a saving of 6.9 cents, but it seems fair to assume that over a life of from 10 to 20 years we should allow at least 0.9 cent for repairs. Our saving is then 6 cents. We would have to realize this saving for about 21 years to get back our \$1.25, and if the new surface lasts less than that period it may well prove wasteful.

But any such figures are of academic interest only, unless we have the organized repair force needed to keep our roads in repair and a system of accounting that will give accurate data and that is based on an outlook over a period somewhat longer than that covered by next year's tax bill. On the basis of such a system and with

* Read at Fourth American Road Congress, Atlanta, Georgia, November 9th to 14th, 1914.

such a force are our railroads operated. Their problem is of the same kind as ours—a matter of cheap and efficient transportation. It is, perhaps, curious that while the tendency of the day is to regulate these and other public service corporations as to the safety and adequacy of their service, and as to their methods of financing, the people of this country have in no case insisted on such safeguards as to the work of those entrusted with their roads.

The engineering problems of railroading have been solved in their broad lines. We will probably be able, as in the past, to keep on increasing axle loads and reducing ton-mile costs, but along lines indicated by carefully collected and thoroughly digested data of many years' work. This, as in the past, will be done by thoroughly trained and competent men knowing their business and eagerly looking for ways and means of getting better results.

With our highways problem we are now searching for the best solution. We have, generally speaking, inadequate and untrained or only partially trained forces. We have no accepted traffic unit and no generally recognized system of accounting. These must be supplied if we are to solve our problem as it should be solved.

HYDRATED LIME IN CEMENT AND CONCRETE.

Bulletin No. 10 of the National Lime Manufacturers' Association contains a report by Henry S. Spackman, of Philadelphia, on the effect of hydrated lime on strength and change in volume of cement mortars and concrete. The report is the result of tests on mortars and concretes with varying percentages of magnesium and calcium hydrate. The pieces were exposed under water and in air, outdoors, and alternately in water and in air. Examination was made to note the expansion of the pieces with variation in moisture content. The conclusions drawn by Mr. Spackman are as follows:

Variation in moisture content as well as change in temperature affect the volume of the test piece; when kept from contact with water other than the moisture in the air there is a marked tendency to shrinkage of the test piece, which tendency continues up to and beyond the six months' period; where the test piece is in constant or frequent contact with water, the general tendency is toward expansion in volume, and with the draining off of the excess gauging water there is a marked shrinkage in the 24-hour period followed in some cases by expansion at 48 hours and further shrinkage if test-piece specimens are out of contact with water and expansion if in contact with water; the addition of hydrated lime, while increasing somewhat the maximum expansion and contraction when the test pieces are constantly exposed either to water or dry air, markedly reduces the shrinkage due to the draining off of the surplus gauging water and also the extent of the movement when the test piece is alternately wet and dry.

Further tests for strength indicate that Portland-cement mortars and concrete, either with or without the addition of hydrated lime, develop the greatest strength when in continuous contact with water, and where allowed to harden in air out of contact with water there is a marked diminution of strength. Considered broadly, the addition or substitution of 10% of hydrated lime has no marked effect on the strength of the mortars, the test showing increase in strength at some periods and decreases in strength at others.

THE LAW OF STEAM POWER-HOUSE ECONOMY.*

By R. H. Parsons, M.Can.Soc.C.E., Assoc.M.Inst.C.E.

THERE are figures in abundance as to the performances of the component parts of a power-station, such as boilers, turbines, generators, etc., under test conditions, but nothing appears to have been published with respect to the efficiency with which the whole aggregation of machinery performs its functions. It is the purpose of this article to examine the performance of a power-plant, considered as an organic whole and to suggest a basis of comparison between different plants which has hitherto been lacking. The development of the method, moreover, will furnish an answer to many important problems of the central station engineer, as will be shown later.

The subject may be conveniently approached by an analogy. The efficiency of a steam-engine, under any conditions of working, depends upon a vast number of factors, mutually independent for the most part, such as cylinder condensation, radiation, friction of the various parts, leakage, etc. However carefully each of these items might have been investigated independently, their aggregate effect upon the economy of an engine would be an extremely difficult thing to forecast, and still more difficult would it be to deduce a law for the efficiency of the engine throughout its range of load, from the various rates of change of its multifarious sources of loss. By analogy we could hardly hope to determine the efficiency of a power-station at various loads from a consideration of the efficiencies of the different machines and apparatus which constitute its component parts.

The problem of the efficiency of the steam-engine was solved empirically by the late Mr. Peter Willans, who discovered that the total steam consumption per hour could be plotted as a straight line against the load on the engine. Thus, if the steam consumption at two different loads only were known, the consumption at any other load could be at once determined. This discovery placed in the hands of engineers an extraordinarily useful method of analyzing and tabulating the results of steam-engine trials. Experience proved the Willans law to have a remarkably wide range of application to prime movers, and for many years it has been utilized by manufacturers so far as it concerns their products.

By considering the analogy between the numerous sources of loss in a power-station and the almost equally great number of losses inherent in a steam-engine, it appears reasonable to suppose that there may be some rule corresponding to the Willans law which will correlate the efficiency of a power-station with the load upon it. Experiment proves this to be so, at any rate in the case of the particular power-station for the management of which the author is responsible, and no doubt a similar rule would apply generally.

In Fig. 1, above, the total steam consumption of the station per eight-hour shift is plotted against the gross electrical output of the station in the same period. The figures refer to the station performance during the month of September, 1914, and ninety records are plotted, covering a range of output varying from 4,500 to 24,300 kilowatt hours per shift. It might have been better to have taken the readings hourly instead of at eight-hour intervals, as this would have eliminated the effect of varying load-factors; but, on the other hand, the error

* From Engineering (London).

due to varying water-level in the boilers would be accentuated by the shorter intervals. The steam consumption during the shift is taken as being equal to the water pumped into the boilers, and the gross electrical output is the sum of the main-generator meter-readings.

By referring to Fig. 1, it will be seen that the mean of the observations is approximately a straight line, having the equation:—

$$S = 22\ K + 80{,}000,$$

where S is the total steam consumption per shift expressed in pounds, and K is the gross output per shift expressed in kilowatt-hours. It thus appears that there is a constant loss of steam, amounting to 80,000 lbs. per shift, and that there is in addition a consumption of about 22 lbs. of steam per kilowatt-hour.

Fig. 2 represents the steam-consumption curve of the station, expressed in pounds of steam per kilowatt-hour, the curve being deduced from the line shown in Fig. 1. The assumption has been made that the load-factor per shift was unity. From the equation it can be deduced that at an output of 80,000 kw.-hours per shift, which is the rated capacity of the station, the steam consumption would be 23 lbs. per kilowatt-hour. The consumption evidently tends to a limiting value of 22 lbs. per kilowatt-hour with an infinite load on the station.

The principle illustrated in Figs. 1 and 2 may be applied with equal instructiveness to the investigation of the quantity of coal consumed in the power-station. Fig. 3 shows the total coal consumption per eight-hour shift, plotted against the gross station output per corresponding shift, during the month of September, 1914; we see again that the total coal consumption follows a straight-line law, and may be expressed by the equation::—

$$C = 20{,}000 + 2.917\ K,$$

where C is the total coal consumption per shift expressed in pounds, and K is the gross electrical output per shift as registered by the generator meters. The diagram shows that 20,000 lbs. of coal are burned per shift to provide for the constant station losses, such as steam leakage, radiation, and general stand-by requirements. An additional 2.917 lbs. of coal per hour are needed for every kilowatt actually generated. With the station carrying its rated load of 80,000 kw. it may be deduced from the above equation that the coal consumption would amount to 253,360 lbs. per shift, or 3.16 lbs. per kilowatt-hour. In Fig. 4 is shown the coal consumption per kilowatt-hour corresponding to the line drawn in Fig. 3. The limiting value of the coal consumption is 2.917 per kilowatt-hour, which, of course, could only be obtained with an infinitely great load on the station.

From the two equations given above, namely—

$$S = 22\ K + 80{,}000,$$

and

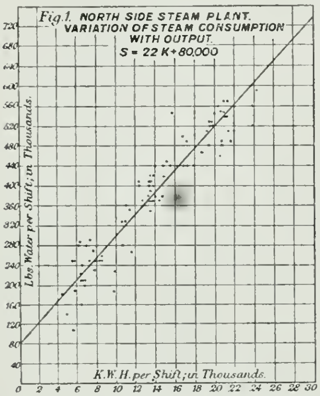
$$C = 2.917\ K + 20{,}000,$$

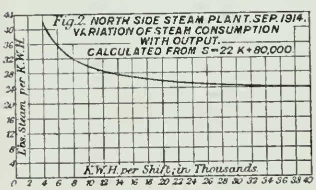
we may deduce a third equation, representing the variation of the amount of water evaporated per pound of coal, as the load on the boilers is increased. The equation is:—

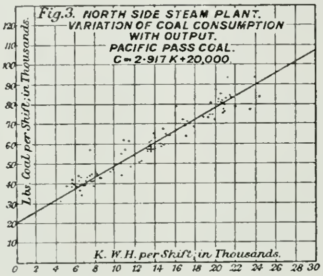
$$S = 7.54\ C - 70{,}820,$$

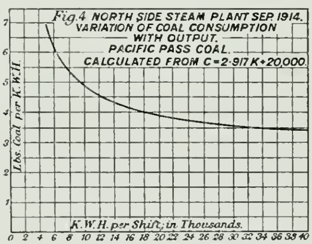
By equating it to zero, which represents the condition when no steam is being taken from the boilers, we get $C = 9{,}388$, showing that 9,388 lbs. of coal are required per shift to maintain the head of steam in face of radiation and other losses. This quantity may be compared with the amount of 20,000 lbs. per shift, which has already been found to be necessary to operate the station at no load. Thus about half the constant loss is attributable to the engines and half to the boilers. The equation further shows that the boiler-room losses are equal to the condensation of 70,820 lbs. of steam per shift, and that if they were absent we could evaporate 7.54 lbs. of water per pound of coal.

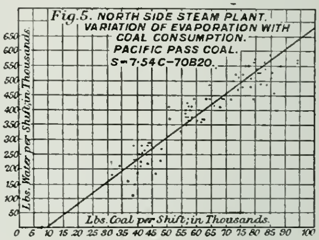
The last equation, correlating the total evaporation per shift with the total coal consumption per shift, could, of course, have been obtained graphically by plotting down the readings of the water-meters against those of the coal scales. In Fig. 5 this has been done, the line

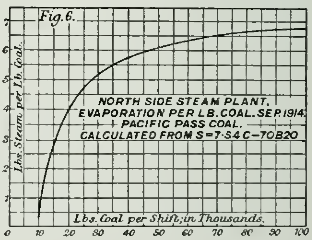












representing the mean of the observations being, however, drawn to agree with the calculation above. Nevertheless, it falls very fairly among the points. Fig. 6 shows the evaporation per pound of coal in accordance with this line.

In Figs. 1, 3, and 5, it may be objected that the variations among the observations do not allow a straight line to be drawn with any certainty, and hence a rather large amount of theory has been built up on a somewhat uncertain basis. This may be so, but the records are not put forward as being absolutely accurate. They are subject to corrections for water-level in boilers, coal on grates and in stokers, meter approximations, blow-off losses, etc., and they, of course, have a great dependence upon the economical operation of the plant, during the shift to which they refer. Nevertheless, they do undoubtedly appear to give evidence of certain laws of economy to which it is the object of this article to call attention.

The first question which will be asked by the practically-minded central-station engineer will be, "What use can be made of the results obtained from such an analysis of the operation of a plant?" One very important use can be made. The curves show at once the coal consumption or the steam consumption of the plant for any load which the station may have to carry. Hence the fuel cost for any additional load is readily obtained. For example, in the plant under consideration two problems were presented. One involved the question as to whether it would pay better to do the main waterworks pumping electrically or by steam-driven pumps. Steam had always to be maintained in the waterworks boilers, because the low-lift pumps were exclusively steam-driven; but the writer had the option of running either the motor-driven or the steam-driven pumps, as he thought fit. The combined labor costs of the two plants were unaffected by the decision. The waterworks load, when pumping was done electrically, was of a reasonably uniform nature, the load-factor per twenty-four hours being about 75 per cent. This load, as the equation corresponding to Fig. 3 shows us, can be carried on the steam plant at the cost for fuel of 2.917 lbs. of coal per kilowatt-hour. In an average month this would amount to 440 tons of coal, which figure can be directly compared with the extra coal burnt in the waterworks when the steam-driven pumps are operated. A definite solution of the problem can thus be obtained.

The other question related to the advisability of operating a large producer-gas engine, which normally runs in parallel with the main steam-power station. The gas-engine uses a low-grade lignite, costing about 0.16d. per kilowatt-hour. We see, as above, that the load could be transferred to the steam plant at an extra cost of coal of 2.917 lbs. per kilowatt-hour. But as the steam plant uses a more expensive fuel, the cost of 2.917 lbs. of steam coal amounts to about 0.26d. The fuel bill alone would therefore, be increased by 0.1d. per kilowatt-hour by making the change, but against this difference must be set the saving in labor, etc., which would result from shutting down the gas plant. The problem, like the former one, is, therefore, capable of an almost exact solution, which is only rendered possible by the foregoing analysis of the coal consumption of the main station.

The figures concerning the water and coal consumption of the power-station per shift, which have been taken as an illustration of the method, are actual working results obtained during the normal operation of the station. The month of September, for which they are given, was the first month for which it was possible to obtain them. They are put forward merely to illustrate a principle, and the writer is not concerned to defend them. Criticism should be directed not at the figures themselves, but at the use made of them. However, a brief explanation of certain points with regard to the station may not be out of place.

The power-station serves a non-manufacturing town of about 70,000 inhabitants, and furnishes alternating current for lighting and power, and direct current for street railway purposes. The plant comprises water-tube boilers with chain-grate stokers and superheaters, but without economizers. The generating machinery operated during the month of September consists of turbine-driven alternators for the lighting load and vertical high-speed engines and motor generators for the traction load. The condensing plant is partly steam-driven and partly motor-driven, and exciting current was furnished by a steam-driven exciter. In the diagrams above referred to the gross output of the main generators is given, this including the electrical energy used for auxiliary machinery and induced-draft fans in the station. The fuel used was a class of coal intermediate between lignite and bituminous coal, its average analysis being about as follows:

B. Th. U. per pound of dry coal	10,100
Moisture per cent.	7.3
Volatile matter per cent. (dry coal)....	26.5
Fixed carbon per cent. (dry coal)......	52.0
Ash per cent. (dry coal)..............	21.5

Although the writer trusts he has disarmed criticism of the operating results by the statements given above, it must not be assumed that the results are considered worthy of publication, except for the purpose of illustrating what appears to be the law of power-plant economy. The power-station is still rapidly approaching a higher degree of efficiency, as the following table of total generation costs will show:—

Period.	Total cost (including capital charges).
1st six months, 1912....	1.56d. per kw.-hour.
2nd " 1912....	1.37d. " "
1st " 1913....	1.12d. " "
2nd " 1913....	1.02d. " "
1st " 1914....	0.94d. " "

The costs per kilowatt-hour include the whole of the operation and maintenance charges of the plant in question, as well as the interest and sinking fund on the capitalization, which is particularly heavy.

In conclusion, it is suggested that a method of analysis has been indicated which will enable engineers to compare the working results of different power-stations by studying the respective equations of cost. It is also hoped that a means has been provided for forecasting with reasonable accuracy the cost of generating any extra load which may be offered to the station. The method might have been made more general, though less practical, by giving the results on a thermodynamic basis.

OTTAWA BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

On Friday, December 4th, a goodly attendance of the Ottawa members was present at a luncheon. Mr. W. P. Macoun, Dominion horticulturist, gave a ten-minute address on "A New Country Club." Mr. A. St. Laurent, chairman of the Branch, presided.

SEWER WORK IN NARROW ALLEYS.

The problem of putting down a large sewer in a narrow alley, say, 16 ft., is one which frequently presents itself to the contractor. Methods vary, depending upon conditions governing disposal of excavation, etc., and upon contract requirements of various kinds, but the problem is sometimes made difficult by these conditions, if by nothing else.

In a letter to "The Contractor" some little time ago Mr. Ernest McCullough, consulting engineer, Chicago, describes a method that will be found of interest, differing more or less from other methods with which our readers may be more familiar. He assumes adverse conditions as regards dumping earth on paved streets at the end of the alley, breaking fences, etc., with operations confined entirely to the alley.

To begin, explains Mr. McCullough, the sewer trench will take up considerable space in the 16-foot alley. It is 48 inches in diameter, which means an over-all width of 6 feet to be excavated. The depth is 12 feet. The space along the sides is only 5 feet on each side of the trench. It is a shallow depth to work in by tunneling, but in this case I would tunnel. First, go along the line of the alley and brace all the fences inside the yards so dirt piled against the alley side will not destroy the fences. Where the fences have a fine appearance and the owner will resent keenly any defacement, place a lining of thin boards along the fence to a height of 5 feet.

Divide the alley into 12-foot lengths. On alternate lengths pile the material to be used in the construction of the sewer. Along the edge of the trench place boards about 1 foot high to keep the earth from falling back into the sewer. These boards can be tied by scantlings to posts driven along the fence line. Then we have on either side a 5-foot space ready to contain the excavated material. On the spaces holding material will be piled the sheeting to use for the sides of the trench. Set men at every space between the piles of material and let them get to the bottom as fast as possible. All the dirt will be thrown to the side except some direct from the tunnels under the material spaces, which may be left on a staging. The workmen will go straight down on the clear spaces, sheeting as they go so the heavy burden placed on the sides will not cause caving. They will begin to burrow under the material piles when they reach the depth which will cover the top of the proposed sewer and must place timbers under the material piles and line the tunnels to avoid caving and falls. When the burrowing begins the stagings appear; they should be not more than 5 feet long at first and even this length will leave an uncomfortably short throwing space at the ends. Such work is not cheap, although on a similar job our cost for 650 feet was done at 62 cents per cubic yard of excavation, which included back fill.

No time should be lost in starting the sewer when the cut is down to depth. Pumps may be required to take care of old sewers, etc., but such items are in addition to the excavating problem and must be solved when met. Rain is the greatest danger. On one job I put a canvas roof over the alley and sent the rain into the neighboring yards. Such work, of course, must be done only by permission of owners and damages must be repaired. When the sewer is in, side boards are removed after the sheeting is drawn and the earth shovelled in until the sewer is covered. The earth over the tunnel is broken down by picks so it falls on the sewer and takes care of uniform settlement. If possible no water should be used but the earth should be tamped dry. The tamping cost depends upon the intelligence of the man in charge. It should be merely enough so horses will not mire in the fill. This leaves a lot of earth still piled against the fences and this should remain until the whole block is sewered.

The next step is to run rollers over the trench and the loose earth should be plowed in until the alley is restored to grade, or a little above it. Horses' feet are the best possible tampers and the surface is finally settled by light rollers followed by heavy rollers. A light roller for such work is 3 tons and a heavy roller is between 7 and 10 tons. The surplus material, which should not be large in amount, is to be hauled away in wagons. Personally I prefer to place all the material over the sewer and raise the level of the alley for a time, later removing the surplus earth after settlement. In the case of a paved alley no plowing in can be done from the sides and the paving over the entire trench should be removed before the sewer goes in, over tunnel spaces and all, for the top of the tunnel should be broken down on the sewer. In a paved alley, of course, all the earth should be put in by shovel filling and tamping.

Usually not more than three sections will be opened at a time, for this permits of wagons going in and out from one end of the block. However, when plenty of men are available it is best to work along the entire length.

McGILL UNIVERSITY ATHLETIC FIELD.

Work started last August on the construction of an athletic field for McGill University, Montreal. It includes the construction of a reinforced concrete stadium with athletic field and running track, an out-door skating rink, a gymnasium and other accessory buildings, amounting in all to about $2,000,000. The contract has been awarded to L. A. Ott & Company, of Montreal. The excavation includes about 12 to 14 ft. of loose rock and earth amounting to 50,000 cu. yd. of shovel work and a considerable quantity of rock. A ⅞-yd. Bucyrus revolving shovel is being used on the work. Rock is being handled by hand into 1½-yd. dump cars which convey it to a crushing plant, where it is crushed and stored for use in the construction of the reinforced concrete grandstand. This structure is to be 400 ft. long with a seating capacity of 12,000.

The contract calls for completion in September, 1915. Work has closed down recently owing to weather conditions.

NEW C.P.R. STEAMER FOR PACIFIC COAST.

The first of two new passenger steamers that are being built for the Canadian Pacific Railway Company by Messrs. Denny Bros. & Company, was launched recently. The steamers will be used in the British Columbia service between Vancouver, Victoria and Seattle. The first, "Princess Margaret," measures 395 ft. in length and 54 ft. in breadth, with a 28-ft. 3-in. depth to promenade deck. It is driven by geared turbines, steam supplied by oil-fired water-tube boilers. Manoeuvring in port is effected by a large windlass forward and a steam capstan aft. Steering is effected by steam tiller acting on a balanced rudder and controlled by telemotor from the flying bridge. The vessel is to be fitted out with wireless telegraphy on the Marconi system and a special petrol-driven generating set is installed on the boat deck which is capable of working the wireless system as well as lighting the decks, even if there be no steam in the boilers.

Editorial

HIGHWAY LEGISLATION IN ONTARIO.

Ontario municipal corporations will welcome with avidity the recently issued publication of the provincial Department of Public Works, it being a compilation of Ontario highway laws, prepared by Mr. W. A. McLean, Commissioner of Highways. While members of municipal councils are largely taking advantage of the opportunity to equip themselves with this source of information in such convenient form, road and municipal engineers should not fail to add a copy to their own libraries for ready and reliable reference.

In the Province of Ontario the control of public roads was originally vested in the Crown, or Provincial Government, but responsibility has since been conveyed to city, town, village, township and county corporations, principally by the general Municipal Act of the Province. This Act defines the procedure whereby municipalities are created, and fixes their powers. Under it, townships are given control of all roads within their borders, except those that lie within towns, villages, or cities situated therein. In the latter case each urban municipality is responsible for the roads within its boundaries.

The more important provincial statistics relating to highways are given by Mr. McLean as follows:

Highway Section of the Municipal Act; Local Improvement Act; Statute Labor Act; Highway Improvement Act; Colonization Roads Act; Highway Travel Act; Motor Vehicles Act; Snow Roads Act; Tolls Exemption Act; Toll Roads Act; Snow Fences Act; Traction Engines Act, and Tree Planting Act. These are enumerated in the publication, with the exception of the Toll Roads and Tolls Exemption Acts, the reason for their omission being that there are now only 100 miles of toll roads in the province.

Mr. McLean draws special attention to the Local Improvement Act under which townships are now empowered to conduct road improvement in the same way as towns and cities, assessing the cost on the property benefited. Under this method the township council is authorized to pay a portion of the cost of the work, and payment of the balance levied on the property may be distributed over a term of years.

NEW WHARF ON RED RIVER.

The Department of Public Works will shortly commence the construction of one of three wharves recommended some time ago by the Winnipeg Harbor Commission. It will be known as the Rover Street wharf, and will be 400 ft. in length, 30 ft. in width and will cost in the neighborhood of $25,000. It is to be constructed of piles. A considerable amount of dredging is necessary, much of which has been done during the past season and which, when completed, will have reached an expenditure of about $90,000.

Further improvement on the river is being executed by the Department in the way of hydrographic surveys. Measurements have been made in the vicinity of St. Andrew's Locks, and others are under way at the present time between Selkirk and Lake Winnipeg. Still others are being carried out on the Winnipeg River.

During the year the Department of Public Works has performed improvements to the value of $400,000, of which about $75,000 has been done by contract.

WATERPROOFING OF MASONRY.

The following conclusions, prepared by the committee on masonry, of the American Railway Engineering Association, were adopted at the 1914 convention in Chicago:

(1) Watertight concrete may be obtained by proper design. Reinforcing the concrete against cracks due to expansion and contraction, using the proper proportion of cement and graded aggregates to secure the filling of voids and employing proper workmanship and close supervision.

(2) Membrane waterproofing, of either asphalt or pure coal-tar pitch in connection with felts and burlaps, with proper number of layers, good materials and workmanship and good working conditions, is recommended as good practice for waterproofing masonry, concrete and bridge floors.

(3) Permanent and direct drainage of bridge floors is essential to secure good results in waterproofing.

(4) Integral methods of waterproofing concrete have given some good results. Special care is required to properly proportion the concrete, mix thoroughly and deposit properly so as to have the void-filling compounds do the required duty; if this is neglected, the value of the compounds is lost and their waterproofing effect destroyed. Careful tests should be made to ascertain the proper proportions and effectiveness of such compounds.

Integral compounds should be used with caution, ascertaining their chemical action on the concrete as well as their effect on its strength. As a general rule, integral compounds are not recommended, since the same results as to watertightness can be obtained by adding a small percentage of cement and properly grading the aggregate.

(5) Surface coating, such as cement mortar, asphalt or bituminous mastic, if properly applied to masonry reinforced against cracks produced by settlement, expansion and contraction, may be successfully used for waterproofing arches, abutments, retaining walls, reservoirs, and similar structures; for important work under high pressure of water these cannot be recommended for all conditions.

(6) Surface brush coatings, such as oil paints, and varnishes, are not considered reliable or lasting for waterproofing of masonry.

SURGE TANK PROBLEMS.

Of the series of articles entitled "Surge Tank Problems" by Prof. Franz Prasil, of the Eidgenössische Teknische Hochschule, Zurich, Switzerland, published some few months ago in *The Canadian Engineer*, and being an authorized translation by Messrs. E. R. Weinmann and D. R. Cooper, hydraulic engineers, New York City, the "Engineering Record" has this to say:

"The treatise here offered is the best and clearest on surge-tank phenomena so far published in the English language."

BOW RIVER HYDRO-ELECTRIC PLANTS.

An article in *The Canadian Engineer* for December 3rd, 1914, dealt with stream flow investigations, relating specially to those of Mr. M. C. Hendry, of the Water Power Branch, Department of the Interior, based upon his studies of the Bow River above Calgary. His recent report describes, in brief, the existing developments on the river, and outlines the possible developments which other stretches of it and its tributaries possess.

The following is a brief résumé of the characteristics of the existing plants, and is presented in a complementary way to the information which has already appeared in these columns relative to the two largest developments, *viz.*, at Horseshoe Falls and Kananaskis Falls.

Eau Claire Plant.—The first hydro-electric development on the Bow River, in the section from Calgary west, is that of the Eau Claire Lumber Co., situated within the city limits. The development makes use of the natural fall in the river, by means of a diverting dam (pile and timber construction) and a canal, and the head developed is in the neighborhood of 12 feet. The diverting dam is situated just above the bridge crossing the Bow River at 9th St. W., and the intake and canal are on the south side, the canal following the south bank for about ½ mile. Advantage is taken of small islands or gravel bars, and these, together with timber pile structure, form the stream side of the canal. At the lower end, an island forms the north side of the canal or forebay, the original channel between it and the mainland forming the tail-race. Leffel wheels, set in an open timber wheel case, spanning the channel, are geared to two jack shafts, bolted to two generators. The installation is for 600 h.p.

The head developed is about 12 feet, the total flow of the river at low water being utilized. The company has the right to the total low flow of the river at that point, and an amount equal to the low flow at high and normal stages of the river. This plant supplies power for lighting throughout the city of Calgary, having a franchise for the distribution of power. The water-power is assisted by steam-generated power, and in consequence the service is liable to very few interruptions, but it is understood that during the winter season the operation of the water-power plant is interrupted for considerable periods, owing to ice troubles.

Lake Louise Power Plant.—An interesting power development in the Bow basin is that operated by the Canadian Pacific Railway in connection with the hotel at Lake Louise, near Laggan. This plant supplies light to the hotel at the lake, the station and surrounding houses and buildings. During the summer of 1912, the plant was enlarged and changed, and the output of the station increased.

The original plant was operated under a head of 45 feet, obtained by means of a concrete dam 75 feet long built across the bed of Louise Creek, about a quarter of a mile below the outlet of the lake; from the intake a 16-inch wooden stave pressure pipe led to the power house situated further down the creek, the head obtained being secured by the natural fall in the creek. A 35-kw. machine belted to the turbine, together with a switchboard, formed the station equipment.

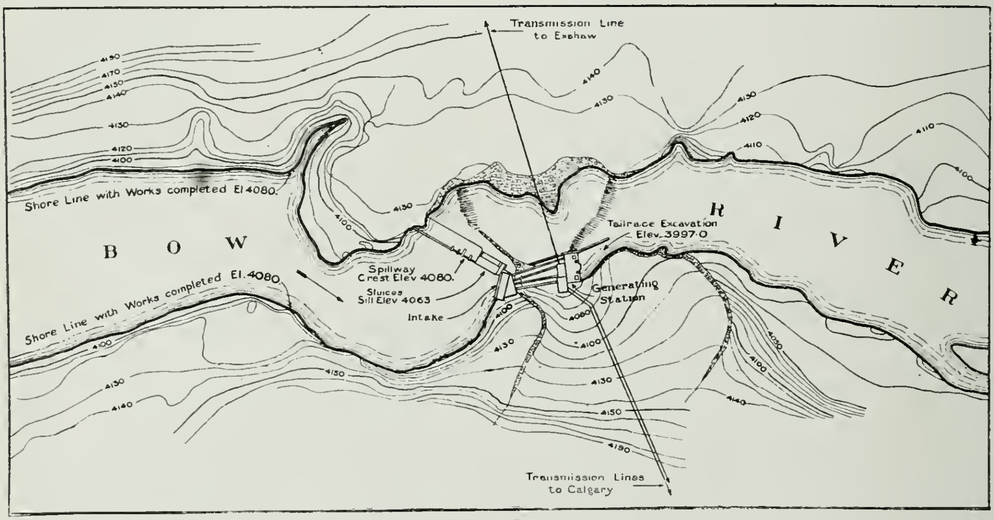


Fig. 1.—General Layout of the Horseshoe Falls Development.

The new installation, rendered necessary by the increased hotel accommodation, involves a concrete dam placed at the outlet of the lake, and forming part of the intake. The structure is in the nature of a bridge having the spill sections situated between the piers, and is so built that the former high, low and normal levels of the lake will still obtain. The pipe line which conveys the water to the plant is a wood stave pipe 20 inches in diameter and approximately 2,800 feet long. It is laid on the east side of the creek for the greater part of the distance, and the gross head developed is approximately 140 feet. The pipe line leads to a 24-inch S. Morgan Smith wheel which runs at 600 r.p.m. The wheel is rated at 100 h.p., and is belted to a 75-kw., 3-phase generator which operates at 1,200 r.p.m. and has an exciter mounted on the shaft. The current is transmitted at 2,500 volts and stepped down to 125 volts for lighting and other uses.

The development is interesting from the standpoint of utilization of the flow, which is very limited at all seasons, during the high-water period, and illustrates the value of small hydro-electric plants to the tourist centres.

Horseshoe Falls Plant.—The largest power development on the Bow River, at present completed, is that of the Calgary Power Company. This plant is located at Horseshoe Falls, about 50 miles west of Calgary, and here one of the very few concentrated falls to be found upon the Bow, is utilized.

At this point the Bow River in its natural state flows through a deep gorge, the walls and bed of which are formed of a shale banded with sandstone. At the point of development a rock outcropping, which is in the nature of an anticlinal dip, occurs. This has been considerably eroded, and forms a drop in the bed of the river of approximately 25 feet. A solid concrete dam has been built across the gorge upon the lip of this outcrop, and this, with the natural fall, produces a head of 70 feet.

The dam is of solid spillway type, with an inspection and drainage tunnel. In addition to the spillway there are 8 sluiceways, provided to take care of flood discharges; four being simply stoplog openings and four being supplied with sluice-gates. The former are 7 ft. by 22 ft., the stoplogs being handled by means of hand winches. The other four are controlled by sluice-gates 19 ft. by 14 ft. of a modified "Stoney" type, operated hydraulically. The spillway section is 140 feet long and, together with the sluices, is sufficient to discharge a flood of 40,000 c.f.s. The inspection tunnel, access to which is gained by means of a well situated midway between the stoplog openings, extends under the spillway section into the rock at the west abutment of the dam. The intake structure is distinct from the dam and occupies a position adjacent to it, approximately parallel to the stream flow. The water, which is admitted through racks and concrete chambers to the 4 penstocks, is controlled by means of stoplogs and butterfly valves placed in the inlet chambers.

The penstock arrangement was described in *The Canadian Engineer* for August 6th, 1914, page 266, to which description the reader is referred. The power house, the main part of which measures 118 ft. by 56 ft., is situated in the gorge below the dam. It is of steel, concrete and brick construction, and houses the turbines, generators, exciters, etc. At the back of the power house, and partly over the penstocks, the switch and transformer rooms are built. The tail-race is protected from back water in time of flood by means of a wing wall, which separates the tail-race from the river for some distance below the power house.

The complete turbine installation consists of four turbines of the horizontal double-runner type in steel wheel cases, and two exciter turbines of the single-runner type, the latter being of 330 h.p. capacity each. Two of the main units are of 3,750 h.p. capacity and, with the governors, were supplied by the Jens Orten-Boving Co. They are of Swedish manufacture, as are also those of the exciter sets. The other two main units are of 6,000 h.p. each, built by Wellman Seaver Morgan Co., of Cleveland, Ohio, and are controlled by Lombard governors. The smaller units are directly connected to two generators, of 2,500 k.v.a. capacity, being 3-phase, 60 cycles, 300 r.p.m. machines and operating at 12,000 volts. The other two units are direct-connected to generators of 4,000 k.v.a. capacity, operated at 12,000 volts, 3-phase and 60 cycles. The generators of the exciter sets are 175 kw., 125-volt, and 700 r.p.m. machines. The generators were built and supplied by the Canadian General Electric Company.

The transformer room contains two 3,000 k.v.a., 12,000 to 55,000-volt, oil-insulated, water-cooled, 3-phase transformers, and two more of the same capacity will be installed very shortly.

The company has three transmission lines in operation, one extending to Exshaw, a distance of 8 miles, and the others forming a duplicate line to Calgary. The Exshaw line supplies power to the Canada Cement Co.'s plant at that place. It is a double-circuit, 3-phase, 12,000-volt line, strung on wooden poles, the conductors being of six 00 aluminum stranded cable. In connection with the line there is a telephone line strung upon the same poles, and also a ground wire. The transformer station at Exshaw contains four 700 k.v.a., 12,000-600-volt, oil-insulated, water-cooled transformers, with lightning arrestors and switching apparatus complete. The switch apparatus in this station was installed by the Canadian General Electric Co., and the transformers by the General Electric Co. of Sweden.

The transmission line to Calgary is in duplicate; each is a single-circuit, 3-phase, 55,000-volt line, the conductors being No. 0 aluminum, with telephone line and ground wire carried on 40-ft. wooden poles. The lines are

Fig. 2.—Horseshoe Falls Plant of the Calgary Power Co.

parallel to one another for the first 10½ miles from the power house, and follow the Canadian Pacific Railway. These lines handle the power output of both the plant at Horseshoe Falls and that at Kananaskis Falls, now being built.

The design and construction of the plant was carried out by the engineering firm of Smith, Kerry & Chace. The dam presented some interesting problems which required considerable thought and care in solving.

In order that the site of the foundation might be unwatered, and the discharge provided for during construction, two unwatering tunnels were driven on the intake side of the river, from the under side of the lip of the falls up to the upper level, and at such an elevation that only a low cofferdam was necessary to keep the water out of the foundation of the dam. The rock outcrop which forms the fall, and upon which the dam was constructed, dips across the river at a considerable angle, and upon unwatering and exploration of the lower part (the section near the north bank) it was found that the material which is illustrated in the section shown on the plan of the development was not of a satisfactory nature for foundation purposes. An examination proved that no better material underlay it, and this material necessitated special treatment. While the section containing the sluiceways was being built, Mr. John R. Freeman was called in by the company to advise in the matter. His report of October 10, 1910, accompanied by plans showing layout and proposed changes, was acted upon, and the plans

of the plant as built, included here, embody the recommendations made.

The following precautions were taken, based upon the report:—

1. The hard sandstone ledge, upon which the dam was to have been built, dipped at such a considerable angle that the cost of carrying the foundations down to this rock throughout the length of the dam, would have been excessive. The northern part of the dam was therefore built upon the shaly rock, overlying the hard sandstone, which it was considered would afford a safe foundation.

In order to obviate any leakage that might develop through the underlying seams, 3-inch holes were drilled through the rock, about 2 ft. in front of the face of the dam, 10 ft. apart, and to a depth of about 40 ft., a casing was then placed in the upper part of the hole, and a thin cement grout forced into the holes under a pressure varying between 60 and 80 lb. per sq. in. until they refused to hold any more. By this means the grout was forced into seams in the rock, cross-cut by the holes, and for a considerable distance from the holes. By first filling alternate holes and later filling the remainder, it was expected that all the seams would be completely filled for some distance from the line of holes.

2. The possibility of leakage around the north end of the dam was met by excavating a considerable distance into the cliff, for the total height of the dam. The cliff consists of a soft shale, liable to disintegration on exposure to air, but as the excavations were completely filled with concrete, any water leaking through the seams in the shale would be forced to travel a considerable distance, and the quantity would be greatly reduced by friction, and as the seams are liable to silting, the leakage would be very nearly eliminated.

3. The inspection tunnel also serves the purpose of a drainage tunnel. Drainage holes, about 16 in. square, and placed 16 ft. 8 in. apart, extend from the springing line of the arch of the tunnel upward through the body of the dam, so that any leaks that may develop through cracks will be intercepted and directed into the drainage tunnel. Other holes, 3 in. in diam., and about 12 ft. 6 in. apart, have been drilled down through the base of the dam into the underlying rock for depths of from 10 ft. to 18 ft. These are cased at their upper end, in order that the quantity of any water leaking through them and also the upward pressure may be measured.

4. The tunnel has been extended into the rock forming the north abutment of the dam for a distance of some 30 ft., so that most of the leakage around the end, if there is any, will be intercepted by the tunnel. This expectation has been realized by the stopping of leakage going on before the tunnel was extended. The tunnel itself is drained through an opening in the downstream side of the dam.

5. The protection of the foundation of the dam at the downstream side has required careful consideration. In order that erosion due to the water coming over the spillway section might be eliminated, Mr. Freeman recommended that the apron of the dam be extended downstream about 40 ft., heavily reinforced and anchored to the rock, and that baffle piers be built on the apron to reduce the velocity of the water and thereby prevent any possible erosion. Other recommendations were made, one being the building of a baffle wall on the crest of the old falls at the south end of the dam, and the facing of the cliff below to prevent undermining.

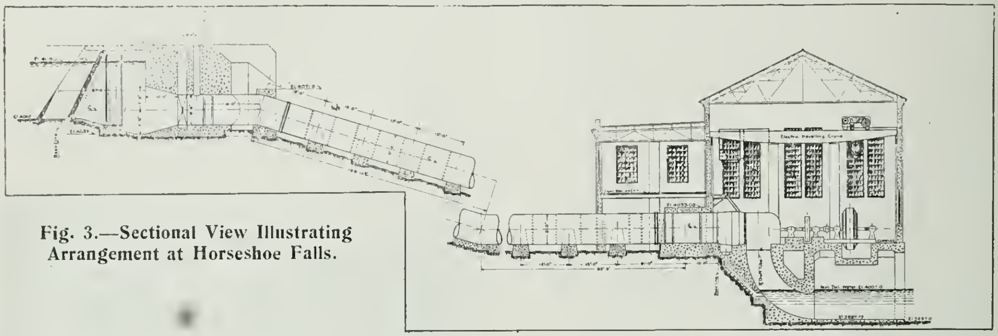

Fig. 3.—Sectional View Illustrating Arrangement at Horseshoe Falls.

The Kananaskis Falls Plant.—This development, the most recent on the Bow River, was described in considerable detail in our issue of August 6th, 1914.

SOUTH AFRICAN RAILWAYS.

The open mileage of Government-owned lines in South Africa at the end of 1913, was 8,281 miles, of these 7,807 miles being 3 ft. 6 in. gauge and 474 miles of 2 ft. gauge, the total increase during the 12 months being 433 miles. The mileage of new lines opened for traffic totalled 385 miles divided between the four provinces as follows:—Cape, 102 miles; Orange Free State, 56 miles; Transvaal, 105 miles; and Natal, 64 miles.

The position of the provinces on December 31, 1913, as compared with the end of the previous two years, was as follows:—

	1913.	1912.	1911.
Cape	3,638	3,492	3,397
Free State	1,162	1,106	1,070
Transvaal	2,362	2,197	2,020
Natal	1,116	1,052	1,052

The figures given above represent Government-owned lines only, with the exception of 50 miles leased from the Natal-Zululand Railway Company. The administration works the section from Vryburg to Bulawayo (597 miles) owned by the Rhodesian Railways, and also 56 miles privately owned within the Union.

Parliament authorized the construction of 14 new lines, but at the end of 1913 their construction had not been entered upon. The total mileage of these authorized lines was 794½ miles, the provincial allocation being: Cape, 306¼ miles; Transvaal, 191 miles; Orange Free State, 166½ miles; and Natal, 130¾ miles.

Coast to Coast

Chatham, Ont.—The city expects to have Hydro-Electric lighting before the middle of January.

Victoria, B.C.—A municipal paving plant, for which contracts were let last spring, will be constructed and made ready for operation during the winter.

St. John, N.B.—The new docks at Carleton were formally opened last week, and the completed structure turned over to the Department of Public Works by the Maritime Dredging and Construction Co.

Victoria, B.C.—The new Canadian Northern Pacific wharf to be constructed at Patricia Bay will, according to an announcement by Mr. D. O. Lewis, divisional engineer of the C.N.P., be commenced immediately, the contract having been awarded to Mr. J. Doe.

Kamloops, B.C.—The Hydro-Electric power plant on the Barriere River (described in *The Canadian Engineer* for November 5th, 1914), has been put into operation. The installation provides for a maximum development of 20,000 h.p. At the present time about 6,000 h.p. is being developed.

Brockville, Ont.—The Hydro-Electric Power Commission of Ontario will shortly construct a transformer station, 20 x 39 ft., at an approximate cost of $4,000, to be used in connection with the new power line now under construction from Prescott. This line will be completed in the spring. It will carry current at 26,400 volts, which will be stepped down to 2,200 volts for use in Brockville.

Welland, Ont.—The new factory of the Tuttle-Bailey Co. of Canada, Limited, has been completed. It is of reinforced concrete and steel, 100 x 200 feet in dimensions, and has been erected at an expenditure of about $60,000. The company will manufacture steel registers. It will employ about 50 men. Peter S. Gordon is local manager. The company has a branch at Winnipeg, Man.

Sydney, N.S.—By the end of the year the Intercolonial will have completed 105 new steel bridges, to take the place of the light bridges so numerous along its line. The railway is making wholesale preparations for the handling of heavier traffic, and the steel structures now being erected are designed to meet the requirements for many years to come. With their construction going on, the purchase of more powerful locomotives and for larger and better transportation equipment are being looked after.

Toronto, Ont.—The Commissioner of Works has recommended to the city council the construction of a highway running north and south through Mount Pleasant Cemetery, to afford a thoroughfare between North Toronto and East Rosedale. The estimated expenditure upon this much-needed improvement is $275,000. Another similar recommendation has to do with a road to run east and west across Prospect Cemetery to create a thoroughfare between Dufferin St., to cost between $25,000 and $30,000.

Vancouver, B.C.—The bulkhead belonging to the C.N.P. terminal scheme in False Creek is nearing completion, and reclamation work will be resumed at an early date. Over 3¾ million cubic yards will be required to build up the area under improvement. Of this amount over 1,000,000 cubic yards have already been deposited by the Pacific Dredging Co. This company is also dredging out the deep-water channel in connection with the harbor improvement scheme of the Department of Public Works.

Toronto, Ont.—As announced elsewhere in this issue, thhe city council has accepted the tender of Messrs. Quinlan and Robinson, of Montreal, for the construction of the Don Section of the Bloor Street Viaduct, according to plans and specifications prepared by the Department of Works of this city, under the direction of Mr. R. C. Harris, Commissioner of Works. These specifications cover a steel structure with concrete abutments and piers. The plans were described in *The Canadian Engineer* for October 29th, 1914.

Winnipeg, Man.—It has been announced that the construction of the aqueduct for the Greater Winnipeg Water District will be commenced in March. The close of the construction season finds the right-of-way located and cleared; a 90-mile railway constructed through country, much of which consisted of muskeg and timber; partial completion of the dyke across Indian Bay, 1½ miles in length; completion of preliminary channel connecting Indian Bay with Snowshoe Bay; a telephone line, permanently constructed for the full length of the system; ballast-pits located and open, and a large amount of fencing done.

Cobalt, Ont.—The Cobalt Reduction Co. has commenced the construction of an addition to their present mill. This addition will be a cyanide plant, to have a daily capacity of between 125 and 150 tons. It is to be completed and ready for operation next March. This plant will treat by the cyanide process the slimes produced by crushing operations in the mill. The building will be 193 ft. x 70 ft., with an additional wing, 80 ft. x 70 ft. The foundations are to be of concrete, and the superstructure of steel and fireproof material. The machinery to be installed will include the usual classifiers, settlers, agitators, and vacuum filters necessary in the process.

PERSONAL

P. B. MIGNAULT, K.C., has been chosen to succeed Hon. T. C. Casgrain as member of the Canadian section of the International Joint Commission.

CHARLES L. WISNER has been appointed to succeed Mr. J. H. Housser, deceased, on the board of directors of the Massey-Harris Company.

A. E. STEVENS, of Vancouver, has been appointed general superintendent in Alberta of the Canadian Pacific Railway, succeeding Mr. D. C. Coleman, with headquarters at Calgary.

A. PRICE, assistant general manager, Canadian Pacific Railway, read a paper at a meeting of the Canadian Railway Club last week in Montreal. His subject was "Some Maximums and Minimums in Train Operation."

SAMUEL HALE, manager of the Algoma Steel Corporation, is about to retire, according to a press report. Mr. J. F. Taylor, president of the company, will take charge of the works and of the operation of the plant.

J. J. FERRIS, superintendent of oil service, Canadian Pacific Railway, delivered an illustrated address on "Fuel Oil and its Application" before the regular meeting of the Vancouver Branch of the Canadian Society of Civil Engineers on December 3rd.

OBITUARY.

The death occurred in Montreal last week of Mr. James A. Baylis, chief engineer of the Bell Telephone Co. of Canada. Mr. Baylis was a graduate of Worcester Polytechnic Institute, and has been in the employ of the Bell Telephone Co. since 1890. Mr. Baylis was a member of the American Institute of Electrical Engineers.

The death occurred in Chicago last week of Mr. R. M. Greene, a structural engineer, of Winnipeg, and a former instructor at the University of Manitoba.

UNIVERSITY OF TORONTO ENGINEERING SOCIETY.

On December 9th the members of the University of Toronto Engineering Society assembled to pay tribute at a memorial meeting to the late Dr. John Galbraith, dean of the Faculty of Applied Science and Engineering. The meeting was addressed by several of the older graduates, including Mr. G. H. Duggan, vice-president and chief engineer of the Dominion Bridge Co., and a graduate of 1883, and Dr. T. Kennard Thomson, consulting engineer, New York, and a graduate of '86. Mr. E. D. Gray, president of the Society, was in the chair.

The speakers referred to their early associations with Dean Galbraith and to the remarkable development of the Institution, as viewed by them from a distance, since graduation. In his remarks, Dr. Thomson reviewed briefly the engineering career of the departed man, touching upon his exceptional character, marvellous foresight and preponderant spirit. The late educationist's policy was reviewed and eulogized as one which developed in the old graduates as time went on the feeling that the course of instruction which they had received from him was of far greater value than could be obtained from any course in the best modern University.

On the following day another meeting of the Society was addressed by Dr. Thomson on the foundations for bridges and buildings, especially as regards pneumatic caisson work.

Compressed-air caissons were first used on this continent in North Carolina, in 1852 for bridges, and in 1893 in New York City for buildings. Now many bridges and buildings are supported by foundations obtained by this method.

Photos were shown of the beautiful stone arch bridge over the Connecticut River, at Hartford, and accidents were described which happened in the Susquehanna, Missouri and other rivers. Many New York skyscrapers were described, especially those whose cellars are 16 to 32 feet below the level of the surrounding ground-water. No difficulty is experienced in keeping them dry, as described.

The difficulties of pile-driving were also shown by photos of many very badly driven piles. The underpinning or placing of new foundations under old buildings as high as 18 stories, without allowing the building to settle, was also explained in detail.

A description was given of the removal of a 17-story building on penumatic foundations, which was removed after 14 years' service from the corner of Wall and Nassau Streets to make place for the 39-story Bankers Trust Building. In this connection it was noted that where the steel columns were in contact with concrete no rusting had commenced, but where there was an air space between the steel and concrete, then rusting had made considerable progress.

AMERICAN CONCRETE INSTITUTE.

The eleventh annual convention of the Institute is to be held in Chicago, February 9th to 12th, 1915. The following is a summary of the programme:—

Concrete Roads, Sidewalks and Bridges.—Papers and discussions relating to the status of concrete road construction will be presented, and special attention given to costs, repairs and maintenance.

Concrete and Reinforced Concrete Tests and Design.—Discussion of the column tests made by the Institute at Pittsburgh, tests of buildings, and other matters of current special interest.

Concrete in Art and Architecture.—Discussion of architectural design in concrete, dimension and art concrete stone, treatment of surfaces, etc.

Plant Management and Costs.—Devoted to concreting plants, covering plant management and costs, the design and cost of wood and metal forms, and the methods of placing, proportioning and selection of concrete materials.

EDMONTON BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

The next regular meeting of the Edmonton Branch will be held on January 6th, and will be addressed by Mr. A. J. Latornell, city engineer, Edmonton. His subject will be a description of the trunk sewer system of Edmonton.

An interesting syllabus of papers for the season has been prepared. On November 4th Mr. R. H. Parsons read a paper entitled "The Prevention of Electrolysis Due to Street Railway Tracks." On December 2nd Mr. J. Chalmers read a paper, "Depreciation as Applied to Public Utilities." Future meetings include a paper on military engineering, to be given in February by Mr. D. Donaldson. Messrs. J. Brodie and J. A. Allan will take up the subject, "Natural Gas in Alberta, with Geology Incident Thereto," at the March meeting. The April paper will be "Electric Railway Operation and Management," by Mr. J. H. Larmouth. The May meeting will be devoted to general business of the Branch. The members meet fortnightly, each alternate meeting being of a more or less informal nature, with a dinner as part of the programme. Commissioner J. Chalmers is chairman of the papers committee.

CLAY WORKERS' CONVENTION.

The annual convention of the Canadian National Clay Products Association will be held in Toronto, January 26th-29th, 1915.

COMING MEETINGS.

AMERICAN FORESTRY ASSOCIATION. — Annual meeting to be held in the Woolworth Building, New York City, January 11th, 1915. Secretary, P. S. Ridsdale, Washington, D.C.

CANADIAN NATIONAL CLAY PRODUCTS ASSOCIATION.—Annual Convention to be held at the King Edward Hotel in Toronto, January 26, 27, and 28, 1915. Secretary, G. C. Keith, 32 Colborne Street, Toronto.

CANADIAN SOCIETY OF CIVIL ENGINEERS.—Twenty-ninth annual meeting, to be held in Montreal, January 26th, 27th and 28th, 1915. Secretary, Prof. C. H. McLeod, 176 Mansfield Street, Montreal, Que.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

AMERICAN WATERWORKS ASSOCIATION. — The 35th annual convention, to be held in Cincinnati, Ohio, May 10th to 14th, 1915. Secretary, J. M. Diven, 47 State Street, Troy, N.Y.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.—Annual meeting to be held at the Iowa State College, Ames, Iowa, June 22nd to 25th, 1915. Secretary, F. L. Bishop, University of Pittsburgh, Pittsburgh, Pa.

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

METHODS OF TREATMENT OF SEWAGE SLUDGE

PROF. P. GILLESPIE, C.E., REVIEWS THE METHODS IN VOGUE IN AMERICA AND EUROPE — ABSTRACTS FROM A VALUABLE PAPER TO THE CANADIAN SOCIETY OF CIVIL ENGINEERS.

A VALUABLE addition to literature on sludge disposal is contained in the paper presented on December 17th to the Canadian Society of Civil Engineers by Prof. P. Gillespie, of the University of Toronto. The formation of sludge is described, the paper confirming the frequently expressed generalization that American sewage contains up to one part per thousand of solid matter. It is with the treatment of this solid matter, partly in suspension, partly in solution, and partly in colloidal state, that Prof. Gillespie's paper deals, this treatment being such that the sludge ceases to possess properties in virtue of which it may prove a nuisance to the community or a menace to its health. The speaker calls attention to the fact that while the noted fifth report of the Royal Commission on Sewage Disposal devotes much space to detailed descriptions of various methods of sludge treatment, including conversion into fertilizer, depositing at sea, pressing, burning and trenching, and while in its recommendations every other matter is referred to, no specific recommendation is made with respect to the disposal of sludge.

The values of the fertilizing constituents (potash, nitrogen, phosphates, etc.) are dealt with, and the methods employed in this field outlined. The effect of decomposition on the fertilizing value of sludge is emphasized, it being due to dimunition of nitrogen content and of phospherous, a more porous non-fibrous constitution of nitrogenous material and a finely divided and more uniformly distributed condition of contained grease.

The paper divides methods of sludge treatment into (1) those which deal with crude sludge and (2) those which deal with decomposed sludge, owing to the radical differences and the methods of disposal best suited to each. These differences are described and explained.

The various methods of treating crude sludge are described. Disposal at sea, for cities fortunately located, is a method in quite general use, satisfactory and reasonably cheap. This method is practised in Providence, R.I.; Boston, Mass.; London, Salford, Manchester, Dublin, Belfast and Glasgow. The latter city reports a cost for this work equal to 3.1d. per long ton of sludge handled, including .9d. per ton for land charges. In London the cost is about 7 cents per ton of sludge, not including the cost of precipitation and pumping into barges.

The following costs per ton of 2,000 pounds of dry matter are reported: London, $1.03; Glasgow, 87 cents; Manchester, $1.26; Salford, 90 cents, and Dublin, 91 cents. Precaution must be taken to avoid pollution of shellfish layings and the deposition of solid matter where it can possibly be carried to any foreshore.

Methods of land disposal include air drying, trenching, and lagooning, none of which have been attended with anything better than partial success. The next method considered is that of treatment by use of the centrifugal machine, whose operation is described in detail. The process of pressing, whereby handling is facilitated, odor diminished, and capacity for putrefaction lessened, is explained. The sludge is here subjected, between plates, to a pressure of about 75 pounds per square inch. Its volume is about 1/5, after the treatment, and the water content is reduced 50 per cent. This method is in use in Hamilton, Ont.; Worcester, Mass.; Providence, R.I., and Bradford, England.

The writer claims the treatment of rotted sludge by filtering it on properly constructed beds, as being the only satisfactory method. The procedure in Great Britain (at Birmingham) and on the European continent (in the Emscher Valley) is described, it being strikingly similar in both cases, the main difference lying in the manner of sludge preparation.

At Birmingham plain sedimentation is employed. The sewage after passing through a grit chamber and being roughly screened is passed into sedimentation tanks, where the sludge is deposited. This sludge is removed from each tank weekly in summer, less frequently at other seasons, and deposited in one or more of a series of twenty tanks where septic action and digestion take place. Following this, the sludge is pumped to the drying beds which are each 150 feet square in area, consist of 6 inches of clinker and ashes, and are underdrained with 4-inch tiles laid in herring-bone fashion toward a main leader, which in turn takes the drainage to the well whence it is pumped to the filtering beds. Each bed gets two fillings per year

In the Emscher Valley the sludge is rotted in the lower compartment of two-story tanks, the upper compartment being the sedimentation chamber. It is periodically removed and dried on prepared beds, similar in construction to those at Birmingham. The drying period is considerably longer.

The writer deals to some length with plain sedimentation, the term denoting the subsiding of solids heavier than water, which takes place when conditions are favorable. The influences affecting it in the treatment of sewage are the velocity of flow, time of retention, specific gravity and size of settling solids. The observations of

Beck and Schwarz, Hanover, in 1899, were cited, where it was found that with a velocity between .014 and .027 feet per second, 55.7 per cent. of the suspended solids were settled out in 2¼ hours. When the period of retention was increased by 50%, this percentage of sedimented solids became 61.5. Steuernagel reported that complete quiesence for 12 hours removed 84%. Of American data the Columbia tests are noted.

The writer calls attention to the criticism which is attendant upon the method of expressing the sedimented solids as a percentage of the total solids in suspension, the latter having been determined by careful filtration of samples, in estimating the efficiency of sedimentation processes.

"Without doubt it leads to confusion in a comparison of results since it takes no account of the fact that there are always some solids which refuse to settle because their specific gravity is practically that of the water containing them or else through fine division they are in a state of semi-solution. A sedimentation plant has no more concern with non-settling solids than it has with matters in solution."

The paper goes on to describe the first attempt, by W. J. Dibden, London, at giving separated sludge a treatment independent of that given to the liquid sewage. Mr. H. W. Clark's observations (1899-90) were outlined, and followed by a full description of the Travis or Hampton hydrolytic tank, patented and put into service in 1903 and now in operation on a commercial scale at Hampton, Norwich and Luton, England. The circumstances surrounding the first German modification of this tank are also described in an interesting way.

Prof. Gillespie then traces the development of the septic tank, outlining the early experiments, particularly those of Doctors Guth and Spillner. The work of the Emschergenossenschaft was described,* and the typical Emscher plant outlined in detail. Each part, *viz.*, storm overflow weirs, screening chamber, detrieus tank or grit chamber, Imhoff sedimentation tank, and sludge beds, is taken up, carefully studied, and illustrated. An interesting parallel is drawn between what is commonly called the "British" and "German" methods, the former, as already described, embodying sludge digestion in separate tanks, and the latter, sludge decomposition in 2-story tanks. Both processes are termed satisfactory; both produce inoffensive and quick-drying sludge. Commenting upon them, the writer states that his observations have led him to believe that sludge which has been thoroughly digested in separate tanks does not differ materially as to character or quantity from that which has undergone digestion in Imhoff tanks, or indeed in ordinary septic tanks. "There are, however, certain objections to the method of decomposition in separate tanks which are significant. In the first place, where separate digestion tanks are employed, the overflowing excess liquid is very offensive and the escaping gases are likely to be very noxious also. Again, for the maintenance of bacterial life, it seems obvious that the food supply (fresh sludge) should enter the chamber continuously, and that the rotted sludge should be withdrawn as nearly as may be in the same way. The separate tank does not usually provide for this, while the two-story tank does. The proper environment seems to require time for its development, and after this environment is once created, it seems like taking a great risk to renew the entire contents of a tank at one operation instead of permitting the supply of food to come in gradually. Experience, moreover, has shown that the time required for complete digestion is likely to be longer in the separate tanks than in those with two stories. The body of water overlying the sludge in the decomposing room of two-story tanks, performs a function which it is not possible to duplicate in the ordinary tank for separate sludge digestion. This body of water is a medium in which the old sludge and the new, through the ebullition caused by the escaping gases, have an opportunity of becoming mixed, and one in which, as explained later, its soluble constituents may often exert an important influence in preventing acid decomposition.

"Fresh sludge separates from its water only with the greatest difficulty, the reason being the attraction of its contained colloid constituents for water. Structurally, the mass is supposed to be divided into cells by a network of amorphous membranes, which cells dilate as the liquid

*See *The Canadian Engineer*, June 25, 1914, for an article entitled "The Method and Work of the Emschergenossenschaft," by Prof. P. Gillespie, C.E.

Data Concerning Two-Story Sewage

	Date of Completion	Population for which designed	Number of Tanks	Radial or Longitudinal Flow	Open or Covered	Depth	Flowing through time	Mean Velocity in Sedimentation Chamber	Capacity of Sludge Room
Carleton Place, Ont.	1914	4,000	2	Longitudinal	Covered	26 ft.	3 hrs.	3 ins. per min.	6,000 cu. ft.
Edmonton, Alta.	Not Started	10,000	2	Longitudinal	Covered	24 ft.	2 hrs.	7.2 ins. per min.	22,000 cu. ft.
Hamilton, Ont.	1914	70,000	4	Longitudinal	Open	28 ft.	2½ hrs.	21 ins. per min.	6 mos. accumulation
Kelowna, B.C.	1913	3,000	1	Radial	....	23 ft.	2 hrs.	....	2,750 cu. ft.
Peterboro, Ont.	Not Started	....	8	Longitudinal	Covered	27 ft.	½ hr.	29 ins. per min.	42,700 cu. ft.
Stratford, Ont.	Under Construction	17,000	2	Longitudinal	Open	24⅔ ft.	1¾ hrs.	....	21,400 cu. ft.
Weston, Ont.	1913	3,000	2	Longitudinal	Covered	18 ft.	2 hrs.	4.8 ins. per min.	1,500 cu. ft.

is absorbed. When such sludge is applied to a bed, only the coarser particles remain on the surface. Owing to its fluidity, much of the finer material penetrates into the interstices in the medium, some of it indeed passing all the way through. The surface layer becomes more and more dense through the accumulation of particles of sludge which penetrate it successively with new applications until finally it becomes impervious.

"The rotting process, however, produces a radical change. The colloids are broken down. The sponge-like structure with amorphous cell walls referred to, disintegrates and loses in the act, its capacity for holding water. In the second place organic matter, such as fragments of animals and plants which are very common in household waste, is destroyed. These substances which have naturally a very large water content, are found in very small quantities if at all in decomposed sludge, so that the difference in the water content between fresh sludge and decomposed sludge must to some extent be regarded as a measure of the completeness of the decomposition.

"The most important element making for the separation of water from decomposed sludge is the contained gas. The gas in decomposed sludge under thirty feet of water sustains a pressure substantially twice that which acts upon it when it comes to the surface. Immediately on release of the water pressure, the confined gas swells and the sludge becomes frothy and foamy. The water being heavier, sinks to the bottom, passes down through the medium and drains away. This phenomenon may be illustrated in a very simple manner. If a glass beaker of decomposed sludge freshly drawn from an Emscher tank be permitted to stand for a few hours, it will be observed that the light and gas-containing portion will rise to the surface, incidentally increasing the depth. Meanwhile, the clarified water will have settled to the bottom. An examination of the floating matter shows the presence of many gas sacks or cells. In the course of time, a portion of the sludge, having lost its gas content, will sink to the bottom, thus indicating that this sludge, without the increased buoyancy given it by entrapped gases, is heavier than water. If, on the other hand, fresh sludge be placed in another beaker, its solid contents will settle to the bottom, and if it be examined later, it will be found that the separated water is at the top instead of at the bottom. In this lies a most important difference.

"Accompanying the destruction of the colloidal and organic matter, is a partial decomposition of the fats. In European sludges the fat content will average ordinarily 15% of the dried constituents."

The difference between good and bad sludge is defined; the effects of metallic salts upon sludge and of acid-forming ingredients are observed.

The paper goes on to enumerate the recommendations of Prof. Hyde and Mr. F. E. Daniels as essentials to be observed in the operation of a sewage treatment plant:—

1. If the velocity in the feeding channels be not sufficiently high to be self-cleansing, the deposits should be swabbed out semi-weekly in summer and less frequently in the colder season. If they become septic they are a source of disagreeable odors. Such deposits in feeding channels in which the flow is periodically reversed, are more likely to be found at the inlet end because of the diminished velocity there.

2. With equal frequency, too, should the sides and sloping floors of the sedimentation chamber be cleared of adhering matter. On floors of flat slope and rough finish the accumulation is most rapid; on others it is less so None are entirely immune. Instances have occurred in which the slots leading to the sludge digestion chamber have been completely choked by this matter. Ebullition of gas from the upper chamber is evidence that it has begun to septicize. A long-handled squeegee should be employed to clean the surfaces and to push with the least disturbance possible, the accumulations into the chamber below.

3. The tendency on the part of scum to collect in gas vents is well known. Since this scum must have been previously heavier than water, its later buoyancy is due in the main to the entrapped gases of decomposition. It will be seen that an existing scum tends generally to become thicker since particles that float up adhere to the mass of accumulations already floating and remain. Otherwise on losing their gas content, they would sink again. Scum formation tends to be greatest where evolution of gas is greatest. This state occurs usually in the comparatively early history of the life of plants when a mass

Sedimentation Tanks in Canada

Hydrostatic Head on Sludge Outlet	Sludge-Drying Area	SUPPLEMENTARY PLANT	Separate or Combined System	Capacity of Plant, Gallons per day	Cost of Plant exclusive of Sewers	DESIGNER	REMARKS
5 ft.	1,200 sq. ft.	Chlorination plant, sludge beds	Separate	1,080,000 (Imp.)	$8,800	T. Aird Murray and T. Lowes, Toronto	Sewage is chlorinated before entering tanks
6 ft.	4,680 sq. ft.	Grit chambers, sludge beds	Combined	1,500,000 (Imp.)	$35,0[illegible]0	Eng. Dept. City of Edmonton, A. J. Latornell, Chief	Filters to be added. Reversible flow
6 ft.	10,900 sq. ft.	Screens, grit chamber sludge pump, sludge beds, percolating filter (future).	Combined	5,880,000 (Imp.)	$70,000	A. F. Macallum and B. E. T. Ellis, Hamilton	Flow is reversible
12 ft.	625 sq. ft.	Grit chamber, pumping station, force main, sprinkling filters, sterilizer, secondary settling plant, sludge beds	Separate	270,000 (Imp.)	$15,000	A. K. Mitchell, Victoria	Vent is provided over central stack. Cost given is exclusive of pumping station
7 ft.	60,000 sq. ft.	Pumping plant, sprinkling filters, final settling plant, sludge beds	Separate	[illegible],000,000 (Imp.) maximum	. .	R. H. Parsons, Peterboro	Sterilizing plant may be added
$7\frac{2}{3}$ ft.	....	Screens, grit chamber, sprinkling filters, sludge beds	Both	1,350,000 (Imp.)	$15,500	A. B. Manson, Stratford	....
6 ft.	1,050 sq. ft.	Percolating filters, secondary settling tanks, with sub-irrigation sludge beds	Separate	540,000 (Imp.)	$19,000	Murray & Lowes, Toronto	....

of sludge has accumulated, most of which is in active decomposition and none of which, or practically none of which, is as yet decomposed and inert. Insufficient scum area or gas vent area will intensify the trouble.

Excessive depths should not be permitted, and need never occur if the scum is persistently broken up from time to time as it forms. A garden rake, or better still, a pressure hose will accomplish this satisfactorily, and since much of the entrapped gases are permitted thereby to escape, the bulk of the material will sink to the bottom. It has been observed also that the occasional discharge of water under pressure through the flushing pipes in the sludge digesting room will mitigate the scum evil. Materials which defy all attempts to settle should be skimmed off and buried or burnt. This last statement applies also to floating materials which are always observable near the baffles and along the walls of the sedimentation chamber. It should not be forgotten that if sewage fresh on its arrival at the works is to be found still fresh on its discharge from the sedimentation tank, its contained solids with their ready capacity for decay must not be permitted to lodge or remain in the upper chamber.

4. In tanks designed for the purpose, reversal of flow should be made monthly.

5. Determinations of the depth of sludge in the lower chamber should be made weekly. This is very conveniently done by lowering through the gas vents by a gradual cord, a disk of No. 20 B. & S. sheet steel, of diameter 15 inches, suspended at three points, so that its plane is horizontal. Its weight in air is about two pounds. The surface of the sludge can be rather closely ascertained through the support which it affords to the disk. The surface should not be permitted to rise higher than 18 inches below the slots at the bottom of the sedimentation chamber. It is observed that when this rule has been disregarded ebullition of gas is often observable in the upper chamber. This phenomenon is doubtless due to the fact that the stratum of mobile and gas-charged liquid overlying the sludge proper has been sufficiently thick to submerge the slots and thus permit some of the escaping gas to enter the settling chamber.

6. If the tank be supplied by pumps whose capacity exceeds the inflow of sewage and which in consequence must operate intermittently, the quantity pumped at each operation should not exceed, and preferably should be less than the volume of the sedimentation chamber.

7. Care must be exercised in the drawing off of sludge that neither fresh sludge nor the overlying sewage be permitted to escape. Thoroughly rotted sludge can always be detected by its color and smell, especially the latter. When a sludge gate is opened, there is always a tendency for the sludge in the immediate vicinity of the lower end of the discharge pipe and whatever overlies it, to be forced out by the weight of the water above. This results from the fact that the semi-liquid mass moves vertically in the centre of the sludge pit with less friction than it can move in the inclined direction along the sloping floor. In consequence, the sludge occupying the figure of an inverted cone lying over and above the lower extremity of the pipe is first forced out, and if care be not taken the liquid above this will soon follow. To avoid this, only small quantities of sludge should be drawn at a time. After the gate is closed the sludge mass will find its level again, especially if the flushing pipes previously referred to be brought into service. The water escaping from these has the effect of assisting and lubricating the movement of the rotted sludge down the slope of the chamber floor toward the extremity of the sludge outlet pipe. Sufficient of the contents of the sludge digestion chamber should be left to insure continuity of the rotting process.

8. To prevent the sludge pipe becoming filled with solidified sludge, after each drawing off, the pipe should be filled from its upper end with water. Similarly if all sludge chambers are cleansed after use with water under pressure or otherwise, both appearance and operation of the plant will be improved. Water under pressure is a great convenience for operating pressure rings in the sludge room, for backfilling sludge discharge pipes after use and for cleansing sludge channels. In cases where secondary sedimentation tank sludge is to be pumped back to the primary sedimentation tank, the pumping unit may be arranged to handle clarified effluent which may then be utilized for the various purposes for which water under pressure may not be available.

9. The depth of sludge run on to drying beds should not exceed 12 inches. After drying, its depth is reduced to about 6 inches. To facilitate the passage of water downward, care should be taken that the surface of these beds has not become clogged through too constant and continuous use.

A description of the Kremer apparatus, providing a method to remove the grease which the sewage to be treated contains, is also given.

Prof. Gillespie gives some very interesting descriptions of typical plants, including Bergedorf, near Hambourg; Essen-Nord; Atlanta, Ga.; Schenectady, and others. A section of the paper is devoted to a discussion of Dr. Imhoff's patents in the United States and Canada, and another to the reception in America of clarification tanks of the Emscher type. In concluding his remarks thereon, the writer states:—

"When it is considered that the Emscher tank has been tried out for seven years in Europe and for three years in America, it is safe to say that it is well past the experimental stage. The history of its operation on these two continents, and the testimony of engineers who have studied it at close range, constitute its vindication. The list of municipalities which have either installed or prorose to install it in America, furnishes additional evidence as to its reception on this side of the Atlantic. While it does not represent a method of disposal complete in itself except in special instances; while it is not easy to construct, is not fool-proof in its operation, and is not either initially or afterwards the least expensive of the appliances from which the engineer may choose, it offers, in the opinion of the writer, the most satisfactory solution for the troublesome sludge problem which up to the present has been proposed."

His paper closes with a list of places in America in which the 2-story sedimentation tank has been or is to be installed. From his list we extract the following as a list of installations in Ontario: Barry Tannery, Bowmanville, Carleton Place, Copper Cliff, Cornwall, Dundas, Guelph Prison Farm, Hamilton, Leaside, New Liskeard, North Toronto, Oakville, Peterborough, Port Arthur, Rockwood Asylum (Kingston), Simcoe, Stratford, Toronto, Vankleek Hill, Vineland Canning Co. (Vineland), Weston, Whitby, Whitby Hospital for the Insane.

The other Canadian installations are: in Saskatchewan, Battleford, Canora, Humboldt, Regina Jail, Saskatoon, Kamsack, Estevan and Battleford hospital; in Alberta, Calgary and Edmonton; in British Columbia, Kelowna and Vernon.

ECONOMICS OF ELECTRIC RAILWAY DISTRIBUTION.*

By Horace Field Parshall, D.Sc.

PRACTICALLY all modern traction systems of the larger class are referable to the same class of power house and transmission system, and these are not affected to any important extent by the sub-station arrangement, which is determined with reference to variations in the operating result occasioned by the spacing of the capacity of the individual sub-stations.

In the book by Mr. Hobart and the author on "Electric Railway Engineering," most of the problems entering into the design of electric railway installations have been dealt with. The question of the economic arrangement of sub-stations and the distribution conductors was not dealt with at length, because at the time the book was written sufficient operating data were not available to furnish a basis for different calculations. Such a wide difference of opinion existed between different engineers as to the cost of operating and maintaining a system of sub-stations that it did not appear advisable to treat the subject except on general lines. Since the publication of that book a great deal of experience has been gained, as a result of which engineers have come into more general agreement as regards sub-station practice. The present paper is written with a view to assist towards the standardization of electric railway sub-station practice. Many years ago Lord Kelvin formulated a law as to the economic use of conductors in transmission systems. The number of independent variables when a complete system with sub-stations has to be dealt with is so great that the mathematical expression, from which might be deduced the minimum cost, would in practice be open to some suspicion. In this paper a complete balance-sheet embodying every item has been worked out for each case, and the tabulated result is included as a part of the paper; hence, for different conditions it would be possible for an engineer to make the necessary corrections, so that, without any great amount of labor, the methods and results of the paper may be applied to practically any class of electric railway installation. The paper has not been extended to include the electric traction installation as a whole, since the process of standardization in respect of motor equipments is still proceeding, and conclusions that might be drawn under present conditions would in another short time be incorrect. So far as the distribution is concerned, the conclusions are likely to be lasting, since the operating conditions on which the general results are founded are likely to obtain for a considerable time to come.

With the given energy-consumption per unit of length of line that follows from a given train-movement, the capacity of the substances increases indirectly with the distance between them. The energy-loss in distribution-conductors of a given section varies with the cube of the distance between sub-stations. The cost of attendance is within wide limits independent of the size of the sub-station. The cost of the plant per kilowatt falls off with the size of the units, but the maintenance and renewals per kilowatt are more or less constant. The paper embodies a series of curves showing graphically the arrangements of substations that will operate different train services on different electrical systems and at various voltages with a minimum total operating cost. With rotary-converter sub-stations and a working voltage of 600 volts, and for certain assumed average conditions of train-weight, speed, and energy-consumption, the most economical sub-station spacings are 8½, 5½ and 3¼ miles for train services of 6, 12 and 24 trains per hour respectively. For a working voltage of 1,200 volts the sub-station spacings are 11, 7½ and 5 miles respectively, while when 2,400 volts is adopted the most economical sub-station spacings are 16, 12 and 8½ miles for the three train services respectively. Curves are also given illustrating the advantage gained by working at higher voltages, and these confirm the author's view that with the present arrangement of rotary-converter sub-stations, there is little advantage in a higher voltage than 2,400 volts for the track conductor. The economy of higher voltages is shown to be approximately the same whatever the train service. As between 600 and 1,200 there is a saving of 14 per cent. in the total annual costs of the distribution system; as between 1,200 and 2,400 volts there is a further saving of 7 per cent., or 21 per cent. as between 600 and 2,400 volts. If the working voltage is further increased to 3,600 volts, there is a decrease in total annual expenditure on sub-station and overhead conductor equipment of only 3 per cent., which will be less than the additional cost of the rolling stock.

For single-phase distribution at 5,000 volts the most economical sub-station spacings are 31, 24 and 16 miles for train services of two, three and six trains per hour respectively. At 10,000 volts single-phase, the most economical sub-station spacings are 45, 34 and 26 miles for the same three train services respectively. With three-phase distribution at 5,000 volts the most economical distances between sub-stations are 38, 31 and 18 miles for the same respective train services. In most of these last cases, however, the economical distance between sub-stations thus determined is greater than would be permissible in practice from considerations of both traffic operation and voltage drop. Further, in the case of single-phase operation, the lower pressure of 5,000 volts is found to be the most economical for certain services and the higher pressures of 10,000, 12,000 and 15,000 volts in vogue on the continent are explained by considerations of voltage drop.

*Abstract of a paper read at a meeting of the Institution of Civil Engineers of Great Britain, Nov. 17, 1914.

POWER SURVEY OF CANADA.

The Commission of Conservation is compiling data respecting power used in the Dominion. A circular has been issued to power users and manufacturers requesting information regarding the consumption of power. The questions asked cover the field fully, embracing water power, electric power, steam power, gas engines, and oil engines, and each division solicits answers which, if given with any degree of enthusiastic co-operation, should place the Commission in the position of being able to compile information that will be found of great value by Canadian engineers and manufacturers. It is to be hoped that those to whom blanks have been sent will furnish the fullest possible information and that any of our readers who may not have been approached by the Commission, will apply for a blank to the Assistant to Chairman, Commission of Conservation, Ottawa. The compilation entitled "Waterworks of Canada," published in December, 1912, has proved of signal value, and it is to be expected that the data which the Commission has now set itself the task of collecting, will have an even greater field of usefulness throughout the country.

CONCRETE CONSTRUCTION AT CEDARS RAPIDS, QUEBEC.

ON December 17th the Canadian Society of Civil Engineers will have under discussion at its general meeting the paper read at a former meeting (October 22nd, 1914) by Mr. John E. Conzelman, chief engineer of the Unit Construction Co., Montreal. This paper had to do with the system of unit concrete construction employed in the erection of the power house and transformer stations of the newly completed hydro-electric plant of the Cedar's Rapids Manufacturing and Power Co. *The Canadian Engineer* has presented, in previous articles, the general details of design and construction of this development, and we abstract herewith some notes on the above method of construction, from Mr. Conzelman's paper, believing it to be one conducive to some very interesting and valuable discussion.

For the essentials of the layout our readers are referred to issues of this journal for January 1st, 1914, and July 9th, 1914. It will be remembered that the superstructure of the power house is built over the dam and that it is of structural steel frame construction with reinforced concrete floors, walls and roof. It was originally intended to construct the walls of brick, but unfavorable transportation facilities, etc., effected a change in the plan, the result being a decision to use concrete throughout.

The power house is about 643 ft. long x 125 ft. wide, with 35 bays 16 ft. 8 in. long and 3 special bays 18 ft. 4 in. long. Fig. 1 shows the typical section. The exterior walls are 12 in. thick, consisting of two independent 4-in. concrete slabs with a 4-in. air space between. The steel columns were provided with slots to receive the slabs (which were lowered down from the tops of the columns) and after two opposite slabs had been set, they were held apart by a piece of one-inch plank which fitted into notches in the slabs. This board also served as a form for the grout which was poured into the space between the column and the slabs. The purpose of this grout is to hold the slabs in place and also to protect the columns against corrosion. The construction is shown in Fig. 2.

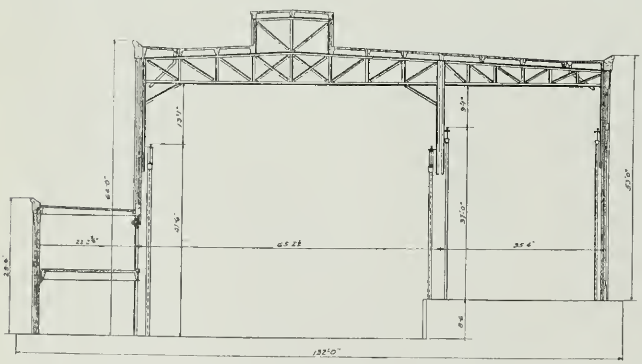

Fig. 1.—Section Through Power House, Cedars Rapids, Quebec.

Fig. 1 shows the form of roof construction. The roof units consist of a reinforced concrete plate 3 in. thick cast integral with the beams, which are carried around the four sides. The units are 16 ft. 6½ in. long and 16 in. deep over all. The entire unit acts as a beam between trusses; the reinforcement in the beams acting as the tension flange and the entire slab providing compressive strength. A uniform distribution of load on the trusses is assured by the stiff end beams of the units, and the mortar bed upon which the units are set. The roof units are so dimensioned that a space one and a half inches wide is left between the ends and over the centre line of the trusses. These spaces, as well as the spaces between the slabs themselves, are filled with grout. Reinforcing

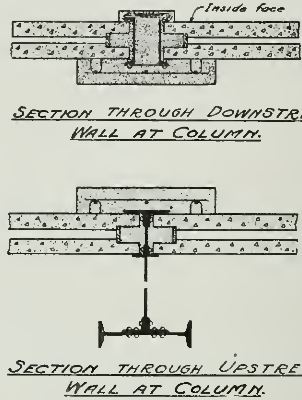

Fig. 2.

bars 3 ft. long are placed in the space between the units and extending over the trusses. These fars form an effective tie after the grout has hardened. Concrete saddles were formed on the roof for the purpose of directing the water to the downspouts. The roof covering is 4-ply Barrett specification material mopped directly to the concrete.

The steel work was erected by the Phœnix Bridge and Iron Works Co., Montreal. The roof trusses are designed to carry a load of 100 lbs. per sq. ft., and the crane girders and main aisle columns are designed to carry two electrically operated travelling cranes of 150 tons capacity. The high columns were spliced at the level of the crane girders. All connections, except the butt joint between the ends of the crane girders, were riveted. One expansion joint was provided.

Erection of structural steel and concrete units was done by means of a structural steel stiff-leg derrick mounted on a triangular steel tower 60 ft. in height with an 80-ft. boom. The weight of the heaviest steel member was about 5¾ tons and of the heaviest concrete unit, 8 tons. Each unit was provided with lifting hooks or bent steel bars for the purpose.

The reinforced concrete transformer house is a 4-story building with basement, and is supported on spread footings with concrete curtain walls. The foundations rest on hard clay about 7 ft. below grade, and each footing carries a load of approximately 4,000 lbs. per sq. ft. Fig. 3 is a typical section. The building is 228 ft. long and 88 ft. wide. It comprises 10 bays 20 ft. long and 4 bays 7 ft. long. A special column spacing was necessary as the transformers are arranged in groups of three. Instead of the typical spacing of 20 ft. and 7 ft., as noted above,

a length of 47 ft. was divided into three equal spaces of 15 ft. 8 in. Above the third floor typical spacing was used.

Heavy construction was used in the ground floor to support transformers estimated to weigh 75 tons, together with handling equipment necessary for their installation. The upper floors were designed for a live load of 250 lbs. per sq. ft., except where special loadings occur. The roof is designed for a load of 100 lbs. per sq. ft.

In this building the exterior walls are of concrete slabs 10 in. thick with a 2-in. air space, formed by means of a sand-core which was washed out before the unit was set. The basement walls are 12 in. thick and of reinforced concrete.

The concrete units were brought to the building on flat cars from the unit yard located some distance from the site. The casting yard was provided with a track about 400 ft. long down the centre from which a locomotive crane with a 50-ft. boom handled distributing buckets of controllable discharge type to forms disposed on each side of the track for a width of 50 ft. The effective area of the casting yard was 36,000 square feet.

There are 3,916 units in the power house and 1,602 in the transformer house, the total amount of concrete being 6,111 cu. yd.

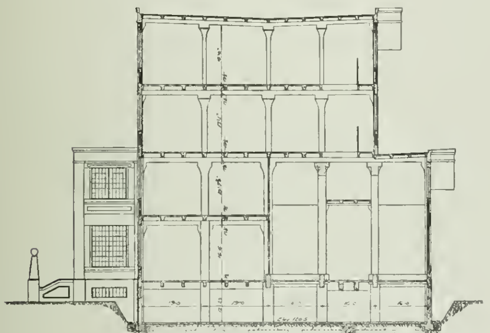

Fig. 3.—Section Through Transformer House.

In his paper Mr. Conzelman presents some very interesting information respecting details of unit construction and laboratory tests covering them. In closing he claims as a chief advantage for the method the fact that the units may be made under what may be called factory conditions. The forms can be strongly built and carefully bedded. The system provides for easy inspection and test, if desired, before incorporation into the intended structure. The reinforcement is easily held into proper position. There is also more certainty, according to the writer, in a unit design as the loads are carried by a definite system of units, and the joints occur exactly where a designer wants them. Although unit methods are not advisable for all reinforced concrete structures, they were recommended by Mr. Conzelman for those consisting of a series of similar bays involving considerable duplication of parts. Again, as in the case of the Cedars Rapids power house, it is often advantageous to cast the units sometimes before foundation is ready to receive the superstructure.

At the recent convention in Jacksonville, Fla., of the American Public Health Association, the convention city for 1915 was chosen to be Rochester, N.Y.

ENGINEERS FROM THE CONTRACTOR'S VIEWPOINT.

IN an address delivered to the Albany Society of Civil Engineers, Mr. Richard W. Sherman, chief engineer of the New York State Conservation Commission, notes the impossibility of complete harmony existing always between engineers and contractors, and attributes this to the fact that they represent opposing interests in a considerable degree. The engineering graduate starts with an educated prejudice against contractors, whom he believes to be, in the main, determined to get the best of engineers, and therefore he is on his guard and purposes not only to take care of himself but to get the best of the contractors.

Contractors dread the "boy engineer" just from college. These young engineers are extremely technical. They expect a literal compliance with every iota of the contract obligations by the contractor.

With rare exceptions, men greatly improve in learning, wisdom and disposition as they grow older. After 20 or 30 years, a man is surprised to find how little he knew when he started his professional or business career. He has grown in riper judgment, and has developed greater caution, discretion and justice toward others. He grows considerate, amiable and kind.

Contractors are largely influenced by their opinions of engineers. The engineer who has a reputation for ability, honesty, fairness and good disposition will attract bidders for any work of which he has charge and the desire to do work under him would be an incentive to reasonably low prices. It is a feature of contracting to "size-up" the engineer with as much accuracy as possible.

In bidding for work, contractors are almost as sensitive as weathervanes. It may be possible to make a profit at a given bid under one engineer and impossible to avoid a loss under some other engineer, with all other conditions similar and the quality and the merits of the work constructed being equally good at the same cost to the owner in each case.

A majority of bids are too high. The highest bid is often twice as much as the lowest even when the lowest is sufficient. Over-anxiety to secure the contract is the commonest cause of low bidding. Low bids are often made to keep a contractor's organization together for future work on which he hopes for better prices.

Contractors who do not care for the contract often bid fairly high up, without any expectation of securing the contract but merely to avoid a reputation among contractors of being low bidders, and with the bare chance of getting the work at good prices. Excessively high bids are usually the result of lack of knowledge of the value of the work and lack of time to become familiar with it.

If an engineer's preliminary estimate is believed to be too low, it drives away bidders and tends to indifferent, high bidding. Some over-anxious contractors may be influenced thereby to bid too low. They may secure the work, in which event the engineer has an unpleasant task during construction. There is almost sure to be a disposition on the part of the contractor to save himself from loss and he is thus tempted to slight the quality of the work. Both contractor and engineer are in some degree injured by the work having been done at less than cost.

An engineer who can make reliable preliminary estimates will find his services in demand by municipalities, corporations and other owners, or if he chooses to practice as a contractor's engineer, he will find his services of

great value in that field. Some prominent engineers of my acquaintance would not under any circumstances do engineering work for contractors, confining their services entirely to the owners. I know of other engineers who confine themselves wholly to engineering for contractors and who do a large business as engineering experts for contractors, in litigations.

These two fields of engineering are becoming more and more distinct and it is my opinion that an engineer is wise who makes his choice and adheres strictly either to the one line of practice or to the other.

The contracts and specifications on very large and important works usually are models of perfection. In smaller works, such as may amount to, say, not over $200,000, contractors are often confronted with bidding papers, contracts, specifications, plans, etc., which are a disgrace to the engineer who drew them.

There are a few engineers who are sometimes called "specification fiends." They write to many places, where work is advertised, for specifications, etc. They read them eagerly and often clip such paragraphs as catch their fancy—usually those which are harsh, severe and unreasonable from a contractor's standpoint. With these clippings to aid them, they draw up specifications, etc., which often deserve the name of "crazy-quilt" specifications.

Such papers are full of contradictions, useless paragraphs and ambiguities which are almost sure to cause contention and trouble during construction and in the final settlement, or lead to litigation. Such engineers are apt to insert severe conditions such as excessive cash deposits with the bids, unreasonably short time in which to construct the work, excessive per diem liquidated damages for overtime, excessive bonds and sometimes excessive retained percentage where monthly payments are provided. About all they can think of is to make the work undesirable and objectionable to contractors. Such engineers and their work are often avoided by the best class of bidders and the contracts are apt to go to rather undesirable contractors.

PROGRESS ON QUEBEC BRIDGE.

At the annual meeting of the Dominion Bridge Co. held last week it was stated that on December 1st about 42 per cent. of the steel for the superstructure of the new Quebec bridge had been fabricated, and about 18 per cent. erected. It is anticipated that the work will be finished in good season, and within the original estimates of cost.

INVESTIGATIONS OF EXPLOSIVES USED IN COAL MINING.

The United States Bureau of Mines have carried on a number of investigations into the nature of the explosives used in mining operations, with a view to changing the character of explosives so as to meet the needs of the various branches of mining, and especially to increase safety in coal mines. Both the improper use of explosives and the use of improper explosives have resulted in coal-mine disasters. The investigation of explosives is also important to metal miners, whose health and efficiency are seriously affected by the use of improper explosives, but the bureau has not yet had the facilities for taking up a thorough investigation into this latter phase of the subject.

THE STRIPPING, QUARRYING AND MINING OF GYPSUM.*

THE methods employed in the exploitation of gypsum deposits are generally of the simplest. The operations consist of stripping, quarrying or mining, and transportation. There are, however, several important points that have to be taken into consideration when opening up a quarry, which, if not considered, would be liable to seriously handicap an operator in competition with his neighbor. A deposit of gypsum may be everything that is desired in the way of quality and extent, but still may not be capable of being worked economically on account of its distance from shipping facilities, ready market, and also its heavy overburden. Its location also with respect to the drainage of the surrounding country may necessitate a heavy expense in keeping a quarry free from water, so that this factor has in some cases to be taken into account. Another factor that influences the operation of a quarry is the availability of a steady supply of labor. When steady labor is obtainable, better work can naturally be accomplished, and new and improved methods can more readily be taught the quarrymen when they are working continuously instead of spasmodically.

Methods of Stripping.—The amount of overburden resting on the gypsum beds which it is desired to exploit, has a great bearing on both the method of operating the quarry and its successful development. Where there is a rock covering over the gypsum and also a deposit of drift material, the stripping of the deposit is out of the question, and mining methods are employed, but where the overburden consists of only soft material, it is generally more economical to remove this overburden and to extract the gypsum by open quarrying. In order to remove this material, great expense has to be entailed, it costing at the present time from 20 to 25 cents per cu. yd. to remove such material. When operations are undertaken on a sufficiently large scale to warrant the use of a steam shovel, the cost of stripping is between 15 and 20 cents, but where only a small quarry is to be opened, and the stripping has to be done by hand, the operator has to consider very carefully what depth of an overburden he can reasonably afford to remove, as in many cases the cost would be so excessive that a quarry could not possibly be worked at a profit.

The methods of stripping usually employed in gypsum practice are: Hand, horse scrapers, and steam shovel.

It is only in very small quarries, or where the material to be stripped is very light, that the work is done by hand. The work has naturally to be carried on during the summer months, as the frost would make the price during the winter months prohibitive. When the dirt is removed by hand, it is shovelled into carts and hauled to the nearest dumping ground, or else it is allowed to cave into the quarry and then sorted from the gypsum and carted away. This latter practice is greatly to be condemned, as the loose waste cannot help getting mixed with some of the white rock, impairing its value for plaster manufacture. It is a practice that is, however, very prevalent, even among some of the larger operators, and is only due to the fact that the Canadian gypsum is of such a high grade that no notice has so far been taken of it.

*From "Gypsum in Canada," prepared by L. H Cole for the Department of Mines.

The horse scraper method has been employed successfully in the deposits in northern Manitoba to remove overburden. These horse scrapers are similar to those used by railway contractors in railway construction work. The nature of the deposits there lends itself admirably to this mode of operation. The surface covering in these northern deposits consists of about 3 feet of clay and loam, loosely cemented together by gypsum, and this material readily breaks up before the scraper, and can then be hauled and dumped into any of the numerous sinkholes which are scattered through all the deposits. This has proved a very satisfactory method for the removal and disposal of the waste material.

In the larger quarries, the steam shovel is gradually coming into use for the removal of the waste material which lies on top of the gypsum. Only in late years, however, have these appliances been employed to any extent. Where the overburden is of any great thickness, the waste material is removed in benches by the steam shovel working on the top of the deposit. In that case a track is generally laid alongside the shovel, and the shovel loads directly into cars, which can then be hauled to wherever the best dumping ground is available. This method proves satisfactory to a certain extent, but considerable material is allowed to fall into the quarry, there to be removed by hand, or else by a second shovel. A second method, sometimes employed, is to remove the overburden over a bench of gypsum, to operate the shovel on top of this bench, and then clean off this bench by hand and carts. This method leaves the greater portion of the gypsum free from danger of being mixed with the waste material.

Hydraulic Stripping.—In many of the gypsum deposits of Nova Scotia and New Brunswick the overburden which rests on the gypsum is of considerable thickness. The present method of removing this waste material is, as already stated, by hand labor, horse scraper, or steam shovels, and this entails a great expense, and in many cases materially reduces the small margin of profit upon which the quarries are operated, or actually causes their shutting down. As this overburden is in all cases composed of loose material, it would seem that stripping of the gypsum beds by the hydraulic method would not only, in many of the quarries, be feasible, but would also greatly reduce the time required and the cost in handling. In order to bring this matter to the attention of the gypsum operators throughout the country, Mr. Cole inserts the following notes on hydraulic methods in his report:

Conditions Required.—Unlike the methods required and employed by most of the large hydraulicking companies of the west, hydraulic methods, when used for the purpose of removing the surface coverings to enable the rock underneath to be mined or excavated, have to be greatly modified to meet the altered conditions. In the first place, the wash from the monitors does not have to be saved, and hence the material can be conveyed in sluices greatly simplified from those which have to be prepared for the gold-bearing gravels. The shortest and most convenient form of sluice leading directly to the dumping ground will answer the purpose, regardless of slope (or grade) or curves.

Then, again, in most cases, when used for the stripping of gypsum, the nozzle pressure of the water would have to be obtained by means of a high pressure pump of large horse-power, and although this would be the greatest expense of the whole installation, it would do away with an extensive and expensive flume or pipe line, as the contour of the country is not such as to enable a high head of water being obtained except by this means.

The supply of water required would be one of the greatest factors in the installation, but this, in most cases, could be overcome by using the water over and over again.

The matter of a dumping ground for the waste material would be one of considerable difficulty, especially where the material was to be sluiced directly to it, but if no convenient place were available for direct sluicing, the waste material could be readily handled by a pipe line and a relay of centrifugal pumps, which would place it in any of the old abandoned quarries nearby.

In phosphate mining in Florida, hydraulic stripping is being employed to great advantage, at a cost of from 5 to 8 cents per cu. yd. of material moved. In the same district, where steam shovels are employed, the cost is 20 cents per cu. yd.

A modified form of hydraulic stripping is being made use of by the Nipissing Mining Co., of Cobalt, Ont. There it is employed to wash the surface covering of drift from the rock, in order to examine the rock closely for the small veins which sometimes would be overlooked by ordinary trenching. A turbine pump is employed, guaranteed to throw 4,800 gallons of water per minute, under a head of 415 ft., through a 3½-in. nozzle. The pumping plant consists of a 675-h.p. turbine pump connected directly to a motor. The water is piped to the point required, and is there forced through a 3½-in. nozzle at high pressure. A space is first cleared by this means, after which the ground is sluiced down in benches, thus, as soon as a certain section has been examined, it is covered over again with the tailings from the section above. The ground slopes gradually towards Cobalt Lake and the water drains back again into the lake from which it is pumped in the first place.

The application of hydraulic stripping to gypsum overburdens is very simple. The water is obtained from the nearest and most constant source of supply and is forced through a pipe line by an approved form of pump, so that a pressure of from 90 to 150 lbs. per sq. in. is obtained at the nozzle of the monitor. A nozzle which delivers a stream of water at the required pressure is placed conveniently near the overburden to be removed, and the stream playing on the soft drift soon disintegrates it and it is then sluiced away by the running water to the dumping ground. If no dumping area is available near at hand, the sump method can be employed, where a sump is made in the floor of the quarry at a convenient spot and the waste material all washed into it. A series of centrifugal pumps and a pipe line are easily installed to keep the sump empty and remove its contents to the nearest permanent refuse pump.

Installation Required.—The following list will cover practically all the machinery and material required for stripping by the hydraulic method: (1) Pumps (*a*) high pressure pump, (*b*) centrifugal relay pumps; (2) pipe lines (*a*) mainpipe line, (*b*) discharge pipe line; (3) monitor (nozzle); (4) sluices; (5) special ball and socket joint, etc.; (6) operating motors and power.

In Mr. J. A. Barr's article on Florida phosphate practice (M. and M., Dec., 1912, p. 265) he gives the following paragraph descriptive of the present practice in pumping machinery in Florida for this type of work:

"The earlier and present universal practice is to use direct acting compound or triple expansion pumps for furnishing water to the hydraulic nozzles at the mines and to the washer. The Florida Mining Co. has a triple ex-

pansion pump capable of furnishing 4,000 gallons of water per minute, which it delivers at a pressure of 150 pounds per square inch. The Prairie Pebble Co. uses a somewhat similar pump made by the Worthington Co. Their pumping plant consists of three triple expansion, duplex, direct acting pumps, size 12 in. x 19 in. and 30 in. x 17 in. x 24 in. These pumps have a capacity of 2,800 gallons per minute each.

"The only centrifugal pumping plant that supplies water to the pipe nozzles is installed by the new French company. This company uses a three-stage turbine pump, direct connected to a 250 horse-power induction motor, and it delivers water to the nozzles at a pressure of 140 pounds per square inch. The experience with this pump in the field has been that when new, it was very satisfactory, but when pumping gritty water, such as must be the case in most of the mines, the pump lining soon wears, and the pump has a low efficiency.

"The newest pumping stations being built contain the Corliss flywheel condenser pump. The principal advantage of this pump for this kind of work over the direct acting pump is principally its high duty, which often is at least one-third more. The duty of the direct acting pump seldom goes over 90,000,000 gallons, while that of the Corliss flywheel pump approximates 120,000,000 gallons in 24 hours. The flywheel pump is less liable to become broken by the failure of the governor to act, or by bursting of the pipe line."

Where the waste has to be transferred from a sump to a dumping ground at a distance, the pumps employed are generally centrifugal pumps of an approved type. To obviate the trouble always encountered when two or three of these pumps are operated in tandem, the best practice is now to make each pump in the relay act independently by delivering into a series of sumps from which the following pump draws its supply.

Pipe Lines.—For the pipe line for the delivery of the water to the nozzles, a 10-in. steel spiral pipe is being employed, and this has been found to work very satisfactorily. There is, however, no reason why other styles of piping could not be used. For the last few hundred feet of piping before the nozzle is reached, a 6-in. flanged, spiral riveted, galvanized water pipe is employed.

When the pipe line is used for removing the waste material from the sump, any approved kind of piping that will stand the wear and tear of gravel, etc., passing through it, can be employed.

Nozzles.—Any of the smaller types of hydraulic monitors that are in use in gold hydraulicking methods can be employed in stripping. From 3½ in. to 4½ in. in size would suit.

Sluices.—The sluices for hydraulic stripping can be of the simplest type, and in many cases no sluice is required at all, as the natural gullies in the rock will be sufficient to carry the waste material to the required dumping ground. Generally small trenches are dug, or else temporary sluices are built which very well answer the purpose.

Special Ball and Socket Joints, etc.—In order to facilitate the easy moving and handling of the monitor from place to place, a special form of ball and socket joint is generally employed in the 6-in. pipe. Several of these are placed in a length of from 400 to 500 ft., and this gives the nozzle sufficient play so as to cover a large territory. Several other special attachments are required, such as a joint to keep the pump from being broken by water hammer, and special suction pipes, etc.

Power and Motors.—The question of power for operating the pumps is a matter of considerable interest. In many of the properties electric power could readily be generated, and current delivered to the motors, which are directly connected to the pumps. Where coal is cheap, steam could be used for generating this power. In some localities, water power could be obtained.

Quarrying or Mining.—The consideration of the best means of the exploitation of gypsum is a matter which up to the present time has not been a serious factor in the development of a deposit. In the maritime provinces, and also in the west, the largest deposits of gypsum are all comparatively near the surface, with only a covering of loose material which can easily be removed, but which would not hold up if undermined. Consequently the only method in most cases is to remove the gypsum by open quarries. This method has a number of advantages over underground mining, which have been greatly to the benefit of the gypsum operators. These advantages may be stated as follows:

(1) Easier supervision. A better idea can be obtained of the class of material that is being quarried.

(2) Better ventilation, as the men are always working in the open air.

(3) Easier handling of the gypsum.

(4) No timbering is necessary, and all the material can be extracted, as no pillars have to be left.

Its disadvantages are few, the principal one being the exposure to all the different kinds of weather, thus hindering the work, and the danger of exposure of the men to heavy rain, snow, or extreme cold.

Quarry Work.—As a rule most of the quarries operating in gypsum have no regular shape, and nowhere does any systematic method seem to have been employed. It has generally been a case of taking the gypsum from wherever it occurred, without any regard to future economy in working. In consequence many of the quarries are just a series of pot holes, with no two parts of the quarries alike. Thus much time is lost by the repeated handling of the gypsum, when in many cases one handling would be sufficient.

The present practice is to obtain as high a face as possible of clean gypsum, and to break it down by caving. This is accomplished by drilling the lower part of the face with auger and hand-power drills, and then blasting the holes with a low-power dynamite, generally about 40 per cent. strength. This brings down a large tonnage of gypsum, which is then broken up by hand sledgehammers to a convenient size for handling. The broken material is hand picked, so as to remove any pieces of anhydrite or foreign matter, and is loaded into small cars or dump carts and hauled either to the mill or wharf direct, or else where there is a railway line, to the nearest siding, where it is dumped into the railway cars.

In the gypsum deposits of northern Manitoba, a steam shovel is being employed successfully to handle the gypsum, thus doing away with the excessive handling which is so frequently met with in gypsum practice throughout the country. After the surface is stripped, the gypsum, which is of a soft variety, is drilled by a series of vertical holes placed regularly at 8-ft. intervals across the working face of the deposit. These holes, when blasted, shatter the gypsum sufficiently so that it can be handled by the steam shovel directly into the standard railway cars, standing on a siding beside the shovel. This method is found to be cheap and economical, and enables a large tonnage to be got out in a very short time.

In all of the gypsum quarries in Canada, the drilling is accomplished by hand power, one-man auger drills, similar to those employed in coal mining practice. They are found to work very successfully, as the gypsum is soft and drills easily. No attempt seems to have been made to install power drills of any sort.

Mining Methods.—Where the overburden is excessive, and consists of a rock capping over the gypsum beds, the deposits are generally operated by underground methods. On account of the small price obtainable for the gypsum, the simplest and cheapest methods have to be employed. The present practice in Canada in gypsum mines seems to be to open up the deposit by an incline tunnel, generally at a slope of 15° to 20°. Why this special method of entrance has been adopted in preference to a vertical shaft is not clear. In the earliest gypsum operations in the country, the deposits were opened up in this manner, and the custom has been to follow the example of these first attempts.

When the bed of gypsum has been reached, main haulage ways are laid out, and the gypsum is recovered by a room and pillar system similar to that employed in coal mines. Tracks are laid to the face in these chambers, and the broken gypsum is loaded directly into cars, which are then taken by hand, or horses, to the main haulage way, where they are made up into trains preparatory to being hauled up the incline by a small hoist. Considerable loss is caused by the fact that the pillars in most cases are composed of good gypsum, which would otherwise be recovered.

Transportation. — Transportation facilities in the quarries are of the simplest nature. In most of the operating quarries in the east, the broken gypsum is loaded by hand into single horse Scotch carts, and taken by them either to the shipping pier, or to the nearest railway siding. This necessitates a great deal of extra and useless handling of the rock before it reaches its final destination. Much time and labor might be saved if a system of radiating tracks were laid through the quarry, and the cars loaded directly at the face.

The method of transporting the loaded material from the quarry to the mill or shipping pier, is, in most cases, by narrow gauge railways, and this affords easy and cheap handling.

Drainage.—Gypsum quarries, as a rule, are seldom troubled with water, but in some places, especially where the level of the floor of the quarry is near the level of the water table of the surrounding country, the problem of handling the water has to be taken into consideration. In this case a sump is located in the lowest part of the quarry, into which all the water collects, and a small duplex pump, generally stationed somewhere well protected from the blasting, is sufficient, being operated only a few hours each day, to handle all the drainage from the whole quarry. In cases where the quarry is below the drainage level of the surrounding country a larger pumping plant has to be installed.

DRILLING HARD STEEL.

To drill a hard piece of steel without having clearance wear off the lip of the drill, which necessitates repeated grindings, hold the drill firmly in a vise and with a light hammer strike the face or cutting edge at the outer corners, raising a light burr. This makes the drill cut enough over size for easy clearance, and it is surprising how much wear it stands. It is much better than grinding off centre, and is especially handy in drilling small dies.

THE MECHANICAL ELIMINATION OF SEAMS IN STEEL RAILS.*

By Robert W. Hunt,
President, Robert W. Hunt & Co., Chicago, Ill.

THE increased weight of rolling stock and speed of traffic has necessitated increasing the size of the rail sections, and hence their weight; as many of the details of rail manufacture have been changed with such alterations, it is not surprising that new and unexpected physical weaknesses have developed in the heavier rails. One of the most notable has been the failure through crescent-shaped pieces breaking out of the rail flanges, followed by at least one, and in many cases several, ruptures across the whole section of the rail. Investigation has showed that in practically every instance of such failure there was a more or less pronounced seam running longitudinally in the bottom of the rail near its centre, and thus immediately under its web. This seam occurs at the top of the curve of the crescent-shaped break and is undoubtedly the point at which the fracture starts.

Those familiar with steel rail making have known that it was practically impossible to make rails entirely free from seams, and that as the seamy conditions of the steel forming the head of the rail increased, its wearing quality would decrease, but I think it was not until the disastrous experiences with the "moon-shaped" failures that the danger from seams in the base of the rails was fully realized. It is true that rails with actual flaws in their flanges have been rejected as first-quality ones and that a very pronounced seamy condition of the bottom of the rail would also cause its rejection. Such rejections were the cause of frequent disputes between the mill operatives and the inspectors, the point being as to how far the inspectors were warrented in carrying their condemnation; but, as already said, it was not felt that a single seam would be dangerous unless very pronounced.

The crescent-shaped breaks were of such frequent occurrence that they indicated a very serious condition and led rail makers to experiment with the design of their rolling passes, with a view to obviating the formation of the bottom seams. It was found that fewer seams were produced by such changes, but they were not entirely eliminated. While more or less successful in preventing the formation of seams through lapping on the bottom of the rails, the formation of seams in other parts of the section was not particularly affected.

T. H. Mathias, assistant general superintendent of the Lackawanna Steel Company, determined that the most certain way of getting rid of seams was to remove that portion of the metal which contained them, and, as applied to steel rails, thus to eliminate them from both the base and head of the rail. Mr. Mathias reasoned that the primary causes of seams existed previous to any rolling of the steel, in fact, were incident to the casting of the molten metal into ingots. He knew that disk-like apertures were formed on the sides of ingots while the molten metal was being cast and were probably caused from air being entrapped against the sides of the ingot molds by the hot steel as it raised in the molds, a condition which was not controlled in regular manufacturing routine. It will be appreciated that, as the section of the ingot is reduced and elongated in the rolling process, so,

*Abstract of a paper read at the annual meeting of the American Society of Mechanical Engineers, New York, December 3, 1914.

of course, will the apertures be stretched longitudinally and thus be formed into seams.

Mr. Mathias demonstrated that there is another constant condition present in the rolling of large steel ingots, in the formation of a decarburized surface, about 5/16 in. deep on all four faces, and containing from eight to ten points lower carbon than the metal immediately under it, the decarburized envelope undoubtedly being produced through the oxidizing conditions to which ingots are subjected in the soaking pits where they are heated preparatory to rolling. A thick oxide scale is always formed on the surface of ingots in the pits, so that conditions are invariably present for the production of such a layer of lower carbon metal on their outside faces.

Mr. Mathias was convinced that during the process of rolling ingots into rails it was practical to remove mechanically the parts of the enveloping steel which would form the top of the head and bottom of the flange of the rail, and experimented accordingly. He designed and his company installed as an addition to their rail train, a milling, or hot-sawing machine, to cut off that metal without retarding the regular operation and thus interfering with the production of the mill.

The ingot is reduced in the blooming rolls to an 8-in. by 8-in. cross-section, and after cropping the ends the bloom is further reduced in the roughing or shaping stand of rolls by five passes. When it leaves these rolls, it is approximately 75 per cent. finished and at this period it is carried to the right and entered between two pinch rolls with its base or flange side up. A bar which will make four 33-ft. rails is about 60 ft. in length at this point in the rolling operation; therefore, the area of metal to be cut off or removed in the milling machine is approximately ⅛ in. deep, 7 in. wide and 60 ft. long. It is driven through the pinch rolls at a rate of 60 ft. in 30 seconds. The pinch rolls have a draft of about ⅜ in. and thus force the bar between the two milling saws, which are so arranged in the housing that they may be raised or lowered as desired. From 1/32 in. to 3/64 in. of metal is milled from the head and base of the bar, the front end of which, immediately on passing from between the rolls, is caught by a second set of pinch rolls which have a draft of about 1/16 in. These pinch rolls force the bar between the tools, pull it from between them, and also hold it in practically perfect line for the milling operation. The milling apparatus is driven electrically and requires about 600 h.p. for its operation.

As the milled dust or particles of steel are thrown out, they are hit by water under pressure which forces them into a chute and also prevents the material from adhering together. They are carried below the mill, through this chute, and are caught in boxes or receptacles suitable for charging as scrap into the open-hearth furnaces.

The milling tool is 5 ft. in diameter with an 8-in. face and revolves at a peripheral speed of 2,500 ft. per minute, thus causing an engagement of about 400,000 teeth per minute on the hot rail bar. The teeth are of 0.80 carbon steel, and it has been demonstrated that they will mill at least 30,000 tons of material without requiring dressing.

The milling on the flange does not reach the extreme edges of the bar, and on the head side does not affect the corners. Either by a modification of the shape of the piece as presented for treatment in the milling machine or, what will probably be more practical, changing the face of the tool, the milling can be extended to the extreme edge of the flange portion of the bar and somewhat around the corners of the top or head side. This will undoubtedly be perfectly practical and thereby eliminate the seams which may be located in those parts of the bar. The primary object has been to eliminate the seams from the central portion of the bottom of the rail which had been the starting point of the moon-shaped failures, and to remove them from the top or bearing surface of the head of the rail. Personally I think it will be desirable to extend the milling by the use of convex-faced tools.

The work of rolling which the steel receives after the removal of the more or less laminated metal, must produce a better product than if such elimination had not taken place, and it should not only make them less liable to breakage on account of seams in their flanges, but also enable them better to resist the abrasive effects of traffic.

During the many years of my connection with rail making I have examined a great many etched specimens of rails, not only directly in connection with the process under consideration, but for various other reasons. From such experience I can fully appreciate what Mr. Mathias has accomplished. The surfaces of practically all rails, when etched, will show some seams on both the base and head, and very frequently the extent of such defects will not be appreciable if the scale has not been removed. Even then, it is not always an easy or certain matter to estimate the depth of the seams. When the rails have been subjected to the Mathias milling operation and still show pronounced seams, it has been found that breaking tests will practically always develop the fact that the suspicious marking is an actual seam.

As the original defects on the sides of the ingots vary in extent, so will the character of the resulting seams vary, and it can be readily appreciated that some of them may have been too deep to have been completely eliminated by the milling.

While I have confined myself to the matter of steel rails, it is patent that the process will be of great value in the preparation of blooms for axles and all other kinds of forgings. As is well known, it is practically the universal custom to endeavor to remove the seams developed in rolling axle billets by chipping them out through the use of pneumatic hammers, and for some of the higher characters of forgings, notably for automobile parts, the endeavor to eliminate the seams is carried to the extent of turning off the whole surface of the billets. I am confident that by the Mathias plan the greater part, if not all, of such work can be superseded, and I regard the invention and its practical installation as a notable achievement in the art.

WORK OF THE U.S. BUREAU OF MINES.

The chief work of the U.S. Bureau of Mines during the four years since its establishment has been the investigation of problems having to do with the causes and prevention of coal-mine explosions and the safeguarding of the lives of coal miners. In addition, work has been done on the testing of coal and other mineral fuels belonging to or for use of the government of the United States. During the past fiscal year investigations were undertaken looking to greater safety and the prevention of waste in the metal-mining and miscellaneous mineral industries of the country. Recently a small amount of work has been done in an examination of several oil and gas fields of the country with a view to eliminating the large waste of natural gas in these fields. The need of such investigations may be plainly seen when it is understood that so large a part of this waste is easily preventable, that the supplies of natural gas are limited, and that the gas wasted yearly may be fairly valued at not less than $50,000,000.

ELECTRIC ARC WELDING.*

By J. H. Bryan.

ELECTRIC arc welding as a commercial process may be divided into two general classes: (1) Benardos or carbon electrode process in which the arc is drawn between the metal to be welded and a carbon electrode. (2) Slavianoff or metal electrode process in which the arc is drawn between the metal to be welded and a metal electrode.

These two processes are generally spoken of as carbon electrode and metal electrode welding respectively.

In addition to these there is the Zerener process, in which the arc is drawn between two carbon electrodes, as in the arc lamp, and the metal to be welded is placed in contact with the arc. This is, however, not considered a commercial proposition in this country, as its field of application is limited, and the apparatus itself is unwieldy.

Quoting from C. B. Auel in the "American Machinist" (1911): "In carbon electrode welding the metal to be welded is made one terminal of a direct current circuit, the other terminal being a carbon electrode. Upon closing the circuit by bringing the carbon electrode into contact with the metal and then withdrawing it to a distance, an arc is drawn between the two terminals. Through the medium of the arc, which is the hottest flame known (having a temperature between 3,500 deg. and 4,000 deg. Centigrade—6,300 deg. to 7,200 deg. Fahrenheit), the metal may be either entirely melted away, molded into a different shape or fused to another piece of metal as desired."

The metal electrode process of welding is a somewhat later development than the carbon electrode method, and differs from the latter in that a metallic electrode is substituted for the carbon.

If direct current is available from a shop or commercial circuit, welding can be done directly from this source of supply, but this method has been found to be very wasteful of power and should not be resorted to except where welding is only to be done at very infrequent intervals. An additional disadvantage of the use of the shop circuit as a source lies in the fact that, unless arrangements are made for insulating the work from ground, the shop circuit is grounded, with attendant danger to other employees in the shop, as well as to the welding operators. A much more economical method is that of using a motor generator set, the motor being constructed with characteristics suitable for operation on the shop or other circuit, and used to drive a low voltage generator. The generator may be either shunt or compound wound, the shunt wound machine being satisfactory where only one arc is to be operated, while the compound wound machine is preferable if several arcs are to be supplied from the same unit. Experience has shown that generators giving a potential of 75 volts or thereabouts will enable satisfactory results to be produced. As different welds require different strengths of current, it is at once evident that there must be some means of regulating the current supply. This is usually effected by inserting resistance in the welding circuit connecting it in series with the arc.

A suitable electrode holder must be provided for both carbon electrode and metal electrode welding. Protective equipment is necessary for the operator on account of the fact that the exposure to the rays of the arc causes an irritation and subsequent peeling of the skin if the exposure has been sufficiently long, say several minutes. The irrigation is very similar to sunburn and is uncomfortable, but no serious consequences ensue, and at the end of a few days all traces of the burn disappear.

When the carbon electrode is used, the filling material is usually of the same metal as that being worked upon and may be used in any convenient form. When metal electrodes are used for welding iron and steel they should be of best quality of soft iron or steel wire and may range in diameter from 1/8 in. to 1/4 in. The length most generally used is about 12 in. Copper, bronze and brasses with a low percentage of zinc may also be welded by this process, in which case the electrodes should be of the same material as that being welded. Where the zinc content of brasses is high, it volatilizes to such an extent as to make the work porous and brittle.

The current required for carbon electrode welding varies from a minimum of about 200 amperes to a maximum of around 700 amperes, or even more in very heavy work. In general, however, 300 or 400 amperes have been found to be sufficient for ordinary carbon electrode work.

The metal electrode process, though a considerably later development than the carbon electrode method, has a field of application very distinct in many cases from the older process. Its principal advantage is on work where it is desirable to localize the heat to the greatest extent possible, thus minimizing strains due to expansion and subsequent contraction. An example of this is in the welding of sheet metal or of a broken bridge in a flue sheet. Another advantage of this process is that it enables welding to be done in a vertical plane or even from the underside of the piece to be repaired. With the metal electrodes much lower currents are used than in the carbon electrode process. The maximum value hardly ever exceeds 150 to 175 amperes. For a greater portion of the work a current of about 100 to 130 amperes is found satisfactory, although the amount of current required will vary with the size of the electrode and the class of work being done.

The carbon electrode process is also well adapted for cutting of metals. In cutting the arc is drawn just as in welding and is played along the line to be cut, provision being made for the melted metal to run off. Very rapid work of this sort can be done, especially if heavy currents are used. The heat generated varies approximately as the square of the current so that a comparatively small increase in current will give a considerable increase in the rapidity with which work may be done.

Among the principal uses of arc welding equipment in steam railroad shops are the following: Flue welding; firebox repairs; frame repairs, and building up of worn parts. Besides these there are innumerable minor tests for the equipment.

General practice varies as regards the best method of welding flues. The time of welding will probably average 15 per hour, although as high as 25 per hour have been reported. This time is for 2-in. flues. Five-inch superheater flues are being welded at about one-fourth this rate. It is interesting to note that the flue sheet is found to be in better condition upon removal of flues than is the case where flues have not been previously welded in. This is due to the fact that the welding builds up the sheet around the flue holes to about the original thickness.

*Abstract of a paper presented before the Western Railway Club, November 17, 1914.

Closely related to flue welding is the subject of firebox repairs. The defects to be repaired include cracks in the side, flue, door and crown sheets, leaky staybolts, leaky seams, etc. Also sheets will often be found to be in such condition that repairs are impossible, and it is necessary to put in patches. All of this class of work can be done very satisfactorily by the use of the arc welding equipment. Broken locomotive frames also are very satisfactorily repaired by the use of the electric arc. One railroad (R. F. & P.) reports that it has in service at the present time 65 welded locomotive frames and has had only one failure; this failure was attributed to the fact that the arc weld was in close proximity to one made by another process.

The following figures are taken from records of actual repairs made in a large railroad shop in the middle west at various times, the figures given being a comparison between the actual cost of welding and that of putting the apparatus back into service by methods previously used, either by replacement or by repair of the old parts. The arc welding costs were based on a power cost of 51 cents per hour for the carbon electrode and 17 cents an hour for the metal electrode, together with cost of labor and an overhead charge of 40 per cent. The power costs used are slightly higher than those usually obtaining in shops of this nature:

	Cost of welding.	Cost by other methods.
Plugging 51 holes in expansion plate, holes 1 in. diam. by ⅝ in. deep...$	2.75	$ 10.15
Repairing mud ring	6.50	34.57
Cutting four 6-in. holes in tender deck sheet ½ in. thick	1.08	8.35
Welding eccentric strap, broken through neck	1.08	41.28
Repairing mud rings	6.50	24.57
Welding two spokes in driving wheel centre	7.98	99.98
Welding cracks in bulkhead in tender tank	2.33	8.00
Welding cracks in side sheets	26.15	31.79
Repairing firebox	134.89	869.58
Building up flat spots on locomotive driver	.40	225.00

No hard and fast rules can be laid down as to the size of outfit required, as no two installations will be alike in their requirements, and the matter of selection of apparatus of proper capacity is largely one of judgment and experience. In steam railroad shops installations are usually made of sufficient capacity to take care of not less than four to six operators, and the larger shops can occasionally use even greater capacities to advantage. Where a greater number of operators are to be supplied, however, it is generally found to be more economical to install additional outfits in other sections of the shop where welding is to be done, rather than to put in one large central plant. This is on account of the fact that as this work is usually more or less scattered the cost of line copper becomes an item for consideration.

Arc welding is not to be considered as a panacea for all the ills that the metal worker is heir to. There are many classes of work for which it is entirely unsuitable, but its range of usefulness is so wide that it has long since fully justified its existence.

BITUMINOUS MACADAM BY THE COLD MIXING METHOD.

SINCE 1906 the Rhode Island State Board of Public Roads has constructed a large amount of bituminous macadam by the cold mixing method. Much of it has been down sufficient time now to admit of some definite conclusions regarding the success of this type of construction. We feel that some of our readers will be interested, therefore, in the paper read by Irving W. Patterson, chief engineer of the board, at the Atlanta Road Congress, this paper giving a résumé of the work since its beginning, 8 years ago. The writer draws conclusions regarding the adaptability of the cold mixing method, based upon his experience with work of this type.

The first attempt made by the State highway authorities of Rhode Island to avoid the deficiencies characteristic of plain waterbound macadam construction by the incorporation of a bituminous binder was upon the Post Road, which is subjected to the heavy through automobile traffic between the famous shore resorts of Rhode Island and the large cities to the south and west. A traffic census upon this road taken during 1913 showed an average summer travel of approximately 600 vehicles daily, consisting very largely of motor vehicles. The construction work upon this section was carried out during midsummer of 1906.

At that time there was little reliable information concerning bituminous macadam available, so the exact methods of carrying out the work necessarily had to be decided upon more or less arbitrarily. It was decided to use a crude tar as a binder and to incorporate this material with the road metal by the cold mixing method. The mineral aggregate employed in the mix was crushed stone of sizes which were retained upon a one-half inch screen and which passed an inch and one-half screen. The stone employed was native field and wall stone, which is a rather coarse-grained, somewhat kaolinized granite. The metalled surface was constructed 14 feet wide with a crown of three-quarters of 1 inch per foot. All rolling was accomplished by means of a 10-ton, 3-wheel steam roller.

The construction in brief was as follows: Crushed stone which was retained on an inch and one-half screen and which passed through a 3-inch screen was first spread over the well rolled sub-grade, to a depth of 4 inches after compression. This course was not filled with sand or stone screenings but was well rolled. Crude tar was very lightly sprinkled over this first course of stone. Crushed stone of the sizes stated previously was then mixed with crude tar in the proportion of 15 gallons of tar per cubic yard of stone. Mixing was carried out upon a portable wooden mixing platform placed as closely as convenient to the point where the mixture was being spread. The mixture of stone and tar was spread over the first course of crushed stone to a depth of 2 inches after compression. The mixture was well rolled, after which a covering of stone screenings was applied.

No foundations and no sub-drainage were deemed necessary upon this work because of the stable character of the gravelly sub-soil encountered.

The results secured upon this first experimental section of bituminous macadam were remarkably successful. No repairs have been required to date. The surface today is perfectly intact and presents a perfect mosaic appearance, due to the top surfaces of the stones in the mixture being all in evidence.

In 1907 a much longer section of bituminous macadam was constructed. The method was almost identical

with that employed the previous year. The results secured upon the section built in 1907 were inferior to the results secured in 1906. The surface began to ravel slightly in 1912, and during that year a seal-coat of refined tar was applied. To-day the surface is somewhat irregular and a few breaks are in evidence, although the riding qualities of the road are very fair. The relatively inferior results secured from work in 1907 is attributed largely to a less stable sub-soil.

It will be noticed from the foregoing that no seal-coat was applied at the time of construction. Subsequent experiments have proved the advisability of seal-coating. The marked success of this early work in spite of the absence of a seal-coat is due largely to the character of the travel. The horse-drawn traffic over both of the above sections is very light. The blows of horses' shoes upon the exposed surfaces of the soft stones would be destructive if horse-drawn traffic occurred in any considerable amount.

In 1908 bituminous macadam by the cold mixing method was taken up to much greater extent. Various experiments both in materials and methods were carried out, and to-day it is evident that these experiments were largely negative in results produced. Many materials and combinations of materials were tried which did not give satisfaction, and no work noticeably superior to the work of 1906 and 1907 was done. Results approximating those secured in 1906 and 1907 were secured, however, upon sections constructed in the same manner as were the bituminous roads built those years. Perhaps the greatest failures in the work during 1908 were upon sections where tar products and asphalt products heated in separate kettles were used in combination as a binder for the top course of crushed stone. Where this combination of binders was employed, ravelling started the following year and increased in extent very rapidly as time went on. In 1913 a heavy seal-coat of asphalt was applied to several of the roads bound with a combination of tar and asphalt and the results secured from this treatment appear highly satisfactory.

In 1909 some very interesting experiments were carried out and these experiments produced some very positive results. It is true that there was work done in 1909 according to methods tried out in 1908 and since proved unsatisfactory, but at the date of the construction of the 1909 work it was not to be ascertained for a certainty what of the 1908 work was satisfactory and what was not, due to the short time the work had been done.

Upon the Nayatt Point Road in the town of Barrington the most interesting and valuable experiments of the year were carried out. The section of this road selected for the experiments offered excellent opportunities for experimental work because of the remarkable uniformity and excellent stability of the sub-soil encountered. Foundation troubles have not been responsible for any of the defects which have developed in any of the experimental sections. These experiments have been completed long enough now that certain definite conclusions may be drawn from them. (Mr. Patterson's paper then presents in detail the chief features of experiments carried out at Barrington in 1909. Their insertion here is precluded for want of space, and only the materials used are given. Experiment 1.—Crude tar and asphalt in mix with asphalt seal-coat; trap rock. Experiment 2.—Same, with native stone instead of trap. Experiment 3.—Refined tar in both mix and seal-coat. Experiment 4.—Asphalt in both mix and seal-coat. Experiment 5.—Refined tar with 20% asphalt in mix and seal-coat. Experiment 6.—Same, but with only 10% asphalt in both. Experiment 7.—All refined tar in both. Experiment 8.—Refined water-gas tar. Experiment 9.—Crude tar in mix, asphalt seal-coat. The paper then goes on to draw the following conclusions.)

These experiments seem to prove that certain forms of the cold mixing method are very satisfactory upon roads subjected largely to motor vehicle traffic. Only two of the sections have necessitated repairs of any account during the five years they have been laid. Both of the sections requiring repair were laid with the same combination of binders, and the much greater extent of repairs necessitated upon the section constructed of trap rock is of interest in consideration of mineral aggregates.

It was shown conclusively that a seal-coat of asphalt is much more permanent than a seal-coat of refined tar, although both the crude tar and the refined tars gave excellent results as far as their binding of the mineral aggregate is concerned. The effectiveness of refined water-gas tar is also proven. The section built of this product is superior at present to either section built of refined coal-tar.

Bituminous Macadam Subsequent to 1909.—In 1910 the typical construction employed was a mixture of crude tar and crushed stone, seal-coated with a heavy asphaltic product. This construction is identical with the construction employed in Exp. 9. The facility with which the crude tar could be handled and the good results secured with this material previously, accounted for its extended use in 1910. The results secured with this type of construction in 1910 were very successful. With one exception these roads have required only the lightest of repairs to date, the exception noted being located upon the main street of a large village and constructed of 2¼ and 1¼-inch trap rock. This road had disintegrated somewhat by the spring of 1911, and from that time on the disintegration rapidly became greater in extent. By the spring of 1913 the condition of the surface was serious. Several breaks of 10 sq. yd. or more in area appeared, and small breaks were very numerous. It was decided to patch the breaks with a mixture of ¾-inch trap rock and refined tar and to apply over the entire surface a seal-coat of asphalt covered with clean ½-inch trap rock screenings. Asphalt of approximately 15 mm. penetration was applied at the rate of ½ gal. per sq. yd. of surface and covered while hot with screenings, which were rolled with a 6-ton tandem roller as soon as possible. This work was done in June, 1913. The results of this treatment have proved very satisfactory, no further ravelling having taken place to date.

Mixing in 1910 was accomplished by the hand-mixing method upon wooden platforms.

In 1911 no appropriation for road work was made and consequently no bituminous macadam was constructed.

In 1912 an attempt was made to duplicate in effect the excellent results secured in 1906 by the use of crude tar by employing a comparatively light refined tar. It was the express intention to apply to the roads built with this refined tar a seal-coat of asphalt as soon as need for such treatment was evidenced, thereby securing eventually the same type of road which was so eminently satisfactory in 1910. Mechanical mixing was introduced for the first time in 1912. The type of mixer employed upon practically all of the work was a cube mixer of approximately one-half cubic yard capacity fitted with a heating device. The stone was not heated previous to mixing, the heating device being employed merely for the purpose of keeping the inside of the mixer warm so that it would not become

clogged. The stone employed was both local 1½-inch stone and commercial 1¼-inch trap rock. The results secured with the local stone averaged superior to the results with trap rock.

The results secured in 1912 were variable. In 1913 it was deemed necessary to seal-coat with asphalt approximately 42 per cent. of the total area of the roads constructed in 1912. During 1914 approximately 6 per cent. of the total area was seal-coated with asphalt. The roads which have not been seal-coated are in very good condition at present, but the necessity is anticipated of applying a seal-coat to all of them during the next two construction seasons. The seal-coating of the work done in 1912 has been very effective to date, but it is as yet too early to draw conclusions regarding the results of the 1912 work after seal-coating as compared with the results secured in 1910 where the seal-coat was applied at the time of construction.

During 1913 the amount of bituminous macadam constructed by the cold mixing method was small as compared with the amount constructed in 1912. Two methods were employed. The type of construction employed in 1910 was taken up to some extent with a refined tar in place of a crude tar—a seal-coat of asphalt being applied at the time of construction in exactly the same manner. An asphalt of characteristics similar to the asphalt employed upon Exp. 4 was used to some extent in both mix and seal-coat. The work by both methods has proved perfectly satisfactory to date, although the construction is so recent that definite conclusions cannot be drawn. Trap rock was employed satisfactorily in the mix for the first time during 1913. The commercial ¾-inch size of trap rock was employed in place of the commercial 1¼-inch size which was previously used, and this product has given excellent satisfaction to date.

It has been proved that the utmost care in constructing bituminous macadam by the cold mixing method is necessary. The crushed stone must be perfectly dry at the time of mixing and all stones must be perfectly covered with bitumen in order that good results may be secured. The manner of carrying out the rolling is also important in its effect upon the results obtained. It is, of course, necessary to secure by rolling as compact a mass as possible, but considerable care must be exercised in regulating the time and amount of rolling. If the weather is cool at the time of construction, the heavy rolling should be postponed until mid-day, when the maximum warmth is experienced, although the initial rolling is done as soon after the mixture is laid as possible.

The character and sizes of the crushed stone employed are also of great importance. We have secured the best results, as far as stone is concerned, with our native rock, which is rather variable in character. As a rule, this native rock is softer than trap rock and breaks with a much more irregular fracture than trap rock. There is more or less breaking of the native stone by rolling, and this appears to be beneficial rather than otherwise in that a denser pavement is secured. We feel that if trap rock is employed, smaller sizes are necessary than with a softer stone, unless there is a certainty of securing a perfect crusher-run from 1½-inch to ¼-inch or less.

We have experimented with heating the aggregate previous to mixing, but these experiments seem to show that inferior results are secured as compared with the results obtained with the same materials where the aggregate is unheated. The aggregate in bituminous macadam contains at best a large percentage of voids, and in the heated aggregate there was noted a tendency upon the part of the binder to run off from the stones, leaving only a very thin coating upon each stone. In several cases, for instance, 18 gallons of binder per cubic yard of stone were necessary to cover all stones in our unheated mineral aggregate, but when the aggregate was heated, 12 gallons would cover all stones and there would be considerable bitumen which would run through the mineral aggregate and be lost. The tendency for the bitumen to cover a heated aggregate very lightly seems to be due to the fact that the heat retained by the stones does not allow the binder to become hard for a considerable time, with the result that it continues to run for some time. We recognize that it is necessary to heat the aggregate in a dense mixture such as a bituminous concrete pavement affords, but in bituminous macadam work by the mixing method we prefer a cold aggregate or an aggregate heated but slightly.

The weather conditions influence the results obtained in bituminous macadam by the mixing method considerably. We have noticed that roads built late in the fall just before freezing sets in are not apt to be as satisfactory as those built in mid-summer, even though the temperature at the time of construction is not low. It seems to be a decided advantage to roads built by this method of construction to have a comparatively long period of warm weather immediately after construction in order that the surface may become freed from the top covering of stone screenings and well smoothed out before snow and ice appear. In Rhode Island we consider the season most favorable to this type of construction to be between the middle of May and the middle of October.

Upon the whole, the cold mixing method of constructing bituminous macadam as practiced in Rhode Island appears to be an economical pavement for motor vehicle traffic. It does not appear to the writer as suitable for heavy horse-drawn traffic or for a heavy mixed traffic. The traffic upon several of the trunk lines in Rhode Island consists of motor vehicle traffic to the extent of over 90 per cent. of the total amount of traffic, and it is upon these roads that we expect in the future to confine our bituminous macadam roads built by the cold mixing method. Through large villages where the percentage of horse-drawn traffic is large, we expect to take up a stronger method of construction.

GOVERNMENT WHARF AT REVELSTOKE, B.C.

The Department of Public Works, Ottawa, has commenced the construction of a wharf at Hall's Landing, Revelstoke. It is 30 ft. wide and 280 ft. long, and is estimated to cost $55,000. It is to be constructed of timber piles.

The Dominion Government will also spend this winter $4,500 on mattress work for the protection of the bank of the Columbia River, near the site of the wharf. The mattressing will start at the end of the wharf and extend 400 yards down the river. The work of construction will start as soon as the water has fallen sufficiently to allow of mattresses being placed.

RAILWAY CONSTRUCTION ON THE GOLD COAST OF AFRICA.

It is estimated that the extension of the Gold Coast Railway from Komfrodna to Kumasi will cost about $6,000,000. The first section, to Komfrodna, will probably be opened early next year.

A SIMPLIFIED METHOD FOR THE LOCATION OF SIDINGS.

By W. F. French in "Railway Age Gazette."

A SUPERVISOR frequently has need of a simplified method by which the curves of a siding may be laid out on the ground, either at the time the preliminary survey is made, with the object in view of showing the applicant for the siding the salient features of the location or of making notes necessary to an estimate of the grading, when a tape line layout may be the only one possible, or at a later time when the siding is about to be constructed and a transit may be unobtainable or its use inconvenient. Doubtless many cases require some instrumental work and it is then useful to know how the processes can be simplified, as the corps will generally consist of the supervisor or his assistant and a trackman or two.

It is thought that probably the greater number of cases of siding layout can be met by the use of the tape line alone. Most supervisors carry with them at all times a 5-ft. extension rule and a 50-ft. steel tape and not a few a 100-ft. length of string to correct the general line of curves. By the aid of the simple rules of geometry and with the use of the accessories mentioned, it is possible to dispose immediately of very many cases and often avoid the necessity of a subsequent visit to the location.

The matter is greatly simplified by the fact that the right-of-way line is nearly always parallel with the tracks and the building which fixes the location of the siding is also parallel. The siding, therefore, is either parallel or at right angles with the track. But even for those cases where the siding is not parallel or at right angles with a tangent main track a special solution is possible which is not unduly complicated and which can be comprehended by most maintainers of track.

It is not claimed that any new theories have been developed, but is it claimed that certain of the solutions offered are not to be found in any of the field books. Of the many which are to be found there only those have

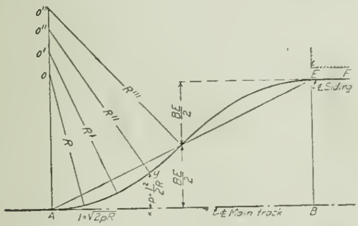

Fig. 1.—A Siding Parallel to the Tangent Main Track.

been selected which tend to simplify the supervisor's work and even to open the way for the safe handling of such problems by the brighter track foremen, not a few of whom are now entering the ranks of supervisor.

It will perhaps be thought by some that in neglecting the tangents introduced into the siding curve by the straight switch and frog accuracy is being sacrificed, but it will be found that for turnouts above No. 5 (and those below have been practically eliminated by the operation of the Safety Appliance law) no sensible error will result from this source. Stakes need not be set at either the point of switch or the point of frog, but their location should be indicated by marks on the rail and care should be taken that the half inch point of frog is always understood.

The simplest case is that of a siding parallel with a tangent main track and flanking a building, the location of which fixes the maximum offset distance. There is no practical need nor is there usually the space for introducing any tangent between the curves, but in order to render the physical conditions at the point of reverse as favorable as at the beginning and ending of the curve, it is quite advantageous to make the curves flatter at the reversing point. This may be done by using the formulae

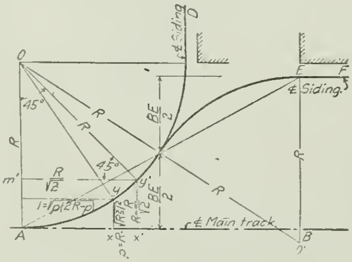

Fig. 2.—A Siding Parallel to or at Right Angles to the Tangent Main Track.

for the parabola. While this increases the length of the curve somewhat, the extension is not more than a few feet even for an extreme case.

The formulae symbolized are $p = \dfrac{l^2}{2R}$ and $l = \sqrt{2pR}$, or expressed in words signify that for a chosen distance from the point of the curve along the tangent, the offset is equal to the square to the distance divided by twice the radius, or conversely, for a chosen offset from the tangent, the linear distance is equal to the square root of the product of the offset multiplied by twice the radius. The field books employ these formulae for staking out a circular curve by offsets from the tangent and chords produced, the value of the offset from the chord produced being twice that from the tangent, when the distance used is a chord of the curve instead of a length on the tangent. The method is undesirable because the operation of successively producing the chords renders the process subject to cumulative error.

By the use of the formulae in the manner suggested, the distance from the end of the curve to the reversing point and from the reversing point to the point of switch may be obtained at once. These distances will be equal if the two curves are of equal radii and the reversing point will be midway between the line of the main track and of the siding. Whether the curves be of equal radii or otherwise, this point will lie in the line joining the two tangent points. Any number of intermediate points on both curves may be set after computation of the offsets. Those for the second curve may be made supplements of the whole distance between the siding and the main track and thus all the measurements be made from an actual base line and every source of error in the field work be eliminated. It should be noted that the offsets vary as the square of the linear distance and if the distances selected are in a simple ratio, the square of this ratio multiplied by the first offset will supply the other offset with a considerable saving in computation.

When the length of radius is not absolutely determined by limiting conditions, as indeed seldom is the case,

one should be chosen which will make the offset at the point of frog equal to the gauge. This radius will be about 5 per cent. larger than the actual radius obtaining through the lead, but this advantage is quite desirable both from the maintenance and operating standpoints. This solution may be used for the case of a crossover between two tracks which are parallel, but which are so far separated that a tangent between the frogs is impracticable.

If it is preferred to make the reversed curves circular rather than parabolic, the formulae outlines for a continuous circular curve should be employed.

The problem of locating a siding at right angles with the main track may likewise be met by the use of offsets

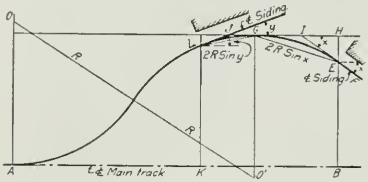

Fig. 3.—A Siding at an Angle with the Tangent Main Track.

and with as great accuracy as the average transit instrument will supply. It is necessary in any event to adjust the detail line of the curve when finally laid, and this can best be done with a string. The formulae for offsets employed in the preceding case will not answer for the circular curve required and the proper formulae for such cases are the following: $p = R - \sqrt{R^2 - l^2}$ and $l = \sqrt{p(2R - p)}$. These symbols signify that for a chosen distance from the point of curve along the tangent, the offset is equal to the radius minus the square root of the difference between the radius squared and the linear distance squared; or, conversely, for a chosen offset from the tangent, the linear distance is equal to the square root of the product of the offset multiplied by the difference between twice the radius and the offset.

This may be used for the offsets from either end to the middle of the curve, for which point it should be noted that the linear distance is equal to the radius divided by the square root of 2, which is 1.414, and the offset is equal to the differnce between the radius and this linear distance.

A test of the correctness of the layout will lie in the fact of the total measured length of the curve agreeing with the length as computed by the simple properties of the circle.

The problem when the line of the siding either converges toward or diverges from the line of the main track may appear to be quite complicated, but when understood becomes really quite simple. The field work necessary to a solution of such a case consists only in measuring the angle of divergence and the offset distance at the point of tangency. The problem then is to determine the position of a tangent parallel with the main track which, for the chosen radius, will make the curve pass through the point desired and be tangent to the line of the siding at that point.

The field books develop with great interest to the mathematically inclined the problem of finding the equal radii for a known position of the line joining the two ends of the reversed curve. But as the effect of such a proposition is to establish a curvature that will generally necessitate the use of special frogs it is clearly not of much use in the solution of the practical track problem.

The angle may be obtained with the tape line by laying down equal distances along the two sides of the angle and measuring the spread at the ends of such distance and by dividing the constant 57.3 by the ratio of these measurements, which it will be noted is the same problem as used in measuring the angle of a frog.

The length of chord subtending a central angle of this computed value may be found with sufficient accuracy by dividing the angle by the degree of curve. The tangent offset for this chord will be obtained from the formula in Example 1, and the linear distance by a solution of the right angled triangle in which the chord is the known hypothenuse and the tangent offset the other known side. The position of the parallel tangent and the linear distance to the point of curve are now known and the solution of the problem becomes simply that of Example 1, except that for the diverging line a portion of the computed curve is imaginary and for the converging line a portion of the computed curve will be duplicated beyond the point of tangency with the imaginary parallel line.

The problem of establishing a connection from a curved main track requires instrumental work in measuring the angle between the siding tangent and the tangent to the main track curve at the point of intersection and of deflecting for the several stations after computing the length of curve between the point of intersection and the p. c. of the siding curve and of the distance on the siding tangent between the main track curve and the p. t. of the siding curve. This distance from the main track curve to a possible point of tangent for the siding curve should be measured as a check on the selection of radius for the siding curve. The choice of curves is limited to those

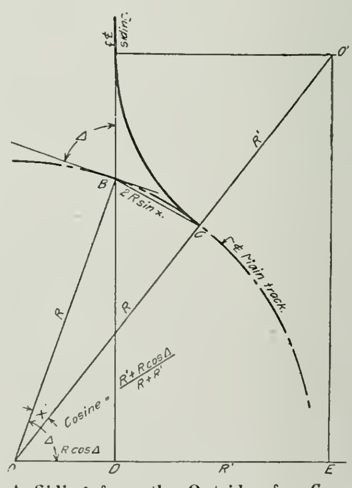

Fig. 4.—A Siding from the Outside of a Curved Main Track.

which will permit the use of a regular number of frog and will thus be the curvature of some regular connection plus or minus the degree of the main track curve, depending upon whether the siding is from the inside or outside of the curve.

There are six cases of this one general problem, of which the two that most commonly occur are given. The other cases include two more from the inside, in both of

N.B.—In Figs 3, 4 and 5, the quantity "2R sin x," should read "2R sin ½x."

which the angle Δ is greater than 90 deg. and R^1 either greater or less than R cos Δ, and two more from the outside in both of which Δ is less than 90 deg. and R^1 either greater or less than R cos Δ. Each case supplies variations which the mathematical skill of the engineer will readily differentiate.

The solution of all is rendered more facile by extending the siding tangent to a normal line which passes through the centre of the main track curve and intersects a line parallel with the siding tangent through the centre of the siding curve. This brings the measured angle Δ, which it will be noticed is included between the radius of the main track curve and the normal to the siding tangent, into direct geometric relation with the two known radii. The solution indicated for the two cases may be applied with apparent modification to all the cases when the angle between the siding tangent and the radii passing through the p. c. of the siding curve may be obtained, as well as the central angle of the siding curve and the distance to the actual p. t. of the siding curve when a test of the correctness of the assumed radius will be had upon comparison with the tentative measured distance.

When it is not necessary to establish the siding curve immediately, the work may be greatly simplified by taking scale measurements from an accurately plotted plan. These will answer every purpose if the original survey was correct and the drawing made to a scale as large as 1 in. to 40 ft., or preferably 1 in. to 32 ft.

The problem of locating a siding on a continuous simple curve which shall pass through two definite points is of very frequent occurrence, as when a property corner must be avoided and farther on a corner of a building cleared. The finite problem is capable only of theoretical solution when the results will be a curve which may or

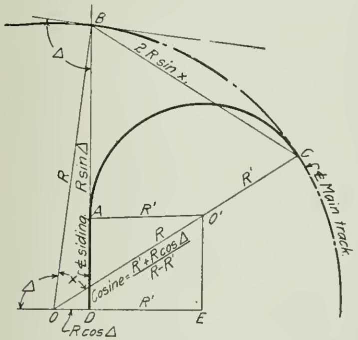

Fig. 5.—A Siding from the Inside of a Curved Main Track.

may not approximate that of some regular connection. But it will generally be possible to change one or both points so that the curve of the nearest regular number of frog may be employed.

The theoretical solution is readily made by means of the geometrical relations indicated in the diagram and furnishes the following formulae by which the radius may first be computed and if this answers the practical requirement, the distance from the point of curve to the foot of the perpendicular through the nearer point.

It will be noted that the formula for obtaining the radius has been reduced with a view of establishing the function R in its simplest form, which will be found to facilitate greatly the detailed solution. Indeed without this simplification the solution is immeasurably tedious.

$$R - \frac{a+b}{2} - \frac{c^2}{2(a-b)} = \frac{c}{a-b}\sqrt{2bR - b^2}$$

$$x = \sqrt{b(2R - b)}$$

The factor preceding the square root sign need only be carried to two decimal places and to the same degree of accuracy when squared. The remaining members may be used throughout of the nearest even whole number.

When the radius found is not of practical application, as when a radius of 375 ft. results, which lies midway between the curve of a No. 6 and a No. 8, No. 7 not being used, the problem becomes one of adjustment within the limits that are possible for changes in the two assumed points. The quarters will seldom be so close that a change of a few feet will not be practicable and in such event the choice will lie between a compounded curve and a special frog.

A solution of the extreme case mentioned will afford some hints that will tend to simplify the solutions of other problems. It should be noted that a radius within 50 ft. will furnish practical results in the use of any particular frog. Thus a radius of 300 ft. will answer for a No. 6 or 450 ft. for a No. 8. But upon the determination of the radius a computation should be made of the distance to the point where the offset distance is equal to the gauge plus ½ in., and this point be used for the point of frog and a proper lead laid off to determine the point of switch, which need not be exactly at the point of curve.

Let $a = 137$, $b = 51$, $c = 100$; then, $R - 152 = 1.16\sqrt{102\,R - 2601}$

Squaring, $R^2 - 304\,R + 23104 = 138\,R - 3511$

$$\begin{array}{l} (138) \qquad\qquad (25737) \\ \hline R^2 - 442\,R + 48841 = 22226 \\ \hline \qquad (\text{diff. } 25737) \end{array}$$

$R - 221 = 149$, or $R = 370$.

Changing to $a = 132$, $b = 56$, $c = 100$, $R - 160 = 1.32\sqrt{112\,R - 3136}$

$$\begin{array}{l} R^2 - 320\,R + 25600 = 196\,R - 5456 \\ (196) \qquad\qquad (40964) \\ \hline R^2 - 516\,R + 66564 = 35508 \\ \hline \qquad (\text{diff. } 40964) \end{array}$$

$R - 258 = 189$, or, $R = 447$ ft., which permits the use of No. 8.

Changing to $a = 144$, $b = 44$, $c = 100$, $R - 144 = \sqrt{88\,R - 1936}$

$$\begin{array}{l} R^2 - 288\,R + 20736 = 88\,R - 1936 \\ (88) \qquad\qquad (14608) \\ \hline R^2 - 376\,R + 35344 = 12672 \\ \hline \qquad (\text{diff. } 14608) \end{array}$$

$R - 188 = 113$, or $R = 301$ ft., which permits the use of No. 6.

Practical Considerations in Siding Layouts.—The feature of clearance in siding layout is a basic one because it concerns not only the switching movements but affects also the question of safety to persons. Some roads prescribe the minimum distance from the track for structures and a few require that this limit shall be followed in the case of movable obstructions. But the addition to this minimum made necessary by the "nosing," overhang or tilt of the cars, which is a variable one, is

not generally stated. Assuming that the widest car which moves in regular traffic is 10 ft. 9 in., a limit of 4 ft. 7 in. from the gauge line of tangents for all obstructions would allow a margin of 1 ft. 7 in. without any correction for accidental unevenness of elevation or for swaying of the car while in motion and with a fair degree of maintenance this would render operation entirely safe.

Car design is such that in a general way the nosing nearly equals the overhang on curves that are without super-elevation. The corrections may be readily computed for cars with 30 ft. truck centres by taking one-fourth the degree of the curve as inches of overhang and assuming that the nosing is no more than that figure and adding or subtracting whatever may be proper for the super-elevation employed. If this is 1½ in. as suggested, the tilt at the eaves of the car would add or subtract 4½ in. from the correction, depending on whether the low or high side were in question. The fact should not be overlooked that at the end of the curve a correction should also be made which is one-half that for the body of the curve. The distance beyond the point of tangency to the point where correction no longer applies is about 18 ft.

The overhead clearance limit is conveniently fixed at 16 ft. above the top of rail which meets the requirements of all present equipment and probably is ample for all future design. As this clearance will not pass a man

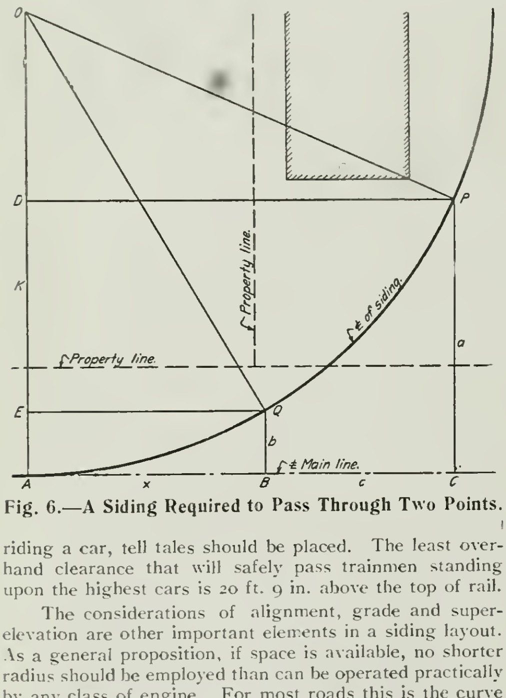

Fig. 6.—A Siding Required to Pass Through Two Points.

riding a car, tell tales should be placed. The least overhand clearance that will safely pass trainmen standing upon the highest cars is 20 ft. 9 in. above the top of rail.

The considerations of alignment, grade and super-elevation are other important elements in a siding layout. As a general proposition, if space is available, no shorter radius should be employed than can be operated practically by any class of engine. For most roads this is the curve of a No. 6 turnout from tangent which is 23 deg. or 250 ft. radius. This requirement is not practical in congested districts and it will often be necessary to modify the curvature to the minimum that a due consideration for safety in coupling cars will permit. This radius has been variously determined, but probably is close to that of a No. 5 turnout from tangent or a 162-ft. radius. Where sharp curvature and maximum gradient are both involved insistence should be had upon the best possible feature for each.

The allowable maximum gradient for siding connections for the best service is 2 ft. in 100 ft. and the maximum for a track upon which cars stand for unloading 1 ft. in 100 ft. It is possible to operate sidings with a gradient as great as 4.7 ft. in 100 ft., but the best drill engines cannot handle more than three loaded cars on such a gradient and the operation is therefore unprofitable. The danger of wrecks from cars running away with the possibility of fouling the main line even when derails are provided renders such a gradient highly objectionable. It is very important that all radical changes of grade in siding connections shall be eased by vertical curves, as the absence of such advantage is a frequent source of accident.

The general feature of gradient concerns the approaches to coal trestles more particularly, and is one where the road must often take a firm stand against the insistence of the applicant for more headroom. The adoption of a limiting gradient by the road many times would supply the means of combating such demands. If greater headroom is desired it can nearly always be had by excavating the site. Any less clear height than 6 ft. 6 in. below the stringers will not permit a horse being driven through and any greater headroom than 14 ft. will break the coal or grind a measurable amount of it into dust with a considerable loss to the dealer.

The question of super-elevation is one concerning which authorities differ. It will be argued that no super-elevation is possible through the connection and therefore none is necessary beyond the connection. But the difference is that the track through the extent of the switch timbers is more rigidly secured in line, surface and gauge, if tie plates be used on the timbers as should be the case, and there is less chance for distortion. It will be found that a super-elevation of 1½ in. for all siding curves is a decided maintenance advantage.

The importance of good line and surface is not fully appreciated. Very many obscure cases of siding derailment wherein the cause given as "truck failing to curve" is really irregular line or uneven elevation. To spend money in siding maintenance is much better than spending it for small wrecks with its annoying interruption to drill work or the possibility of injury to men.

The best maintenance of sidings can only be attained by constant inspection and supervision. The track walker should go over every siding once every day. The foreman should inspect each siding in his territory twice a week. The supervisor should make a careful examination of his sidings and switches once every month and make permanent notes of what he finds. He should also require a report every two weeks from his foremen stating that he has made his inspection and calling attention to any specified repairs that may be necessary requiring material that he lacks. For the best results the foreman should not be overburdened with siding responsibility. Probably 30 switches is the most that one foreman can look after if he has main track duties also.

The first pier of the new Balboa terminal of the Panama Canal is now completed. It is 1,000 feet long and 200 feet wide, the floor being supported on concrete caissons, there being 200 of these sunk to a depth of 61 feet to bed rock. The concrete used in the construction amounted to 27,000 cubic yards. Work was commenced on sinking the caissons in February, 1913, and completed in February, 1914. The superstructure was begun in March, 1914. The new concrete docks when completed will have a water frontage of 5,700 lineal feet.

Editorial

FREE LIME IN CEMENT.

For many years engineers continued in the habit of depending entirely upon the tensile tests of neat cement and 3 : 1 sands, and it was customary for them to ignore entirely the compression tests. It is now definitely known, however, that neat tests have become almost obsolete in European laboratories, the practice being for those interested to confine themselves entirely to the 3 : 1 sands in both compression and tension. But even these tests have been shown to be far from reliable, especially where fine-grain sands are used. In reinforced concrete work the concrete is rarely subjected to tension except in instances of accident in design, and it has been decided that the only use of neat tests is to determine the initial and final set of the cement, of which the initial set should be about one hour. Modern cement is much more finely ground than was at one time the case, and naturally great care should be given to the way in which cement for reinforced concrete work is stored. While previously, in the days of coarse grinding, it was necessary to give plenty of time for aeration in order to render it safe, as it contained a certain proportion of free lime, at the present time, if any of this is present, it is hydrated practically as soon as the concrete is made. If cement is stored in an exposed position it becomes greatly reduced in value, due to hydration, and the only safe method, where it is not required for immediate use, is to stock it in airtight bins. The most accurate test to ascertain the proportion of free lime in cement is still stated to be the "Chatelier," the testing instrument consisting of a section of a small cylindrical tube cut off at a given length, and with a saw cut along its axis. To this two arms are connected, of a given length as compared with its diameter. The cement is gauged with approximately 25 per cent. of water filled into the tube, and stored in cold water for twenty-four hours. After this it is placed in cold water, which is heated to the boiling point, and is then boiled as quickly as possible for six hours. Before this latter process the distance between the pointers is accurately measured, and after the boiling is over the difference in the distance between the arms will show the expansion that has taken place. This difference should not exceed 4 millimètres, and it is said that the concrete made with cement that has passed this test will be absolutely safe in use, and no accident can happen due to the presence of free lime.

CO-OPERATION IN PUBLIC UTILITIES.

This is the time of year when the champions of municipal ownership advance their hobbies into the political arena, and make great endeavors to sway public interest to a general and favorable conclusion with respect to the abstract question. It is interesting to note that, at a large conference of United States mayors held recently in Philadelphia, although there were a number of outcroppings of radicalism, as might have been expected, the dominant opinion was in favor of the privately owned and operated utility, with proper regulation, either state or municipal. Of interest also were the remarks of Mr. A. M. Taylor, director of city transit, Philadelphia, in outlining the city's policy in dealing with public utilities.

"We recognize," said Mr. Taylor, "the great part which the railroads and other public service corporations can take in the development of this city and its industries, but to so take this part they must have credit upon which to raise large sums of money, and they must be assured of an adequate and attractive return thereon and immunity from unwarranted competition or political and public attacks. The capitalists of this country are going to invest their money in communities where capital is justly treated and permitted to earn attractive returns and are not going to invest money in communities where its security is impaired and its productiveness is unduly curtailed by unreasonable legislation, regulation or competition."

One decided advantage of the exercising of the "municipal ownership" hobby at election time lies in the tendency it has to convert antagonistic relationship between public service companies and the public into a relationship of mutual understanding. In the case of street railways, for instance, it should be the purpose of both railway and officials and responsible public officials to place the relations of the companies and the public upon a permanent basis of mutual confidence. It is necessary that the companies and the public understand and trust each other, otherwise the companies will not prosper, the service will be poor, and the public will suffer.

At the winter meeting of the Pennsylvania Street Railway Association the relation between electric railways and the public was discussed by Emory R. Johnson, Professor of Transportation and Commerce, University of Pennsylvania. Prof. Johnson, who is also a member of the noted Public Service Commission of that city, makes the following statements:—

Electric railway and other public service companies can secure the confidence of the public, provided the companies adhere to methods of financiering and management that square with approved moral standards; provided the companies keep the public fully and accurately informed regarding the affairs of the corporations that serve the public; and provided the service rendered is adequate and efficient.

The affairs of public service companies must be matters of public knowledge, and it will be impossible for a company successfully to conceal operations that would not meet with public approval. Electric railway and other public service companies should keep accurate accounts according to uniform methods, and their financial obligations should be so straightforward that the public will be convinced that the companies are not resorting to the speculative methods of financiering which, though prevalent in the past, have now come to be condemned; also the companies should systematically publish information that will help the public to understand and correctly judge the financial and service operations of the companies.

Good service is fundamental and all important. It is essential to the success of the company and is necessary to secure public approval of what the company does. If the public feels that utility companies are straightforward in their financial management and are rendering good services, it will not be opposed to the maintenance of charges that yield adequate profits. The public demand for good service is stronger than for low fares.

The policy of every utility company should be to study the service demands as fully as possible, and the management may wisely study carefully all serious complaints to services. Careful attention to complaints will be helpful to the company as well as gratifying to the public.

Many electric railway companies have been apprehensive because of the increasing degree of public regulation of their finances, services and charges; but I believe there is less apprehension now than there was 10 years ago. Regulation of public service companies in increasing measure by state and municipal authorities has come about naturally and logically. It is necessary for each municipality to have a unified transportation service; and, with but few exceptions, there is now but one street railway company in each city. The requisite unified service is performed by a consolidated company.

Likewise, the larger interests of the people demand that the state shall, by appropriate regulatory, supplement municipal regulation of public utilities. State regulation is necessary, first of all, because the public service company often serves more than one municipal area. The power that regulates must be as extensive as the object regulated; moreover, state regulation is desirable because experience has clearly shown that in the supervision of accounts, finances, services and charges of public service companies there needs to be an executive body whose jurisdiction is state-wide and whose powers are as comprehensive as the tasks to be accomplished. If the regulation of electric railway and other public service companies were left entirely to municipalities, the regulation would be incomplete and would vary greatly as between different localities. Such a condition would be of disadvantage to the companies and not a benefit to the public.

PROTECTING METALS BY CALORIZING.

A NEW process which will lead to economies in various phases of manufacture by preventing metals, especially iron, from burning when subjected to high temperatures for either long or short periods of time, and for one or many heats, is described by data and illustrations in a recent paper by Messrs. H. B. C. Allison and L. A. Hawkins, of the Research Laboratory, General Electric Co. This process, the discoverer of which is reported to be Mr. T. Van Aller, first consisted of heating metals in revolving drums with mixtures containing, among other things, finely divided aluminum, by which a surface alloy containing aluminum is produced. In the case of copper, this alloy is of the nature of an aluminum bronze, but richer in aluminum than the ordinary alloy of that name and more resistant to heat, so that copper thus treated is protected up to the melting period of the alloy from the scaling which occurs when untreated copper is heated above 300 deg. C. The same general result was obtained in the case of iron and steel.

A modification of this process extends its application to pieces which, because of their shape and size, are not adapted for tumbling. It admits of their being calorized by packing them in, or painting them with, a suitable mixture and heating them. There appear to be many places where it is desirable to use iron vessels or apparatus at temperatures above red heat, and at such temperatures, ordinary iron rapidly oxidizes and scales away. After iron is calorized the effect of heating is slight. Instead of burning and the scale falling off, as in the case of untreated iron, practically no effect can be detected after a considerable time—certainly none which injures the surface.

The above facts seem to indicate that this is a simple method for extending the use of iron under oxidizing conditions at high temperatures, and for greatly prolonging the life in those instances where it is now used, but must be renewed at frequent intervals. In the case of small muffles on crucibles, where temperatures are below 1,000 deg. C., this treatment of cheap cast or wrought iron shapes seems very promising. While the life of the coating depends on the temperature at which it is used, as well as on the duration of time taken in its preparation, i.e., the quantity of aluminum which alloys with the surface of the iron, it does not permit of long use at temperatures much in excess of 1,100 deg. C.

Copper parts also, which are exposed to high temperatures, can have their life increased by calorizing. In some cases calorized copper may be used advantageously in place of aluminum bronze. In some cases, also, the life of copper contacts can be increased by calorizing. For instance, a set of railway controller contacts which were calorized showed double the life of the ordinary untreated contacts.

The effect of calorizing is to produce a surface alloy containing aluminum. The thickness of this alloy varies with the length of time to which the piece is subjected to the calorizing process, and the percentage of aluminum varies through the coating being greatest at the surface.

For iron, calorizing is intended only for protection at high temperatures. It does not compete with galvanizing, sherardizing, and other similar processes for protection against oxidation or corrosion at low temperatures. Its usefulness lies within a range of temperature much higher than a galvanized or sherardized coat could stand. For copper, calorizing is effective against corrosion at low temperature as well as against oxidation at high temperature. The upper limit is determined by the melting point of the alloy, which is somewhat lower the heavier the calorizing treatment, since that means an alloy with a higher aluminum content.

The probable explanation of the effect of the aluminum in the surface alloy is that a thin coat of alumina forms which prevents further burning of the metal beneath. It is well known that a pure aluminum wire may be heated in the air to a temperature several hundred degrees above its melting-point, without flowing, when the thin alumina shell which surrounds and supports the molten metal is easily seen.

AT LAST.

The following clipping is from the Kansas City Post, of recent date:—

"An engine that runs itself on its own power, developing energy to operate machinery, has been invented in this city. The inventor has been working for five years on his self-operating engine, and now has it near perfection. A few alterations are to be made. These will increase its efficiency.

"The engine is run by compressed air, making its own pressure as it runs. The exhaust from the cylinders returns through a series of 8-port automatic valves, to a large steel pressure tank. This tank is a double affair, there being a smaller tank within the larger one.

"An air space of 6 in. intervenes between the two tanks. Into the air space the exhaust from the cylinders is forced, the action being such that the nitrogen gases are separated from the oxygen and forming a lighter gas, rises to the top of the tank, at the same time creating a pressure which forces the fresh air down through the inner tank and back into the engine, which is operated by this pressure."

Coast to Coast

Vancouver, B.C.—The large wharf that is being constructed for the Vancouver Island division of the Canadian Northern Pacific Railway will be ready for use early in the new year.

Moose Jaw, Sask.—During the past season 9.85 miles of streets were graded, involving the excavation of 30,680 square yards of material at a cost of $8,530.17, or a rate of 27.8 cents per cubic yard. The city has 36 miles of graded streets.

Moose Jaw, Sask.—The city has 35.66 miles of sanitary sewers, of which 2.33 miles were laid this year. The mileage of water mains is 66.44, of which 2.90 miles were laid this year. The number of fire hydrants on domestic water mains is now 306, of which 22 have been installed during the season.

Galt, Ont.—The Lake Erie and Northern Railway line has been connected up with the C.P.R. line at Main Street. The ballasting of the new road in Galt is now about complete, and work has commenced on the erection of a station on Main Street pond, the filling in of which has been finished.

Victoria, B.C.—The construction of a wharf at Patricia Bay has been commenced by Mr. S. Doe, who has been awarded the contract by the Canadian Northern Pacific Railway Company. The structure will have a width of 64 feet and a length of about 145 feet.

Vancouver, B.C.—The Dominion Board of Railway Commissioners, in session at Vancouver some time ago, cancelled their previous order for viaducts at Pender, Keefer and Harris Streets, over the V., V and E. Railway. A similar viaduct on Hastings Street, ordered at the same time, had not been subjected to delay and is already nearing completion.

Lytton, B.C.—To conclude the section of the C.N.R. between Summit and Kamloops, about 105 miles of track are still to be laid between Albreda and Lytton. Some 65 miles have still to be laid between Port Mann and Kamloops. These are the only remaining sections of the main line. Work is being proceeded with at the rate of 4 miles per day.

Welland, Ont.—The first tubular steel flag-pole made in Canada has recently been erected in Merritt Park. It is 76 ft. long and weighs 2½ tons. It consists of four sections of lap-welded steel pipe. The pole is anchored in a concrete foundation 6 ft. square and 7 ft. in depth. It was manufactured by the Page-Hersey Iron, Tube and Lead Company, Welland.

Toronto, Ont.—Property Commissioner Chisholm recently presented a report showing that the gross value of all civic properties was $35,712,806. The principal items were: City Hall and other public buildings, $6,278,366; Public schools, $6,540,097; parks, $12,352,893; tax sale lands, $1,270,666; High schools, $1,798,922; waterworks, $1,022,795; revenue-producing property, $2,729,191; Hydro properties, exclusive of plant, $269,110.

Saanich, B.C.—On the branch of the Canadian Northern Pacific Railway Company from Victoria to a terminus on the Saanich Peninsula there is a large cut extending for a distance of about 700 ft. and involving the removal of about 50,000 cu. yards of gravel. The excavation is now practically complete, and has been carried out by the firm of McDonald, Nettleton, Bruce, Essbach and Company. Rail-laying on this section has commenced.

Hamilton, Ont.—The Dominion Railway Commission has directed the city's engineering staff, and also the engineering staff of the T., H. and B. Railway, to prepare reports and estimates on the cost of grade separation for submission to it on February 1st, 1915. This is in connection with the old dispute between the city and the company, occasionally referred to in these columns. The Commission has advised the city and railway to get together as much as possible in an attempt to settle their difficulties.

Outremont, Que.—A special feature of the town's new lighting system is that it is entirely served by underground cables, and also that nitrogen-filled tungsten lamps are used exclusively. In both these respects the town deserves publicity, in that it is the first Canadian municipality to inaugurate the above features completely. The town has about 20 miles of lighting system. The installation has cost about $75,000, and has been installed by Town Engineer Duchastel, with the consulting engineering supervision of Mr. L. A. Herdt, of Montreal.

Cobalt, Ont.—The preliminary work in connection with the draining of Cobalt Lake has been completed, and it is at present being lowered, by gravity, to an elevation of 6½ ft. below normal, at which elevation pumping will commence in the spring. The pumping equipment is now in place. The greatest undertaking in connection with this project has been the supply of water for concentrating purposes to the various mills now getting their supply from Cobalt Lake. This has necessitated the daming of a series of lakes and pumping water through an extensive piping system to the mills.

Guelph, Ont.—County Roads Superintendent Young's report outlines the work of two outfits of road machinery continuously employed during the season. Several bridges were built, including the following: Moore's, Pilkington Tp., $845.26; Burnett's, Pilkington Tp., $924.60; Powell's, Peel Tp., $505.26; Parkinson's, Eramosa Tp., $1,037.05; Walker's, Maryboro Tp., $349.11; Scanlon's, Nichol Tp., $458.81; Blyth's, Guelph Tp., $769.02; Moorefield bridge, retaining wall, Maryboro Tp., $2,416.83; Kitley's bridge, Maryboro Tp., $207.51. Considerable drainage, grading and resurfacing on several of the county roads have been proceeded with, the materials used for resurfacing being mainly broken stone and gravel.

Leamington, Ont.—The town has recently awarded the contract for the construction of a drain to consist of 6,500 ft. of open drain, with 6 ft. bottom, 3,371 ft. of 4-ft. concrete tile, 1,456 ft. of 36-inch, 2,935 ft. of 30-inch, 2,956 ft. of 20-inch, and about 2,000 ft. each of 12, 8 and 6-inch, together with 34 catch-basins, 17 manholes, and a small bridge. The contract for the work, which is known as the Selkirk drain, was awarded to the Webster Construction Company, of London, the price being $24,999.50. The contractor intends to manufacture his own concrete tile. Walter Thorold, C.E., consulting engineer, Toronto, was called in to report upon this work some time ago, and it is on his recommendation that reinforced concrete construction was adopted.

Moose Jaw, Sask.—According to a recently issued report of Mr. Geo. D. Mackie, city engineer-commissioner, there are now 40.16 miles of concrete sidewalk in the city, of which 11.25 miles were constructed this year. The Moose Jaw Construction Company had the contract for this season's work, the price being $104,968. The unit price per square foot for the sidewalk was 20.4 cents as against an estimated cost of 25 cents. The total area of the walk laid was 51,000 square feet, curb and gutter 56,000 lineal feet, excavation 20,000 cubic yards, and 7,400 square feet of lane crossings. This contract was stopped in August owing to the outbreak of the European war, and there is left still to be carried out under the contract on the 1914 work about 25,000 square feet of sidewalk.

PERSONAL

ANDREW C. LAWSON, a graduate of the University of Toronto, has been appointed Dean of the School of Mining in the University of California.

PERCY E. JARMAN, who has been acting city engineer of Westmount, Que., since the resignation of Mr. Arch. Curry, about two years ago, has been appointed city engineer.

W. J. FULLER, of the Consumers' Gas Company, Toronto, is conducting a course of ten lessons in illuminating engineering for the benefit of the employees of the company. Courses in other subjects, by other instructors, are being given concurrently throughout the winter.

C. S. J. WILSON, construction engineer with the Dominion Bridge Company, read a paper before the Manitoba Branch of the Canadian Society of Civil Engineers on December 5th, his subject being "Bridge-building in the Rockies, and Engineering Problems Encountered in the Work."

R. G. McCONNELL, who has been acting Deputy Minister of Mines for Canada since the resignation of Mr. R. W. Brock, was appointed Deputy Minister on December 1st. Mr. McConnell graduated from McGill University in 1879, whereupon he joined the staff of the Geological Survey. A great deal of the important exploratory work done by the Survey in Western Canada has been conducted by him.

J. B. CHALLIES and J. T. JOHNSTON, of the Water Power Branch, Department of the Interior, Canada, were in Washington last week by invitation of the United States Secretary of the Interior, Hon. Franklin K. Lane, to explain the water power laws and administrations of Canada to a special committee of the United States Senate, which is drafting a water power bill to cover the administration of water powers under the control of the Federal Government.

CANADIAN SOCIETY OF CIVIL ENGINEERS.

Regular Meeting, December 17th, 1914.

The regular monthly meeting of the Canadian Society of Civil Engineers was held at the headquarters of the Society, 176 Mansfield Street, Montreal, on the evening of the 17th. The first part of the evening was devoted to a discussion of Mr. Surveyor's paper, "Making Our Water-Powers Valuable," a long reference to which was made in our issue of November 26th, 1914. The discussion was participated in by Messrs. Henry Holgate, L. A. Herdt, J. W. Evans, Frederick B. Brown and Ernest Marçeau.

At the conclusion of this discussion Professor Peter Gillespie presented a paper, entitled "Methods of Treatment of Sewage Sludge" (referred to elsewhere in this issue), and gave an illustrated talk on the subject. The greater part of the lantern slides used were made from photographs taken by the author in Europe during the summer of 1913. Prof. Gillespie's address, 1½ hours in length, held his audience in rapt attention. He used no notes, and his familiarity with his subject and his views made it a delightfully smoothly-running and logically-connected discourse.

Mr. Walter J. Francis, chairman of the Meetings Committee, presided at the meeting.

On December 22nd the members of the Ottawa branch of the Canadian Society of Civil Engineers listened to a paper on "Submarines" given by Engineer-Commander P. C. W. Howe, R.C.N.

CALGARY BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

This Branch of the Society held its annual meeting on December 5th, and elected the following officers for the ensuing year:—

Chairman—Mr. F. H. Peters.

Secretary-treasurer—Mr. P. M. Sauder.

Executive Committee—Mr. R. J. Burley, Mr. H. B. Muckleston, Mr. P. J. Jennings.

Auditors—Mr. J. S. Tempest, Mr. F. G. Cross.

The Branch has a number of prominent speakers in view for its winter meetings. It intends to hold a series of luncheons during the season.

At the annual meeting referred to above, Messrs. J. S. Dennis, H. B. Muckleston, F. H. Peters, P. T. Bone, G. Romanes, H. Siddenius and P. M. Sauder were speakers.

VICTORIA BRANCH, CANADIAN SOCIETY OF CIVIL ENGINEERS.

At the annual meeting of the Victoria Branch, held on December 10th, the following officers were elected:—

Chairman—D. O. Lewis.
Vice-Chairman—H. W. E. Canavan.
Treasurer—Frank C. Green.
Secretary—R. W. McIntyre.
Executive—A. W. R. Wilby, A. E. Foreman.
Auditors—E. H. Harrison, H. A. Icke.

In his retiring address, Mr. F. C. Gamble, who has been chairman for the past two years, made the following remarks:—

"To successfully accomplish the advancement of our profession to the position it should occupy, personal aim should be set aside and members should work together unselfishly as a determined body of men, whose sole purpose is to raise the profession of civil engineering to the highest plane of efficiency and influence. By following along the suggestions implied in these remarks we shall soon command a greater confidence and more of the respect of the public. The effect of your efforts may not be immediate nor of direct personal advantage, but indirectly every member will be benefited by the growing influence of our society.

"Each member of this branch should realize his individual responsibility and should not shirk his duty.

"In one direction our activity has not been as great as could be desired, and that is with regard to the preparation and the reading of papers at our monthly meetings. There has been a sad dearth of these. We have men amongst us who can write with ability most interestingly and instructively on subjects they are most familiar with, and I beg of these not to postpone their duty in this respect indefinitely."

On December 10th and 11th the general meeting of the Victoria and Vancouver branches was held. Among the papers presented was that of Mr. J. S. MacLachlan, Dominion Government Engineer, on harbor work at Victoria, who read a paper on "Harbors" and an interesting discussion followed. Mr. G. R. G. Conway, Chief Engineer of the British Columbia Electric Railway Company, and chairman of the Vancouver Branch of the Society, also read a very valuable paper, entitled "Legislation and the Engineering Profession."

The following were appointed to the board of directors of the Ottawa Light, Heat and Power Company at its annual meeting, held last week: Col. D. R. Street, present secretary-treasurer of the company, and Mr. F. W. Fee assistant secretary-treasurer. These vacancies were caused by the deaths of Mr. John Manuel and Mr. Honore Robillard.

A weekly paper for engineers and engineering-contractors

PROGRESS ON THE NEW QUEBEC BRIDGE

SUPERSTRUCTURE ERECTION REVIEWED TO DATE—PROGRAM OF ERECTION—OFFSETTING DIFFICULTIES IN PIN CONNECTIONS ARISING OUT OF ALLOWANCES FOR DEFORMATION OF MEMBERS UNDER FULL LOAD.

By H. P. BORDEN,
Assistant to Chief Engineer.

WITH the close of the present season considerable progress is to be noted towards the erection of the new Quebec Bridge. During the summer of 1913 the approach spans on the north shore from the abutment to the anchor pier were fully erected. These spans were erected by derrick cars on heavy wooden and steel falsework. As these spans would have to carry the 1,000-ton erection traveler, and as the concentrated wheel loads from this traveler were considerably greater than the live loads for which the spans were designed, this falsework was made sufficiently strong to take care of these reactions.

During the winter of 1914 the traveler was erected on the shore, just north of the abutment and it was ready to move out early in May. This traveler was carried on two double lines of tracks, spaced 54 ft. centre to centre. The two inner rails were carried on the top flanges of the outside bridge track girders, the outer rails being carried on special erection girders resting on the falsework and thoroughly braced to the track girders themselves. The traveler was moved out over the approach spans to the anchor pier on May 18th, and proceeded to erect the inside falsework carrying the floor of the anchor arm on which the traveler runs.

Fig. 1.—View Showing North Anchor Arm when Work Closed Down at the End of the Season.

The main floor beams of this floor were supported on special erection girders supported by this falsework and were located in approximately their correct positions. The main track girders, sub-floor beams and stringers were then erected in place and special girders erected outside the track stringers for the erection traveler.

When this falsework had been completed out to the north main pier the main shoes were erected, and the bases for these shoes were accurately placed and the entire shoe erected. An elaborate series of triangulations and measurements, extending over several months, were made to locate the longitudinal and transverse centre lines of these shoes. Once the bases had been placed in their proper position the rest of the shoe went forward rapidly, and a start on the erection of the bottom chords was made.

According to the program of erection, it was proposed to lay the bottom chords complete with their lateral bracing from the main shoe to the anchor pier, the main traveler moving back as the work progressed. When this had been done the traveler moved ahead again to the main pier and started the erection of the web members up to their middle intersection above the floor. This was carried back to the north anchor pier, after which the erection of the upper half of the web members in the top chord was effected, the traveler moving forward as the work progressed.

Work stopped for the season with the anchor pier completely erected with the exception of two upper panels near the main pier.

Owing to the deformation of all members under full load, it has been necessary to manufacture the compression members slightly longer and the tension members slightly shorter than their actual geometric length. On account of this fact there would naturally be difficulties in making the pin connections between the various members of the anchor arm in view of the fact that all these members are erected on falsework and consequently under no load except from their own weight. To offset this difficulty, the bottom chord was given a camber which would correspond to the deformations indicated by the Williot's or deformation diagram. In other words, after the bottom chord had been entirely riveted up from end to end, it was lowered a certain amount at each panel point by means of jacks at the foot of the steel falsework to correspond to this deformation. The final displacement, including deformation of falsework posts, amounted to zero at the main shoe, seven inches at the middle point, and five inches at the north anchor pier, varying practically uniformly between these points.

Owing to the length of this bottom chord, it was able to obtain this deformation without any difficulty.

To offset the effect of deformation of the web members from their own weight, and to enable pins to be driven without any difficulty, elongated holes were bored in the upper end of the upper tension diagonals and in all the eyebars in the top chord. The holes in the diagonals were elongated 2 inches and each eyebar ½ inch at each end, the elongation being made in the side of the hole nearest the centre of the member. By this means it was possible to drive these pins without any difficulty, the play in the holes being taken up as the cantilever arm is erected and stresses applied to the members of the anchor arm.

The driving of pins was materially facilitated by the fact that these pins are in duplicate, each pin going through two webs only of the 4-web members. This also applies to the top chords. In designing the driving rams for these pins it was estimated that heavy rams, weighing in the neighborhood of two or three tons, would be required. It was found in actual practice, however, that these were not necessary, and after the first one or two pins had been driven a steel rail 10 feet long, weighing 80 lbs. per yard, was used and pins in practically every case were driven home in from one to two minutes.

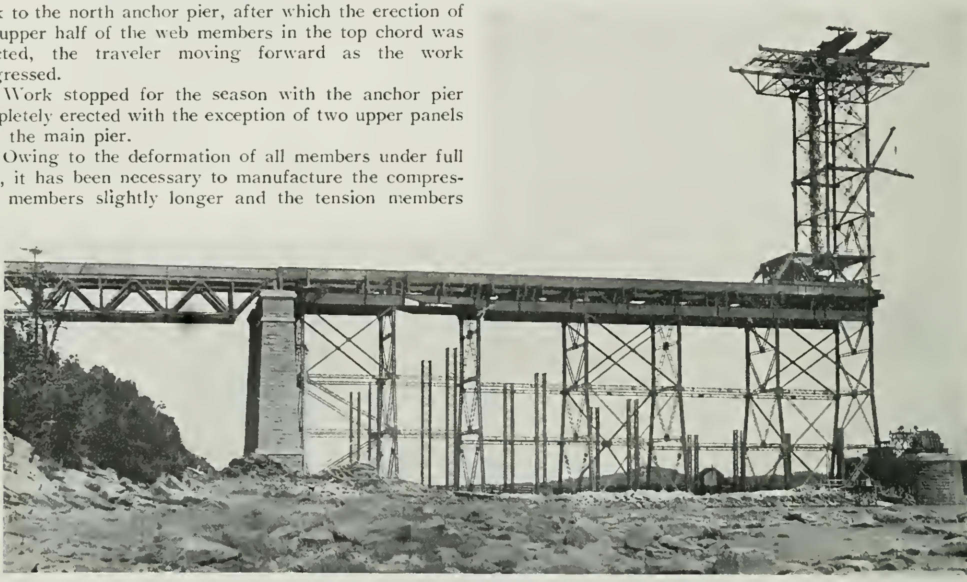

Fig. 2.—Falsework and Floor Erected, and a Start Being Made on the Erection of the Main Shoes.

The maximum clearance allowed in all pin holes is 1/32 inch + 1/100 inch.

The amount of steel erected during the season just passed is about 15,000 tons, and this was practically erected in four months, from August 1st to December 1st.

A duplicate traveler is now being erected on the south side of the river and will be in commission the first thing in the spring. If the work is carried on according to programme, it is expected that the remainder of the anchor arm and the whole of the north cantilever arm as well as the south anchor arm, should be erected next season.

The St. Lawrence Bridge Company, Montreal, are the contractors for the superstructure. The work is being carried out under the supervision of the Board of Engineers, Quebec Bridge, composed of Mr. C. N. Monsarrat (Chairman and Chief Engineer), Mr. Ralph Modjeski and Mr. C. C. Schneider.

ECONOMIC FEATURES OF THE ROGER'S PASS TUNNEL.

FROM time to time articles and notes of engineering interest have appeared in this journal on the five-mile, double-track tunnel which Messrs. Foley Bros., Welch and Stewart are driving through the Selkirk Range, in the vicinity of Roger's Pass, for the Canadian Pacific Railway Company. For a description of the engineering features of the undertaking the reader is referred to *The Canadian Engineer* for April 23, 1914, page 621. Maps and profiles of the old and proposed lines are illustrated therein to good advantage, and a reference to them will be of assistance in the following portrayal of the problem in economics which the revision of railway location has presented.

The following abstract from a paper by J. G. Sullivan, C.E., chief engineer of the western lines of the C.P.R., presents the factors involved in a study of the cost of operation via the present and proposed routes. We are indebted to the "Cornell Civil Engineer" for the information. (Mr. Sullivan is a graduate of Cornell University, Class '88.)

The data to be taken into account is as follows: Present location, total distance 23.1 miles, revised location 18.68 miles; grades consist, on the present location of 16.65 miles up hill for westbound traffic on maximum grade of 2.2%, 6.45 miles down grade same maximum with a total rise of 1,726 ft. and a drop of 692.1 ft. with 1,860 degrees of curvature on the up hill and 1,288 degrees on the down hill portion of the line. The revised location consists of 16.77 miles up hill with about 5 miles of 2.2% pusher grade, the balance 1% and a down hill run of 1.91 miles with a maximum 2.2% grade; a total rise of 1,178.2 ft. and a drop of 144.3 ft., with 635 degrees of curvature on the up hill grade and 66 degrees on the down hill. The average traffic for the years 1912 and 1913, which is made the basis of calculations, was 1,342½ passenger trains in each direction; the average weight of the passenger trains, exclusive of locomotives, was 443 tons; 980 of the passenger trains required pusher engines; the weight of the passenger and pusher engines for passenger trains was 175 tons each; there were 173½ freight trains in each direction per year; the average weight of the freight trains eastbound, exclusive of locomotives, was 950 tons; the average weight of freight trains westbound was 898 tons; all freight trains had to be pushed in both directions; weight of freight locomotives and pushers, 181 tons each. The tonnage eastbound and westbound was as follows:—

Eastbound.

1,342½	trains @ 443 tons each	594,727.5	tons
2,322	locomotives @ 175 tons each..	406,350.0	"
1,738½	freight trains @ 950 tons each	1,651,575.0	"
3,477	locomotives @ 181 tons each ..	629,237.0	"
	Total	3,281,889.5	tons

Westbound.

1,342½	trains @ 443 tons each	594,727.5	tons
2,322	locomotives @ 175 tons each..	406,350.0	"
1,738½	freight trains @ 898 tons each	1,561,173.0	"
3,477	locomotives @ 181 tons each ..	629,237.0	"
	Total	3,191,487.5	tons

Comparison of Comparable Factors Affecting the Cost of Operating Over Roger's Pass, via Present Line and via Tunnel Line, Now Under Construction, Average Traffic for the Years 1912 and 1913.

E. B. tonnage per year, including weight of engines, 3,281,890 tons.

Resistance to overcome, on present line.

Actual rise, 692.1 ft.	692.1 ft.	
Curve resistance, 1,288° × .04′	51.5 ft.	
Friction resistance, 6.45 mls. × 15′..	96.7 ft.	
Total		840.3 ft.

Resistance to overcome, tunnel line.

Actual rise, 144.3 ft.	144.3 ft.	
Curve resistance, 66° × .04′	2.6 ft.	
Friction resistance, 1.91 mls. × 15′	28.6 ft.	
Total		175.5 ft.
Difference		664.8 ft.

3,281,890 tons × 664.8 ft. equals 2,181,800,472 foot tons.

W. B. tonnage per year, including weight of engines, 3,191,488 tons.

Resistance to overcome, present line.

Actual rise, 1,726 ft.	1,726.0 ft.	
Curve resistance, 1,860° × .04′ ...	74.4 ft.	
Friction resistance, 16.65 mls. × 15′	249.7 ft.	
Total		2,050.1 ft.

Resistance to overcome, tunnel line.

Actual rise, 1,178.2 ft.	1,178.2 ft.	
Curve resistance, 635° × .04′	25.4 ft.	
Friction resistance, 16.77 mls. × 15′	251.5 ft.	
Total		1,455.1 ft.
Difference		595.0 ft.

3,191,488 tons × 595 ft. equals 1,898,935,360 foot tons.

Total work done (extra)	2,181,800,472 foot tons
	1,898,935,360 foot tons.
Total	4,080,735,832 foot tons.

1,000 foot tons equals approximately 1 horse-power hour. Assuming that 5 pounds of coal is consumed in doing one horse-power hour's work and that coal on locomotive costs $4.60 per ton, the saving in fuel will amount to:

$$\frac{4{,}080{,}736 \times 5 \text{ lbs.} \times \$4.60}{2{,}000 \text{ lbs. (one ton)}} = \ldots\ldots \$46{,}928.46$$

Extra Wages, Train and Engine Crews.

Present line.

6,162 trains for 23.1 miles, 142,342.2 train miles.
5,437 push. engs. for 23.1 mls., 125,594.7 push. eng. mls.

Tunnel line.

6,162 trains for 18.68 miles 115,106.2 train miles.
5,437 push. engs. for 13 mls., 70,681.0 push. eng. mls.

Amount saved { 27,236.0 train miles.
54,913.7 pusher engine miles.

27,236 train miles at 22 cents .... $	5,991.92
54,913.7 pusher miles at 25 cents	13,728.40
NOTE—25 cents to cover engine crew wages, cost of repairs to pusher locomotives and extra cost of maintenance account of running pushers.	
Extra cost maintenance of way, 4.42 miles at $200 plus 27,236 train miles at 20 cents	6,331.20
Extra cost, maintenance of way, account of extra number of degrees of curvature, assuming that 400° of curvature per mile would increase rate at 20 cents per train mile for maintenance by 30%.	
6,162 trains × 2,447° × 1/40 cents	3,769.60
Special maintenance, account 4½ miles snow sheds	85,000.00
Extra cost, maintenance of equipment 27,236 train miles at 21 cents	5,719.56
Extra cost maintenance of equipment, account of extra number of degrees of curvature, assuming that 400° of curvature per mile would increase rate of 21 cents per train mile by 40%.	
6,162 trains × 2,447° × 21/1,000 cents	3,166.47
Total annual saving in cost of operation.	$170,635.61

The rate at which traffic has been increasing would indicate that shortly after the work of constructing the tunnel was completed the traffic would have doubled. In this case, if no further economics were made in methods of operating this section of track, the annual saving on account of operating over tunnel line would be,

$85,635.61 × 2 plus $85,000 = $356,271.22

In arriving at the above figures no account is taken of whether line was single or double track and for comparative figures it was assumed that methods of operation would be the same. Now, as a matter of fact, the present single track line with double the present traffic would make the business too congested for economical single track operation. Therefore, it was apparent that it was time to study the question of double tracking the present line or seeking a new line for double track. It was decided to double track on the five-mile tunnel location with grades as noted above. Now, to operate successfully a five-mile tunnel we will require the installation of an electric plant and the purchase of electric locomotives. All the details of the proposed electrification have not as yet been worked out, but even if they were, the reader is not interested in the details of cost. He can see at once that the problem was to find out if the cost of operating and maintaining the tunnel line, taking into account the extra costs of operating on account of having a short section of electric operation and extra cost of maintaining tracks in the tunnel, plus the interest on the cost of building the new double track line including the cost of electrifying the tunnel would be less than the cost of operating and maintaining a double track line on the present location plus the interest on the cost of building the second track. The figures would not have been very decisive one way or the other were it not for the fact that there is now 4½ miles of wooden snow sheds on the present location which will be all done away with on the new location. The maintenance and cost of renewals of these sheds cost between $85,000 and $100,000 per year. To maintain and renew a double track wooden shed would probably cost at least 50% more than the above, so that with a saving of about $125,000 per year in maintenance and renewals of snow sheds and a calculated saving in operation and maintenance of $171,271.22 on a traffic that surely will be reached in the near future, there was no doubt as to the proper course to pursue.

As to the details of figuring economics of railway location, the writer is well aware that it is impossible to devise any method that will show absolutely that saving in cost of operating one line over another, but he believes that the method herein followed, namely, that of comparing cost of fuel on the basis of work done rather than on a train-mile or any other unit is much more logical and will give more reliable results than other methods that have been followed. The train-mile is possibly the best unit for comparison in cost of wages and for cost of maintenance of equipment. In figuring maintenance of way a fixed sum should be taken plus a rate per daily train rather than a fixed rate alone per train-mile, for the reason that a certain amount of expense must be incurred regardless of whether trains are run or not. The fixed sum of $200 per mile taken in this problem is probably about one-half the actual sum that would be assumed if the entire cost of maintenance was to be included in this fixed sum per mile plus the rate per train mile for the reason that cost of maintenance of terminals and other items are not affected by the details of location between fixed terminals.

Frictional resistance, normal conditions, warm weather, modern freight equipment, speed between 7 and 35 miles an hour,

$R = 2.2\,T + 121.6\,C.$

R = total resistance on level tangent.

T = total weight cars and contents in tons.

C = total number of cars in train.

This amounts to 4 lbs. per ton to 8 lbs. per ton, depending on whether cars are fully loaded or empty. This is equivalent to a rise of from 10 ft. to 20 ft. per mile. For mixed traffic a conservative estimate is train resistance equals rise of 15 ft. per mile.

It may appear that the rate of 25 cts. per actual pusher-mile covering the cost of repairs and engine crew wages and extra cost of maintenance is too high, but as a matter of fact it is very conservative for the repairs, maintenance and renewals of the locomotives alone will run somewhere between 7 cts. and 10 cts. per mile and we have had cases where the engine crew wages alone averaged 25 cts. per mile for the actual mileage run, on account of delays to the pusher.

The progress made since the commencement of operations was reviewed in an article in *The Canadian Engineer* for October 1st, 1914. A few weeks ago reference was made to the establishment by the contractors of a new record for hard rock tunneling of 817 feet in 30 days, with a maximum footage of 37 feet in a single day.

C.P.R. FREIGHT TERMINAL AT QUEBEC.

The Canadian Pacific Railway has under construction at Quebec a large freight terminal, consisting of an inbound shed 50 ft. x 600 ft.; an outbound shed, 30 ft. x 300 ft., with a transfer platform, 300 ft. in length between. The W. S. Downing-Cook Co. have the contract, and Mr. S. G. Newton is their superintendent on the work. Steel is furnished by the Dominion Bridge Co. Terminals were designed by the building and construction department of the C.P.R., of which department Mr. D. H. Mapes is superintendent.

The foundation and floors of the two sheds are of reinforced concrete, supported on Raymond concrete piles.

IMPROVEMENTS TO NAVIGATION IN AND AROUND MONTREAL HARBOR.

THE season's grain export from the Port of Montreal has been stated to be the greatest in history. The total amount of grain passing through the two elevators of the Harbor Commission, the Grand Trunk elevator and the floating elevator, was 73,628,132 bushels, not including a million and a half bushels of grain which had been bagged and shipped direct, or over 10,000,000 bushels handled by the elevators for local consumption.

During the year the Repentigny channel from Isle St. Therese to Lanoraie has been finished, completely buoyed, and opened to navigation for boats drawing less than 14 feet. Later it will be extended through the Sorel Islands by way of the Grand Channel to Lake St. Peter. This dredging is now nearly completed and the necessary lights will be placed in position next spring. As the result of dredging all season in Lake St. Peter, there is now a 35-foot channel for almost the entire length of the lake. Elevator dredges at St. Anne, Sorel, St. Tours, The Traverse, Varennes and Point aux Trembles, are doing the same work. In Montreal Harbor they are widening the ship channel.

Four elevator dredges, a stone cutter and two stone lifters have been removing rock in the Cap a la Roche district to make a channel with a minimum depth at low water of 30 feet and a width of from 450 feet in the straight parts to 600 feet at the curves. New lighthouses will be erected in this district next year to mark out the new lines.

In the north channel below Quebec dredging has gone ahead for a channel 1,000 feet wide with a minimum depth at low tide of 30 feet, as far east as the foot of the Island of Orleans. Two dredges have worked at it this season, and the Dominion Government has awarded the contract for a seagoing hopper elevator dredge to the Canadian Vickers Company. This will hasten the work, but with the rocky bottom it will probably take nearly five years to finish it.

About $2,000,000 has been expended by the Harbor Commission this year in dredging, renovating piers and wharves, building new sheds and wharves, and other work incident to the five-year programme of development undertaken by them at a total cost of $15,000,000. All this work has been under the direction of Mr. W. G. Ross.

The main dredging in the harbor was south of St. Helen's Island to a depth of 20 feet. The renovation of Victoria Pier and the old low wharves east of it has been continued with the ultimate object of completing 2,700 feet of new high level and 4,800 feet of low level wharves. This will provide new berths for small river boats opposite Bonsecours Market, and for ocean steamers just below shed sixteen and in the neighborhood of the two new steel and concrete sheds, which have just been completed, at a cost of about $400,000. Similar sheds will be built parallel to the current on the new Victoria Pier where a stretch of 1,800 feet of dock is completed.

The $15,000,000 programme for five years includes a new warehousing system, the electrification of the railway system and the extension of the tracks from Racine Pier to Point aux Trembles, and ultimately to Bout de L'Isle. The Canada Cement and the Armstrong-Whitworth companies have had wharves built this year.

In connection with the Lachine Canal, $500,000 has been spent this year to eliminate the curve, which proved dangerous to navigation at Cote St. Paul, and the new power house nearby will be completed next year. A larger intake at Cote St. Paul was finished this season. Above Cote St. Paul, a mile of new cement wharf has been built.

Adjoining the easterly limits of the harbor are the newly completed works of Canadian Vickers, Limited, where $3,000,000 worth of construction has been completed during the year in addition to the floating dry dock valued at $1,750,000. These works consist of an iron-workers' shed, constructed in 3 bays, one being 300 feet long and the others 500 feet each, the width being 50 feet; mechanics' shop, 100 ft. x 50 ft.; joiners' shop, 120 ft. x 100 ft., 2 stories; ship building berth, 500 ft. x 132 ft.; power house, gas plant, etc., in addition to a 1,000-ft. x 500-ft. filling out basin with reinforced concrete retaining walls. Between 4 and 5 miles of service tracks give connections with the C.P.R., C.N.R. and G.T.R. In this plant some 600 men are now busy, most of them on a million-dollar icebreaker for use in the St. Lawrence River by the Dominion Government, the second largest icebreaker in the world. It is hoped that the launching will take place next June. Next month they will start a new $835,000 bucket dredge, ordered by the Dominion Government. It is to be delivered early in 1916. During part of the season as many as 1,500 men were engaged. Twenty-seven vessels have been repaired in the dock during the summer.

A NEW SWISS TUNNEL.

The tunneling problems incident to the projection of railways in Switzerland and Northern Italy present features of considerable interest to engineers on this continent. The fact that several tunnels have recently been pierced has received comparatively small publicity owing to the prominence of military affairs in Europe. The Hauenstein base tunnel is 5 miles 94 yards in length. The Munster-Grenchenberg tunnel is slightly longer, being 5⅜ miles in length. The latter was commenced in November, 1911, and is being constructed by the Bernese Alpine Railway Co., the builders of the electrically equipped Lötschberg tunnel. (See *The Canadian Engineer*, October 30, 1913.)

The Munster-Grenchenberg tunnel is, according to "The Engineer" (London), costing about $5,000,000. It is being laid with a single track only, and will have steam traction. It will be used under the direction of the Swiss Federal Railways. The new tunnel pierces the Jura Range, the height of mountain overhead having a maximum of 2,624 ft. The chief difficulties encountered in its construction appear to have been due to subterraneous springs and water pockets. As in the Simplon tunnel (see *The Canadian Engineer*, May 14th, 1914) a difficulty arose, prior to piercing, owing to water having accumulated in one shaft, and great care had to be exercised not to allow it to flood the other shaft.

The tunneling has been done for the most part with Meyer hand-boring machines.

The period allowed for building is 3½ years. The masonry lining of the tunnel is already well advanced, and it is confidently expected that it will be entirely finished within the specified time.

A list of European tunnels with their locations, lengths, summit levels and dates of operation appeared i this journal for March 26th, 1914, page 508.

The Canadian members of the International Waterways Commission were in conference in Washington last week It is stated that the subject under discussion was the matter of polution of boundary waters.

DESIGN, MAINTENANCE AND OPERATION OF PLANTS FOR TREATMENT OF SEWAGE.

At the recent convention of the American Public Health Association, held in Jacksonville, Fla., the question of sewage treatment received worthy consideration in the valuable progress reports presented by several committees of the association. One meriting careful perusal had to do with the design and operation of treatment works, and was submitted by the committee on sewerage and sewage disposal, consisting of Messrs. Geo. S. Webster, chairman; Frank A. Barbour, Geo. A. Johnson, Langdon Pearse, and F. Herbert Snow. A portion of the report is as follows:—

All disposal works should be recognized as machines which require intelligent supervision and which, if properly designed and maintained, can be made to produce just that quality of effluent which the diluting capacity of the local stream will render satisfactory. In this way greater general progress in the betterment of stream conditions will result.

It will frequently happen that, in small streams, the dry-weather flow can, with profit, be increased by the intelligent use of stored upstream water, and the discharge of a partly treated sewage thus made possible at all seasons.

Where the two-story type of tank is adopted care must be exercised that the tanks are not made too large, as under such circumstances they are liable to fail of their purpose by reason of the sewage in the settling chamber becoming septicized and creating nuisance.

Patented Processes.—Town authorities should not deal with the proprietors of any patented processes or devices for sewage treatment without the assistance of some competent advising engineer.

The treatment of sewage has always seemed to be a particularly fertile ground for the exploitation of patented methods, from the early days of the many processes of chemical precipitation to the present-day electrolytic treatment; many of these schemes, while apparently successful in the experimental plants, are entirely infeasible on a practical scale. There is danger in deducing results from small test apparatus without scientific study by a qualified expert; often the cost of such treatments, when undertaken practically, is prohibitive. The proprietor of a process who is looking for a contract will give a bond and make various propositions which appeal to the people of a town and in this manner lead them to favor the acceptance of such propositions. Many costly mistakes have been foisted on communities in this way.

Processes of Treatment.—Sedimentation and Sludge Digestion.—Usually the first process of treatment is the removal of the solid matters which have been maintained in suspension by the velocity of flow in the sewer. In the past, when the solids were allowed to settle in tanks in which the sewage flowed over and in contact with the putrescent deposits in the bottom, odors resulted. Also, when the deposit from such tanks, called sludge, was placed upon the ground or upon drying beds, the foul emanations added to the nuisance. But within recent years, two-story tanks have been devised and are in successful operation whereby the sewage is settled for a short period of time in the upper story and the sludge allowed to remain in the lower compartment of the tank sufficiently long for the decomposable matters to digest, and the settling sewage is kept from coming in direct contact with the digesting sludge.

Such tanks will discharge an effluent practically free of settleable matter in nearly as fresh a condition as when received. The gases evolved during digestion of the sludge away from contact with the sewage are principally methane or marsh gas and carbon dioxide, both of which are inodorous. Sludge withdrawn from such tanks after digestion is inoffensive, dries quickly and may be used for filling low land or for agricultural purposes with no danger of nuisance.

Oxidation.—If the conditions require more refined treatment than sedimentation, it becomes necessary to adopt processes for oxidation. This may be accomplished by means of intermittent sand filters, contact beds or sprinkling filters, the choice of which is largely dependent on the availability of different construction materials and the size of plant to be installed. Intermittent sand filters are only economical where large areas of sandy soil are available. The sprinkling filter, on the score of economy and on account of the maximum efficiency secured on a minimum area of land, is generally given preference; yet under certain conditions contact beds are justified.

The present-day tendency is to adopt processes which will maintain, as far as possible, aërobic conditions in the liquid at all stages through the plant; the maintenance of such aërobic conditions is the primary consideration in avoiding nuisance.

Disinfection.—As the purpose of disinfection is the destruction of pathogenic bacteria, in order to provide a double safeguard against water-borne diseases, it can be generally said that disinfection of sewage is an unnecessary refinement, unless the effluent of the sewage-treatment works is discharged into a water course adjacent to and above the intake of a water-purification plant, and even in such a case the responsibility of protecting the public health should rest upon the purification of the water.

It is not practical to disinfect crude sewage containing particles of organic matter of appreciable size, as with the usual period of contact it is impossible for the disinfectant to penetrate the solids.

Odors and Their Avoidance.—The amount of odors depends largely on the freshness of the sewage and the method of treating and handling the sludge. The freshness of the sewage depends largely on time of travel and the design of the collecting system, on the adaptation of size to discharge, the provision for self-cleansing velocities and on the ventilation of the sewers so as to provide as much natural aëration to the liquid as possible. If the sewage is fresh or if, in other words, it contains dissolved oxygen, there will not be serious odors from the application or treatment of the liquid portion, provided the plant is maintained with no lodgment of sewage in pools or overloading of the surface of the filters.

There is a potential cause of odors in the sludge. But by the use of the more modern type of tanks, with thorough digestion of the decomposing solids and discharges on properly prepared sludge-drying beds, under favorable weather conditions, no odor of serious moment, noticeable more than a few hundred feet, should ever occur. Odors can be largely eliminated by good design, but their occurrence depends more particularly on proper supervision of the plant.

By the use of the two-story sedimentation tanks, which provide for the digestion of sludge, and by care in the management of the works, plants are operated in Europe and in this country where no odors are noticeable either from the sewage or from the sludge during drying.

In plants where other methods of treatment are adopted it is probable that odor will be produced. It has been estimated that at such a plant capable of treating the sewage of 50,000 people, with good management no odors should ever be apparent beyond 1,000 to 1,200 ft. from the works, even when sludge is being discharged upon the drying beds or in the spring when the filters are in bad condition, due to the past winter interfering with work being done on them.

With smaller plants this distance should be less, and with larger plants possibly more. By diffusion, of course, the odor becomes more faint as the above-named distances are reached, and beyond these distances no odor should be noticeable. What might be termed odors, strong enough to be disturbingly disagreeable to a person whose nasal sensitiveness is not affected by his knowledge of the source of the odor, should, perhaps, never be found at a distance more than one-third of those mentioned. It should, however, be noted that an odor from a sewage plant which, if from a farm would never be noticed or would be accepted as simply natural and reasonable, will generally develop complaints of nuisance. Sentiment, regardless of facts, frequently blames on an inoffensive sewage-disposal plant bad odors from other sources. In short, sewage-treatment works should be as isolated as is economically possible.

For the avoidance of odors, the fundamental considerations are the delivery of the sewage as fresh as possible at the plant, the application of the liquid portion to filters before the sewage has become stale, and the proper treatment of the sludge so as to render it comparatively odorless and easily handled.

Sewage-Works' Attractiveness. — Disposal plants should be made attractive by planting and parking, and no money can be better spent than this. The trees to some degree prevent the spreading of the odors, and in the planting of trees and shrubs the direction of the prevailing wind should be taken into account.

Local authorities, when they first take up sewage-treatment for consideration, frequently look upon the plant as a dump for municipal waste, and it never occurs to them that it is good policy to spend money to make the works so attractive that people will voluntarily make it the objective point of their Sunday afternoon strolls.

Such beautification and the proper maintenance of the appearance of the plant are the surest and best means of preventing complaints of odors or nuisance; this because of the psychological effect on those living near the plant, and also on the attendants, who unconsciously adopt a higher standard of cleanliness and care of the works.

Another notable report was that presented by the committee on sewage works operation and analytical methods. This committee consisted of Messrs. W. L. Stevenson, chairman; C. B. Hoover, H. C. McRae, Langdon Pearse, Geo. C. Whipple, and F. E. Daniels. One interesting feature of the report is its recommendation to the laboratory section of the association that it take up for consideration the improvement of the test for suspended matter in sewage. In respect to this test, to which it refers as a test for not only the amount but also the condition and physical characteristics of this suspended matter, the committee states:—

Suspended matter was first determined by the difference in the weight of the residue upon evaporation of a portion of the sample filtered through paper and another unfiltered. At the present time, the Gooch Crucible is generally used to obtain the weight direct. In both procedures the organic portion of the suspended matter was estimated by determining the loss of weight upon ignition. The Royal Commission on Sewage Disposal attempted to devise a method for determining the amount of suspended matter by means of the centrifuge. In the works of the Emschergenossenschaft a simple field method is in use for determining the bulk of the settleable matter by subsidence in graduated conical glasses.

None of these methods, however, furnish information concerning the size, physical condition or other characteristics so essential to know in the preliminary treatment of sewage. One of the reasons for this is the small size of the sample examined and the difficulties of obtaining a representative portion for analysis; for the inclusion or exclusion of a large size piece of suspended matter in a small sized sample will cause large variation in the result obtained.

The efficiency of all preliminary processes depends upon the removal of the settleable solids and, therefore, a test to measure them is of great importance.

It is, therefore, recommended that in sewage works operation some procedure for the determination of suspended matter be used and that analysts be urged to devise a technique to supply the information required.

Another recommendation of the committee urged that during the coming year analysts direct their attention to the simplification and standardization of the test for avidity for oxygen, or, in other words, a test for measuring by incubation the avidity of the sample of sewage or effluent for dissolved oxygen or its equivalent. The Royal Commission on Sewage Disposal developed a technique for such a test. Another method was developed by Mr. C. B. Hoover and is in use at the sewage treatment works at Columbus, Ohio, and still another has been devised by Dr. Arthur Lederer and is in use in the laboratories of the Sanitary District of Chicago. At present, a committee of the laboratory section of the association was about to propose a provisional procedure for such a test.

A NEW MANGANESE STEEL.

An improvement in manganese steel alloys is announced in a recent United States patent. Commercial manganese steel contains from 11 to 14 per cent. of manganese, and hitherto any attempt to produce a steel lower in manganese than 10 to 11 per cent. has tended to make a metal nearly as brittle as glass and unfit for commercial use. The invention is based on the discovery, made by the inventors, that a certain critical relation exists between the percentage of manganese and the percentage of carbon employed with it in the alloy, and that by proportioning the carbon ingredients in accordance with this relation, a steel may be obtained containing from 6 to 9 per cent. of manganese, or as low as 5 per cent., and "possessing to a very valuable degree the characterictic combination of ductility with hardness and the other important properties of the richer alloys." It is believed that there is a practical limit, around 5 per cent., for the diminution of the manganese, according to the invention. The ingredients of the product are perfectly brought together in a molten state, as is usually the custom with manganese steel alloys. After casting, the metal is properly water-toughened. The new alloy is a poor conductor of heat and practically non-magnetic.

LARGE EGYPTIAN PUMPING PLANT.

One of the largest installations of pumps in the world is being made for the Egyptian government, to drain Lake Mareotis, near Alexandria. The plant will consist of eighteen pumps of the Humphrey type, each capable of delivering 100,000,000 gallons of water a day through a lift of twenty feet. Each pump is eight feet eight inches in diameter.

AN ALTERNATIVE METHOD OF MACHINE-FIRING BY COAL OR GAS.

As the question of gas-firing is apparently coming into prominence again in some parts of the Dominion, and as in some directions there is plenty of discussion on the subject, our readers will no doubt be interested in the interesting installation recently completed by Edward Bennis & Co., Limited, Little Hulton, Bolton, Eng., at the South Staffordshire Mond Gas (Power and Heating) Company's works at Dudley Port, Tipton. The plant comprises eight producers, each capable of gasifying 20 tons of fuel per day of 24 hours, and generating sufficient gas to drive gas-engines of 2,000 h.p. continuously. The total capacity of the present section is thus equal to 16,000 h.p.

The fuel is brought by boat into the canal basin, or by rail onto the siding, both having been specially constructed, and is loaded by hand into bunkers; the entrance to these from the boats is a little above water-level, and at the ground-level from the trucks. From these bunkers the fuel is automatically fed into two conveyers, each having a capacity of 40 tons per hour, and which convey and distribute the fuel into the storage bunkers over each set of producers. The bunker over each producer will hold 40 tons; i.e., sufficient to keep the producer working for two days.

The gas, after leaving the producers, is thoroughly washed in mechanical washers, and after passing through the ammonia recovery and gas-cooling towers, is further purified by large centrifugal fans and then passed through the scrubbers and the meters, before being compressed and sent through the mains for distribution. The machine-stokers, which are arranged to burn either coal or gas, are of the Bennis sprinkler type, of which an integral feature is the self-cleaning compressed air furnace. The boiler plant of the gas company consists of three Lancashire boilers each 9 ft. x 30 ft. with extended flues, working at 120 lb. pressure. They are fitted with superheaters, the gases discharging into an economizer containing 4,000 sq. ft. of heating surface. The total grate area of each boiler is about 57 sq. ft.

Some time ago it was decided to substitute mechanical firing for hand-firing, and a definite guarantee was given by the stoker-makers that the evaporation of each boiler should not be less than 12,000 lb. of water per hour, with an over-load evaporation of 15,000 lb. per hour when desired for short periods, and an efficiency of 72% was also conceded.

The qualified staff of practical chemists employed by the gas company were entrusted with the task of making tests which should establish the results of the work actually done by the boilers. The tests showed not only that the guarantees were maintained, but an appreciable increase on the figures had been achieved. For instance, the overload evaporation of 17,000 lb. of water per hour from each boiler, instead of 15,000 lb. per hour, was obtained.

The gas company, prior to the installation, had found no little inconvenience owing to the fact that steam was required to be kept both during the night and from midday Saturday until Monday morning, when it was desirable that labor duties should stand at a minimum.

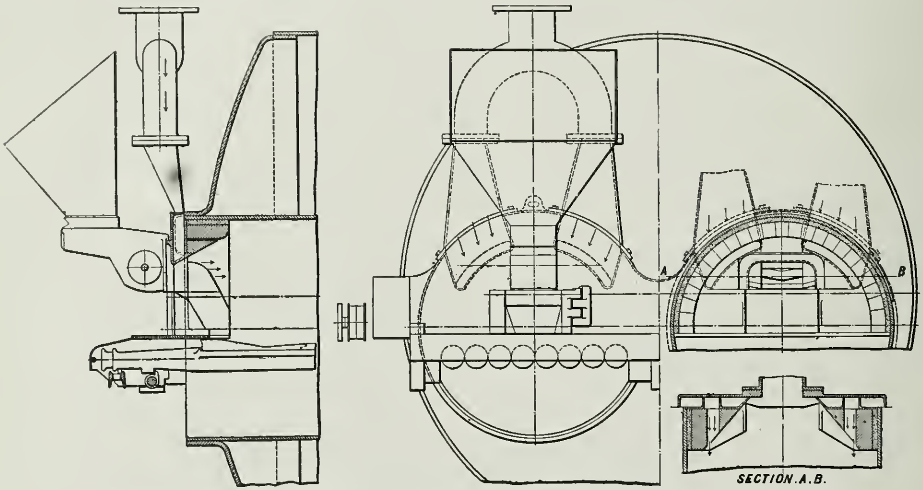

Fig. 2.—The stoker and self-cleaning compressed air furnace arranged for coal and gas-firing.

The problem was: could the mechanical stoking plant be so arranged that it could be coal-fed in the ordinary manner at ordinary times and the boilers gas-fired during the hours of night and at the week-ends? It was shown that, owing to the flexibility of the system of machine-stoking, illustrated herewith, the desired duality was perfectly practicable.

A reference to the illustration will show the gas ducts let into the top flange of the stoker front and secured by means of a gas-tight joint. The baffler plates which are situated behind the front are arranged with a passage, the outlet being over the grate; the gas passes thus from the ducts to the furnace. There are two ducts to each flue; that is, of course, four to each boiler, each pair containing a breeches pipe placed immediately behind the hopper and passing thence to the gas supply, constituting an extremely simple and satisfactory arrangement. It is, of course, essential that air should have access to the gas; a valve is, therefore, placed on the furnace front with an adjustable cover to regulate the amount of air supply. The air is conveyed into the furnace through a separate

air duct and does not mix with the gas until it reaches the inside of the flue where ignition takes place.

For four years this dual system of firing boiler furnaces has been in operation at the works mentioned, and the results have been such as to justify the firm in applying the idea to all their extensions of boiler plant, since the method was first adopted. Repeat orders have been placed for machines of the same pattern to those already supplied, for their new installation of boilers. The secretary of the gas company states that the thermal efficiency obtained during a six months' run under all conditions and variations of load, including times when parts of the plant were off for cleaning and inspection, was 73%. The average quantity of water evaporated per boiler per hour for a month's run was 14,880 lb. During this period the boilers were fired with slack during the day, and gas-fired during nights and week-ends.

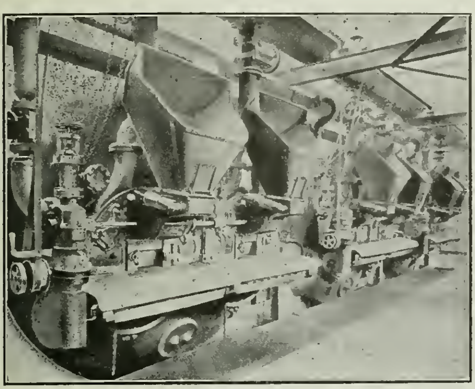

Fig. 1.—Stokers installation in the boiler-house of the South Staffordshire Mond Gas Company.

PRINCE RUPERT SHIPBUILDING PLANT.

The Grand Trunk Pacific dry dock and shipbuilding plant at Prince Rupert is being rushed to completion, and the close of the year will probably see all shops and tools ready for operation. The ship shed, served by two overhead cranes, is finished, as are also most of the auxiliary shops, including the boiler plant with its battery of six 400 h.p. water tube boilers; the power house, with two 1,000 k.w. generators, and electrically driven compressors to furnish air for the boring and driving tools. There is also a foundry capable of handling 20 tons of iron a day, a boiler and blacksmith shop with tools of large capacity and a machine shop with tools including a 76-inch swing by 50 feet between centres engine lathe, a 10-foot boring mill, a 6 by 6 by 20-foot planer, a drilling and milling machine, a 6-foot radial drill and many other similar tools.

Seven large pontoons have been built, three of them under the ship shed and four for the dry dock. Three of the latter are in place and the erection of the steel wings upon them is under way.

The machines have come in over the Grand Trunk Pacific lines. A yard locomotive crane has been used in their transfer to the shops. A 50-ton derrick has also been erected at the outer end of one of the piers.

PUBLIC UTILITIES AND THE PUBLIC.

At the Conference of American City Mayors, held at Philadelphia November 13 and 14, 1914, Mr. Delos F. Wilcox, consulting franchise and public-utility expert, New York, presented a paper which dealt in a clear-cut way with the factors which enter into the problem of relationship between the public and the privately owned public utilities serving it. The antagonism between the two bodies was commented upon in our issue of last week. This antagonism is responsible for the undue prolonging of many sorely needed developments, as the experiences of many of our cities will testify. Mr. Wilcox approaches the question from an intelligent and thoroughly studied position as the subjoined extracts from his paper show.

In discussing the antagonism mentioned above he observes that while this antagonism often assumes exaggerated, unintelligent and even fantastic forms, and while there is a substantial community of interest along many lines between the public and the utility corporations, we must not blink the fact that there is a permanent and fundamental conflict of motives between them. No amount of regulation and no possible development of good-will and the spirit of co-operation can change the fact that private corporations operating municipal utilities do so for profit and for as much profit as they can get, while the consumers and the public strive to get as much service as they can at the least possible cost.

The discussion of plans of campaign against high rates, poor service, political interference, financial tyranny and all the rest of the evils which we have set out to smite can only lead to confusion of counsels unless we clearly grasp certain underlying issues involved in the relations between the cities and the public utilities. Without having definite thoughts on these issues, we can not think straight on anything else, and without knowing what any particular speaker's thoughts upon them are, the rest of us can have no measure by which to gauge the importance or fathom the meaning of what he says.

The underlying issues are:

(1) What shall be the recognized character of public-utility investments

(2) What shall be the attitude of the city toward public utilities as money-earning enterprises?

(3) What attitude shall the cities take toward ultimate municipal ownership?

Mr. Wilcox answers these questions in the following manner:—

Character of the Investment.—Public-utility investments should be placed upon a non-speculative basis, and their security should approximate that of municipal bonds.

In the establishment of the non-speculative character of these investments, cities should not undertake to make good past losses.

So far as future investments in the standard utilities are concerned, the cities should assume the risks of loss due to unforeseen causes, and should substantially guarantee the integrity of all investments made at the request or with the approval of public authority.

Public Utilities as Money-earning Enterprises.—In my judgment, public utilities should not be regarded as a legitimate source of profit to be used for the relief of general taxation.

Compensation for franchise grants, and special taxes or license fees imposed upon public-service corporations should not be encouraged, unless the proceeds of such compensation or taxes are to be used in paying for the property.

Every individual public utility should be made to render a clear account of itself and, as a general rule, should be self-supporting.

Public-utility services should be rendered as nearly at cost as practicable, except that the rates should include a sufficient contribution to retire the investment within a definite period of time.

Public utilities should receive credit for all the service rendered by them to the city and its various departments, but only under unusual conditions should the city assume to subsidize a public-utility service out of the proceeds of taxation or otherwise.

Ultimate Municipal Ownership.—In my opinion, cities should not assume that public utilities are to remain permanently as private investments under private operation.

On the contrary, they should assume that all the well-established utilities will sooner or later be publicly owned, private capital being entirely excluded from the public streets except as it is loaned to the city.

In their franchise grants, and in all contracts affecting rates or granting privileges, the cities should establish the option to take over the utilities either at pleasure or at reasonable fixed intervals.

Wherever possible, the cities should go still further and without more delay definitely set in motion the machinery necessary to compel the gradual withdrawal of private capital from the public streets and the gradual acquisition of the utility plants by the cities as public property.

HIGHWAY INVESTIGATION IN SASKATCHEWAN.

The highway commissioners of Saskatchewan are endeavoring to secure accurate information dealing with every road in the province, and with this end in view the board has asked the collaboration of all councillors and secretary-treasurers of the rural municipalities. The officials are being supplied with maps and asked to supply information dealing with the following points: Graded roads in good condition, proposed roads already graded or new roads which should be graded, parts of proposed improvements that require immediate attention, graded roads that should be improved by cutting down hills and widening grades, government bridges not shown on the plan, bridges urgently required, etc. It will be seen from these questions that when the information is accurately tabulated the highways commission will have an accurate record of the condition of all roads in the province.

MANUFACTURE OF WOOD ALCOHOL.

In the course of investigations of the wood-distillation industry of New York by the college of forestry at Syracuse, it was found that the removal of the tariff on grain alcohol had hurt the market on wood alcohol in such a way as to make it hardly profitable to produce wood alcohol at this time. Chief products of the destructive distillation of wood are charcoal, wood alcohol, and acetate of lime. Charcoal is used for gunpowder, for fuel, in the manufacture of iron, and for various poultry and animal foods. Acetate of lime is used almost wholly in the dye industries. Wood alcohol is used largely as a solvent and for various chemical purposes. Beech, birch, and maple are the best woods for the production of wood-distillation products; heartwood is better than sapwood because it does not contain so large a percentage of moisture. Elm, chestnut, and cherry are not desirable woods for the wood-distillation industry because they contain too much tannin, gums, etc.

A Consolidation has been effected of the Lake Shore Railway Company and the New York Central Railway Company. The merger involves $300,000,000.

ROAD IMPROVEMENT.*

By W. A. McLean, C.E.,
Commissioner and Chief Engineer of Highways for the Province of Ontario.

THE present era is remarkable as one of rapid and convenient travel, transportation and communication. In this it is distinguished from all preceding ages. Invention has shown more marked advance in this phase of modern civilization than in any other. Every refinement has been sought, and vast expenditures have been made on steam and electric railways, ocean and lake steamship lines, harbors and canals, express, postal, telephone, telegraph and cable services. The motor vehicle is becoming a necessity for the transaction of business and even the air has been conquered as a practical medium for human locomotion. All these have not lessened but rather have increased the need for better common roads, and the demand for their improvement is accumulating with marked intensity.

The road situation of to-day presents many problems. It is doubtful if road conditions will ever be without their problems, for changes are constantly taking place, requiring an equivalent adjustment in methods of dealing with them. But it is also true that the present generation has opportunity to advance in this regard far beyond reasonable heritage or desires—for in general common road construction has been neglected, has been side-tracked and forgotten in the hurry of railroad construction.

New demands are pressing; advanced methods of construction are needed; old systems of organization are inadequate; old abuses and prejudices are persistent; opportunity for reform and progress is abundant and urgent.

The work of this association, and particularly that of the annual convention, is to its active members a matter of continuous but ever-reviving interest. Until the last ten or fifteen years, road construction in the open country was well served by water-bound stone and gravel, and was governed by established practice. Roads were built for horse-drawn traffic only, and the weight of loads was comparatively light. With the general use of rapid motor vehicles an entirely new form of wear has been added to that of steel tires and steel-shod horses; the weight of loads has largely increased, placing a much greater demand on road foundations and on bridges; the use of roads has greatly increased, especially on highways carrying suburban and interurban traffic. Road-building is in a reformative stage, and the annual accumulation of experience is steadily shedding new light on a very complex problem.

The growing difficulties of road construction and maintenance are not without their reward. The increased use of the roads means their increased usefulness. The possible service that may be performed by the common road is in proportion to the efficiency of the vehicle. The motor passenger vehicle and the motor truck have greatly advanced the general public value of the common road; and whereas good roads were regarded, a few years ago, as solely of rural concern, urban centres have become keenly alive to their value, and are willing to bear a fair proportion of the cost. The value of roads as a means of travel and transportation has increased manyfold. Instead of the farming population being expected to meet the entire cost, it is now fully conceded that, as regards

*Presidential address, American Road Builders' Association Convention, Chicago, December 15th, 1914.

main roads, cities must share the burden as with any other department of transportation.

Correlation of Facts.—The number of elementary materials used or dealt with in road-making is strikingly few, and, with minor exceptions, these materials are included in a brief list—sand, clay, gravel, broken stone, asphalt, tar, oils, vitrified brick, creosoted wood, stone setts, and Portland cement.

To these may be added a few materials of local service, such as oyster shells; or proprietary binders, such as Rocmac or Glutrin. While the elementary materials are few in number, the range in quality is wide, their combinations are many, conditions of traffic are of varying degree, and such factors as climate, workmanship and cost must be considered.

In the solution of road problems, at the present time, effort should be largely given by scientific engineers to the accumulation of facts respecting road materials and their action under climate and traffic. Much has been done in the past five years in this regard, and it is confidently expected that the next five will do more. Experience will then more nearly approximate the anticipated life of new materials and new methods. The status of knowledge respecting road construction in the next five years will largely depend on the care and thought with which we, at the present time, assemble and correlate obtainable facts. This is a matter which should be especially impressed upon municipal bodies, and co-operation with their engineers obtained, in order that experiment, test, and the collection of data may be effectively carried out.

Roads should be built according to traffic. To a proper solution of the problem of road construction and maintenance, there is much need of the general acceptance of uniform traffic standards. Traffic, in relation to the results from a paving material, is sometimes loosely described as "light," "medium" or "heavy." These terms have all grades of meaning according to locality. In one district 200 vehicles a day would be considered heavy traffic, while in another 2,000 vehicles might be medium traffic. When traffic standards have been clearly defined, and data is accumulated as to behavior and cost of a material under definite degrees of traffic, our experience can become of much greater usefulness. What is needed is a greater accumulation of fact, correlated with definite standards of traffic.

Work Should Not be Delayed.—Road-building is a slow process. In the northern States and Canada there are only about one hundred actual days in the year to be fully depended on. A mile a month for six months of the year is reasonable progress for one outfit of machinery.

There are limitations as regards labor and material which cannot be exceeded without greatly increasing the cost of the work. If a community needs a good general system of roads to-day the work should have been commenced twenty years ago. If a system is needed twenty years hence, it should be commenced now.

Permanent Roads.—The term "permanent" as applied to roads is somewhat misleading, and is not always appreciated by the general public. In the full sense of the word, there is no such thing as absolute "permanency." It is merely a relative term. But it is important, in making safe provision for financing road undertakings, that the matter be clearly understood. For all practical purposes, expenditure for the purchase of road allowance may be regarded as permanent; earthwork and certain drainage of an adequate kind may be regarded as permanent; substantial concrete culverts and bridges may be regarded as permanent; heavy road foundations may be permanent. But there is no such thing as a permanent road surface. Traffic and natural disintegration cause the wear and decay of any road surface that can be employed, and adequate provision should be made for the repair and renewal of the surface.

To meet the immediate needs of traffic throughout the United States and Canada, a large amount of construction must necessarily be carried on that cannot be considered of a "permanent" kind. To attempt the task of immediately building, for all traffic, roads that would have a maximum of permanence would be as impossible as it would be economically unwise. A large part of the farm traffic can, for the present, be best served by roads of moderate cost, lightly surfaced with broken stone or gravel, but carefully graded and drained. In many localities even good earth roads (but well graded and drained) maintained by use of the log-drag must be depended upon to meet the needs of traffic, owing to sparse population or the absence of local gravel, stone, or other suitable surface material.

The most unfortunate results have, however, arisen in the treatment of main roads on which, though expensively built, an effort has been made to maintain a heavy bituminous or other high-class surface on a totally inadequate foundation.

Much discussion has taken place during the past year on the subject of road foundations, and has arisen largely from those who attended the International Road Congress in London last year, as a result of their observation of practice in Great Britain and in Europe. European practice in all classes of permanent road construction has undoubtedly in the past tended to greater mass in the foundation than has been generally adopted on this continent. If past practice abroad has proven the need for the massive foundation, it would seem that, on this continent, the use of light foundations should be critically considered, with a view to the adoption of a greater depth of stone and the more general use of Telford or equivalent foundations, particularly for main roads, on which heavy traffic is assured. In the construction of strong foundations there is opportunity for permanency, which will at the same time reduce the cost of repair, for a large outlay may readily arise from attempts to maintain a good surface on an insufficient and yielding foundation.

Fair Distribution of Cost.—A fundamental necessity in creating a system of roads is that the cost shall be fairly and equitably levied on those who benefit. Failure to do so has done much to retard road-building in the past. If the general public feel that the cost of roads is borne in a reasonable degree by those who should contribute, much opposition will vanish. If the farmer feels that he is being asked to build roads for motorists of the cities, he is naturally opposed to proposals for road development on such a basis. Out of this has grown much of the opposition in some localities to the construction of trunk and State roads. A close study of the farmer's viewpoint by advocates of trunk roads will throw light on the road situation as a whole, and will indicate that a successful road policy in any province or state should make provision for the improvement, if not of all roads, at least of those more directly serving farm traffic. Broadly, trunk roads run from city to city, and are commonly parallel to the steam railway. The market roads on which rural traffic most frequently concentrates, radiate from the station, villages and shipping points, and are, in general, at right angles to the trunk roads so often advocated for motor traffic.

Trunk roads are a necessary adjunct of any system of roads. They are desirable, and should be built. They

frequently form part of a system of local market roads, but must be more substantially built to serve the more severe traffic.

It is difficult, however, for even the most patriotic farmer to rest satisfied with beautiful pictures and illuminative newspaper descriptions of the splendid roads of his own state—roads he never sees—while he has still to drive through the mud axle-deep to his local market or shipping point, with nothing being done to remedy that condition. Rural residents of every good farming community want good roads, and are willing to meet a reasonable outlay for them—nor are they opposed to trunk roads if the cost is levied upon the proper source.

A farming community, insofar as is consistent with its prosperity, can fairly be asked to contribute such amount per mile of road as would properly meet the needs of local traffic. For more expensive construction for motor traffic the remainder of the cost should be met from a source representing the contribution of cities or other communities benefited.

Market roads without trunk roads are commonly opposed by cities quite as much as the farmers oppose trunk roads when provision is not made for market roads. Upon a plan of road improvement which includes both, all the people can agreeably unite.

It is not intended to convey the impression that all roads can be built at a stroke, and that a durable road can be at once built to every farmer's gate. There must be a starting point. For this purpose certain roads must be selected for the immediate improvement, others to take their turn later. A study of local traffic conditions will indicate the roads on which traffic seeks to concentrate, and, commencing with these, the general system can be developed from year to year.

There should be no conflict of interest between the two classes of roads. The one is a necessary adjunct of the other in a complete system of roads. The great need is that the value of both should be recognized and adequate measures taken to develop both concurrently; but there should be no effort to substitute one for the other.

Bond Issues.—Much difference in opinion and practice exists with respect to the issuance of bonds for road construction. At one extreme are those who oppose all bonded debt for public roads, while at the other are those who advocate bonds maturing in forty and fifty years. It is probable that, as in most cases of widely divergent opinion, the true solution is in a moderate middle course.

The primary construction of a great system of roads has, in all countries, required large initial expenditure, such as can only be procured by distributing the repayment over a term of years. The construction of main roads, and even good market roads, is as a rule carried on in very disjointed sections, and at a sacrifice of workmanship, if the cost is provided by annual levy only. The necessary initial outlay can, as a rule, be sustained only by borrowed funds.

It may be asserted as a further truism that the term for retiring the bonds should not exceed the useful life of the work. Again, repayment in the briefest possible period is favorable in that the total interest charges are reduced.

In considering the matter, the road structure may be divided into several portions: The system of drainage; the earth sub-grade; the foundation; bridges and culverts, and the wearing surface.

Judging the future by past experience, it may be estimated that long-term bonds for certain portions of the work are justifiable. An effective system of open and under drains, deep cuts, extensive fills, and an adequate width of earthwork; a Telford, concrete or other heavy foundation; concrete or heavy steel bridges and culverts are all of long durability, and may justify long-term debentures. The road surface, on the other hand, has a comparatively short life, and will seldom justify a debt of more than five or ten years' duration. Adequate maintenance is in all cases essential.

The methods of finance as regards the issuance of bonds may thus be based on the life, not of the surface only, but of the several portions of the structure; the bonds for surface costs to be retired in not more than five or ten years, while the long-term period may be applied to what may be more truly termed the "permanent" portion of the work.

It might be logical to approach the matter on the basis of a general estimate, meeting a proportion of the cost, approximately 50 per cent., by long-term bonds, the remainder, or 50 per cent., covering surface costs, to be retired, according to the life of the pavement, in from five to ten years.

To go even further on the ground of safe finance, and to pay something for immediate benefit, a portion of the cost might be met out of the annual levy; but that as a rule is difficult, and may tend to reduce the amount available for adequate maintenance. It need not be added that to meet the cost of maintenance by the issue of bonds should be regarded as a criminal method of finance.

Town-planning.—Town-planning is a matter with which road-builders, we believe, should be closely identified. In this let us not be misunderstood. By "Town-planning" we do not mean the preparation of artistic plans and beautifully imaginative reports frequently employed for municipal advertisement and the promotion of speculative subdivision schemes.

The essential principles of town-planning are largely based on adequate provision for present and future traffic requirements, together with subordinate matters of street and road design.

The question of town-planning is one which should arouse interest in every progressive town and city. The United States and Canada are passing through a period of growth and expansion which, we trust, may long continue, and proper foresight in this regard is a necessity.

The past tendency to allow towns and cities to follow unguided growth has resulted in many objectionable and unfortunate conditions which could readily have been avoided, but which may now only be remedied at much expense.

The Housing and Town-planning Act of England, a recent measure, is accomplishing much, in enabling land-owners and municipalities to enter into agreements for mutual benefit. Main and radial thoroughfares are provided, parks and open spaces are laid out subject to agreement, industrial areas are set apart, residential districts are fixed, and streets, drainage, grades, water supply and many other details are decided upon in a manner that gives every opportunity for favorable and least expensive growth. The advantage to both the public and the land-owner is apparent.

No doubt many towns and cities on this continent, now comparatively small, are destined to a very considerable growth, and by well-devised measures, the gradual widening of existing streets, the opening of new streets, grouping of public buildings, etc., could be provided for; so that town-planning may be applied not only to new areas, but to the favorable treatment of old districts and the removal of existing defects. Practical town-planning

is of much value in meeting the present and future traffic needs of urban communities.

Present Financial Influences.—The influence of the war on the financial situation is a feature of much importance as regards the present and immediate future of road-building on this continent. On the declaration of war by European powers in August last, while much uncertainty was felt, there was remarkable freedom from panic in the money markets of the world. Since the commencement of hostilities there has been a decided improvement. Crops, on the whole, in the United States and Canada have been good, and farmers are receiving good prices for their produce. While the flotation of municipal bonds is difficult, and capital is showing a natural timidity, there is a growing tone of optimism which promises much.

While municipalities and state governments of the United States are feeling the effect of war conditions, Canada is more directly influenced, and is, at the same time, meeting a heavy war expenditure.

The borrowing opportunities for Canadian governments are restricted, and while loans for large undertakings are seriously handicapped, means are being developed through local capital to meet necessary and desirable outlay.

The construction of roads for war relief has been largely accepted as a logical measure, and while rural municipalities, with a continuance of good crops and prices, will be in an excellent position to carry on the work, the ability of provincial governments to aid large undertakings may not be correspondingly favorable. Here private capital has, in at least one marked instance, stepped into the breach, and the construction of a concrete highway from Toronto to Hamilton (about forty miles) has been organized and commenced since September 1st. A proposal to construct a main road from Montreal to Windsor, across the Province of Ontario (over 500 miles in length), as a great memorial to the Canadian expeditionary forces, has been received with much public favor, and it is not improbable that construction may be commenced as a war relief measure.

The final effect on road construction must largely depend on the duration of the war. Should the struggle, with its tremendous waste, be prolonged for three years, as is predicted by an eminent authority, the ultimate influence on financial conditions is impossible to estimate. Should it be concluded in a year, as many hope, the present feeling of optimism will assuredly not be without substantial foundation.

RAILWAY CONSTRUCTION AT SALISBURY, ENGLAND.

Large numbers of the Canadian troops at Salisbury have recently been engaged in the construction of a light railway to serve their various camps. The roads, which were of a temporary nature, had given way under the strain of heavy tractor and motor truck traffic, engaged in the haulage of supplies. A contract was awarded to Sir John Jackson & Co. for the construction of this service railway, and Canadian engineers, many of them graduates of the universities of this country, Toronto, McGill and Queen's, are engaged in its construction.

In addition, the Canadian engineers have charge of the construction of a water supply system at Bulford and Larkhill.

THE EFFECT OF FROST UPON CONCRETE.*

By John Hammersley-Heenan, Assoc.M.Inst.C.E.

THE engineer who is called upon to carry out work in Canada during the winter finds that the methods of construction which were satisfactory in the summer will need considerable modification to suit winter conditions.

Concrete work, especially the lighter forms of reinforced concrete, used in building construction needs greater care and supervision. As a result of considerable experience gained during the last few years, it can be said that the freezing of concrete will not damage it if it has first had a chance to set under favorable conditions for about two days. The effect of the freezing is simply to delay the process of hardening, which will again proceed under suitable conditions, and will eventually attain its full strength. If concrete is frozen before it has commenced to set, it will not be injured if precautions are taken to prevent it from freezing again after it thaws until it is sufficiently hardened to withstand the effects of subsequent freezings. It is alternate freezing and thawing during the process of setting that causes the damage.

To meet the foregoing conditions, when carrying out concrete work in winter, it is necessary to devise means of mixing the concrete with materials freed of frost, placing it in the forms before it has commenced to freeze, and then protecting it and keeping it warm for about two days. After that it may be allowed to freeze without fear of its being damaged.

In the case of concrete in mass, of large bulk, it is unnecessary to apply external heat, as the large body of concrete will generate sufficient heat during the process of hardening to enable the mass to set; all that will be necessary is to protect the outside of the concrete so as to keep the heat in. This can best be done by covering the concrete with clean straw.

For light sections of concrete, such as in reinforced concrete, poured at a temperature not below 22 deg Fahr., some engineers allow salt to be used in a proportion not exceeding 10 per cent. There are many arguments for and against its use. The author prefers not to use it, except in marine works when the concrete is mixed with sea-water and the salt is admitted in that form. He has found that, instead of using salt, good results will be obtained for temperatures that do not fall below 22 deg. Fahr. by heating the water with a steam-hose taken from the mixer-boiler, and when necessary placing a few coke or wood fires on the heaps of sand and crushed stone, the usual precautions being taken to protect the concrete when in the forms, as described later.

For lower temperatures than those referred to above greater precautions must be taken to heat the ingredients by means of steam coils or radiators.

The concrete having been mixed, and the portion of the work to be carried out decided upon, the floor immediately below it should be partitioned off with tarpaulins, and coke stoves arranged under the floor slab, allowing about one stove to every 800 sq. ft. of floor space. All loose dirt and snow must be removed from the forms with brooms, and a steam hose should be applied to remove all ice and frost, the steam playing continuously over the forms in advance of the concrete, thus

*From a paper read at a meeting of the Institution of Civil Engineers (Great Britain) December 2, 1914.

warming them in readiness for the concrete. The concrete should be poured quickly and continuously, and as each section is completed a tarpaulin may be drawn over it, supported on wooden strips about 6 in. above the surface of the concrete. In most cases this protection will be sufficient, but during very cold weather it will sometimes be found necessary to form a sort of tent over the floor, in which extra stoves are placed to protect the workmen and the upper surfaces of the concrete.

Great care must be taken to have the fires kept burning continuously for two days, after which the concrete may be allowed to freeze without fear.

The work must be examined from time to time until it is found to be hardened sufficiently. During summer working the author has allowed the supports from the underside of slabs to be removed in four days, but on other occasions four weeks have not been found to be too long.

There are many examples of concrete works which have stood the test of time without showing any signs of being affected by frost; but, on the other hand, a few cases have been reported of very serious corrosion due to the action of frost, such as bridge piers and reinforced-concrete piles.

Judging from the information available at present, concrete exposed in air in a dry locality need not be affected by frost any more than good building stone, and probably it will stand much better. Concrete always submerged under water is protected and need cause no anxiety. But concrete alternately wetted and frozen must be protected from frost. On work which is being carried out at Halifax, Mr. John Kennedy, M.Inst.C.E., is protecting the concrete piles between high and low water with a covering of wood about 2 in. in thickness, which it is hoped will prevent the action of frost.

TWO TELEGRAPH SYSTEMS AMALGAMATE.

An arrangement has just been consummated between the Great North-Western Telegraph Company and the Canadian Northern Telegraph Company. Commencing on January 1st, 1915, these two large telegraph systems will be operated as one under the name of the Great North-Western Company. Within the next few months, the lines and offices of the Western Union Telegraph Company in the Maritime Provinces will be operated by the Great North-Western Company, which will then have the largest telegraph system in Canada, it covering the country from the Atlantic to the Pacific. They will have over 1,700 offices in Canada and direct connection with 22,000 offices of the Western Union Telegraph Company in the United States, as well as with eight transatlantic cables, six of which have landing stations in Canada. This insures to the Canadian public a telegraph and cable service with and from Canada unique in its completeness.

Mr. Z. A. Lash, K.C., continues as president, and Mr. Geo. D. Perry as general manager of the Great North-Western Company.

Scientifically speaking, there is no such thing as a waste product, and the word waste has become current because of the lack of knowledge of how to transform residual matter into a marketable commodity. In the study of fuels, for instance, the enormous quantities of carbonaceous substances which exist in different forms, and which have not been utilized or treated in order to extract from them the valuable products they contain, are now being brought into the sphere of commerce by the introduction of new processes. A study of the history of these processes is exceedingly interesting, and indicates very clearly how the theorists have been groping towards the end which appears now to be susceptible to early attainment.

SHEAR AND PROBLEMS ARISING THEREFROM.*

By H. Kempton Dyson.

THE determination of stresses and strains in materials has formed the subject of many investigations. The usual mode of attacking the problem involved has been often referred to as the "mathematical theory of elasticity," which is, however, an all-embracing title that should rightly cover the whole subject. In its narrower aspect it means the mathematical analysis of stresses and strains in an elastic medium that is homogeneous and non-granular. Seeing, however, that such a material is purely imaginary, the mathematical analysis, though strictly exact in itself, may not conform to the facts of the experiment. The mathematical analysis that has arisen from such consideration is a most powerful assistant to the engineer, and by the adoption of suitable functions to suit the peculiarity of the composition of each material, will, within the limits of elasticity, afford many important relations that accord with the facts determined by experiments. Mathematics, including, in large part, the processes which have been evolved by consideration of the ideal elastic substance, have only comparatively recently been applied to another mode of approaching the determination of the stresses and strains in materials in which their granular nature is recognized and their resistance and deformation expressed in terms of the intermolecular forces and motions. Prof. Sir J. A. Ewing has put forward in a tentative way a theory of electrical attraction between molecules, while Prof. A. Rejtö, of Budapest, has worked out in considerable detail a theory dependent upon molecular friction.

Various hypotheses to account for rupture in bodies under stress have been advanced by writers from the point of view of the mathematical relations of a homogeneous, non-granular elastic material. Lame assumed that material was ruptured when the greatest tensile stress reached a limiting value. Poncelet, followed by Sain-Venant, assumed that failure occurred when the greatest extension reached a certain limit. Tresca, followed by G. H. Darwin, suggested that rupture occurred at a limiting value of the largest difference of the greatest and least principal stresses, while Colomb made a somewhat analogous suggestion that failure occurred when the greatest shear reached its limiting value. This view, in recent years, has received much support from experiments conducted by Mr. J. J. Guest, with the consequence that it is often termed "Guest's Law."

The stress at any point can be completely specified by only six components on rectangular axes, three being normal and three tangential to the three planes, in which three axes lie, and further, three planes can be determined upon which the resultant stresses are wholly normal. Such planes are called principal planes, and the stresses across such planes are called principal stresses. The directions of the principal stresses are generally called the axes of stress.

Various experiments on steel and cast-iron specimens under combined stresses clearly seem to show that when rupture occurs the maximum shearing stress is far more constant for ductile materials than the maximum principal stress, but not so for a brittle material like cast iron, where the reverse order of things applies. Brittle materials are weak in tension, and the author of this paper

*From a paper read December 3, 1914, before The Concrete Institute (Great Britain).

offers the opinion that rupture of materials ductile occurs by shearing, but that rupture of brittle materials occurs by tension. Rupture by compression stress alone never occurs. If materials are ruptured under a thrusting load it is by the shear or the tension that is induced thereby, as will be referred to in greater detail hereafter. It is suggested that ductile materials are distinctive in their structure in that they are crystalline in structure and appear to break down by sliding along the cleavage planes of the crystals.

The writer, working on his assumption that brittle materials of distinctly granular structure fail by weakness in tension, has made an analysis of the conditions of rupture of a granular mass in which there is cohesion. The analysis proceeds on allied lines to Rankine's analysis of frictional stability, with the difference that cohesion is not ignored. Various analyses of the stresses existing under such a mode of failure have been put forward by writers on the strength of materials. It has been supposed that brittle materials under stress should fail on planes inclined at an angle of 45 degrees to the direction of the stress. With ductile materials under direct tension the analysis appears to be approximately correct, though Prof. Rejtö contends that the angle of slipping is a characteristic property of the materials and varies with different materials. It is well known that tension specimens draw out at the point of rupture into a conical and cup-like form of fracture, the angles at the faces of the cup being approximately 45 degrees.

In compression, however, with ductile materials the relation does not appear to hold with the same degree of accuracy, the very nature of ductile materials being to swell in compression, and as they swell so their area increases. The stress cannot be increased beyond a certain point, at which they become permanently deformed, according to geometric laws, so that there is no indication of elasticity or tendency to return to the primitive shape. By microscopic inspection of the faces of such compression blocks a justification of the ordinary analysis is, however, found in that ridges are noticeable upon the surfaces showing where the material has slipped upon the cleavage planes of the crystal structure, which slippings occur approximately at 45 degrees. The customary mode of analysis proceeding on the lines of the mathematical theory of elasticity for non-granular and homogeneous elastic solids, as we have seen, leads to the reasonable explanation as regards ductile materials. Navier made a further assumption in an attempt to explain why brittle material did not fracture on planes at angles of 45 degrees, but, as with cast iron and concrete, at some angles inclined in the neighborhood of 30 degrees to the axis of the compressive stress. His assumption was to consider that materials failed by sliding on an oblique plane, and that the friction on that plane had to be overcome as well as the shearing resistance of the material. The author of this paper was led to his other mode of analysis whereby the material was considered as a granular mass with cohesion, by knowing that later experiments did not appear to agree with the values derived by Navier's analysis. Experiments had, indeed, shown that the resistance of concrete to direct shear was very different to the shearing value which was found by Navier's analysis, and punching experiments on concrete specimens again showed different values. The shearing values for concretes determined by different modes of analysis and experiment were found to be different. It remained, therefore, to see if some reasonably uniform relation could be found between the resistance to shearing forces derivable from experiments on direct shear, and from the analysis of the shear stress induced by direct compression. This relation appears to consist in the dependence of the resistance to shear upon friction and cohesion, or as the latter might equally well be termed, tension. A uniform relation is found between the experiments on building stones, concrete, and cast iron in respect to failure under tension, compression and shear. The author next refers to the relations between the bending moments and shearing forces on beams.

Reference has already been made to the fact that experiments tend to show that rupture of ductile materials under compound stress occurs by shearing stress on oblique beams, to have regard to the point where maximum shear will occur. This is often calculated for vertical or horizontal planes, but it requires determination on oblique planes. As regards joist sections, if the web were fairly slender the maximum intensity of shear stress is found at the connection between the web and the flange and not upon the extreme fibre. This points to the conclusion that our standard sections ought to be investigated with regard to their possible weakness at the shoulders,, as such weakness might be very serious in beams of short span.

It is well known that webs need to be stiffened by the provision of vertical stiffeners under point loads to prevent crushing and buckling of the web, and the provision of stiffeners to prevent the rib buckling by diagonal stress is also adopted more or less empirically (seldom by theoretical determination) in the case of plate girders. From the fact that the directions of the principal stresses crossed each other at right angles, at an inclination to the neutral axis of about 45 degrees, the web is in the condition of a strut, so that stiffeners may require to be provided either in the form of vertical or inclined members in order to convert the plate girder into a lattice girder.

In reinforced concrete we have a somewhat analogous position. Reinforced concrete beams are quite a distinct type in themselves, because they pass through two stages in their resistance to cross-breaking. In the first stage the steel remains uniformly connected to the concrete in which it is imbedded. In the second stage the steel slips through the concrete for part of its length and the concrete cracks in the tension portion, so that the beam becomes converted into a form of construction which, in different modes of reinforcing, would appear to consist of either a concealed arch with a steel tie, a trussed beam analogous to the trussed timber beam, or a frame. Frames subjected to transverse loading are, of course, subjected to shearing forces, but the effect of the shearing forces is naturally very different on frames from that on a girder with a solid web or upon arches. A shearing force diagram only consists of the plotted values of the tendency to shear it asunder which the load exerts upon the structural member. We can, therefore, have a shearing diagram equally applicable to a beam, an arch, or a frame, but the manner of using the diagram for determining the internal stresses which result from the shear forces must be different in each case.

Persons may be misled in connection with shearing force diagrams as applied to frames by reason of the similarity between the use of the diagram for calculating stresses in a beam and frame. Whereas the application is close in the case of concentrated loads applied at the connection points of the frame, in the case of distributed loads the shearing force diagram is not so closely related. The fact that the area of the shear force diagram up to any point is equal to the numerical value of the bending moment at that point in the case of freely supported beams will often be found of considerable service in

practice, while the feature that the point of maximum bending moment is the point of zero shear, which is of general application to free, fixed, and continuous beams, is of common employment for the determination of the maximum bending moment.

The fixing of one end and one end or the other have an effect upon the distribution of the shear along the length of a beam. Partial fixity as occurs with continuous beams will affect the shear in similar fashion, and it should be noted also that partial loading of continuous beams (i.e., loading any or all of the spans wholly or in part) will result in different distributions for the shear and gives different reactions on the supports. For this reason the current practice of generally taking the load on the support next to the end of three or more continuous equal spans as equivalent to the load on one span is considerably in error, as is the practice of taking the shear as the same as on a freely supported span. For the determination of shear throughout the length of beams required to sustain travelling loads where these point loads are applied at several points of the span and can move throughout the span, use is made of influence line methods. The shear in the webs of beams is applied to the flanges. This may be considered generally as a gradually increasing thrust from the ends of a beam and tends to cause lateral flexure of the compression flange considered as a long strut.

When the web is stiffened either vertically or obliquely, the stiffeners act as struts, and the web takes diagonal tension like the diagonals of a frame. This diagonal tension tends to cause vertical secondary bending of the flanges between the panel points, which should again be taken into account in the detailing of plate girders.

If the stiffeners are arranged vertically, they convert the girder into practically a Pratt truss, where the stiffeners are in compression. If the spacing of the stiffeners is closer together than the arm of the beams apart, the diagonal tension may still be considered as inclined at 45 degrees, the system becoming one of superimposed trusses. If the stiffeners are diagonal the girder becomes an N-truss. In riveted joints not only the shearing resistance of the rivets but the safe-bearing stress on the plates or other members through which they pass must be studied. Very often the bearing stress is less than the bearing resistance. In using that value, however, it should be remembered that the holes in which the rivets are inserted are punched or drilled large enough to enable the rivet to be inserted easily. Consequently, when the rivet is closed it will have the larger diameter of the hole.

Reinforced concrete beams are quite a special form of construction, because the stresses are induced in them in different ways according to different modes of arranging the reinforcement, and according to the amount of reinforcement; that is to say, a reinforced concrete beam may prefer to act as a flat arch with a tie rod if it is able to hold up in such a form with less stress than it would in some other fashion. On the other hand, if it acts as a beam, the conditions are different in the case where the stress is such as not to have ruptured the concrete by tension therein from the case where the concrete is cracked. Generally, some parts of all reinforced concrete beams are in the uncracked condition, and really require analysis on the lines of a homogeneous section, the materials, however, having different moduli of elasticity both for the concrete in tension and compression and the steel. In the majority of cases the reinforcement is insufficient in amount to prevent cracks occurring at some point or points in the beams, and then when cracks appear it means that the steel has moved in the concrete, and that the construction either consists of a trussed beam or a framed beam in part or in whole. Where the reinforcement is inclined at the ends there is an obvious analogy to a trussed timber beam. Such a type of reinforcement is quite appropriate for point loads. When the cranked bars are in combination with straight horizontal bars a practical type of reinforcement is provided which forms a sort of half-way house, and can equally well resist point loads or distributed loads. In the latter case not only do the straight bars produce one sort of beam action, but the cranked rods resist the shear in that the inclined pull in the bars affords a vertical component at every part of the length to resist the shear.

The resistance to the shearing force of a beam must, in the presence of cracks, be altered to the manner in which an arch, a truss, or a frame resists shearing force. Diagonal cracks in nowise preclude the concrete from taking diagonal compression parallel to such cracks.

It was early found in practical work that it was advantageous to reinforce beams against shearing force in other manners than by trussing members. Either alone or in combination with such vertical reinforcements, web members (either vertical or diagonal) were provided. Numerous patents have been taken out for various forms of separate web members, though often they can be economically provided by turning up the main bars. Where other practical and theoretical conditions preclude one from using so many bars as would enable one to turn up the bars at the proper additional separate members the system may be a double one. The frame action of vertical and inclined web members generally belongs to two types. In the first case, where vertical web members are employed the construction becomes a kind of N-truss, in which the concrete forms compression members and the steel the tension members. In the diagonal form the construction becomes practically a lattice girder. In both types of construction the frames may be, and often are, superimposed; that is to say, the spacing of the vertical members or of the diagonal web members is frequently fairly close.

It should be borne in mind that the theoretical analysis of the stresses in materials is in the nature of a speculation; it is an attempt like all scientific theory to explain the facts, but with the progress of investigation further facts come to light which cause us to modify the former theory. In that way there is a gradual improvement and greater exactitude about theories. But their chief purpose must always remain to draw the attention to the practical engineer to what is happening, likely to happen, or what may possibly happen, and in practical design the complications of refinements in theory are too great to permit of adoption. The practical engineer, by study of the theory, will, however, be able to make his own simplifying assumptions for approximate calculations, which will enable an economical and safe structure to be erected satisfactory in all the directions indicated by elaborate analysis.

Moore's wharf, which handled all the shipping at Skagway, Alaska, including freight for the interior over the White Pass Road and the Yukon River, was destroyed by fire, the loss being estimated at $60,000. Warehouses and contents valued at $150,000 were also wiped out.

Asphaltic concrete must be laid hot and rammed until the surface is smooth. Care must be taken that the materials are properly heated, that the place where it is to be laid is absolutely dry, and that ramming is done before it chills or becomes wet. The rammers should be heated in a portable fire.

Editorial

NICKEL PRODUCTION AND CONTROVERSY.

Since the beginning of the war the daily press has given much space to editorial discussion of the export of nickel. Last week the president of one of the large refining companies issued a statement, as a result, no doubt, of the adverse criticisms which have been given publicity here and there. The point at issue is whether or not the metal, or its oxide, finds its way either directly or indirectly to the armament manufacturers of the enemy, after it has been reduced at refineries, none of which are situated in Canada, the metal therefore being exported before treatment.

A statement of the world's nickel production, and the demand that there is upon it, may not be amiss.

Of the total production, that of Canada forms by far the greater part, and this country has been looked forward to by all world powers, as the source of the metal. The nickel mines of Ontario, chiefly around Sudbury and Coniston, loom large in the affairs of the manufacturers of many important commodities. Of the mineral output of Canada, Ontario comes first with over 40%, British Columbia produces 20%, Nova Scotia 13.4%, while the output of the other provinces is in each case below a rating of 10%. Of the metallic output, nickel is second in quantity (copper leading by a wide margin), and third in value (silver and gold being ahead of it). Of this nickel production, the Sudbury and Coniston mines turn out all except 0.06%, which comes from Dundonald Township, also in Ontario. Compared with the output of the world, Ontario's production in tons is as follows:—

Year.	World's production.	Ontario's production.
1913	30,000	24,838
1912	28,500	22,421
1911	24,500	17,049
1910	20,100	18,636
1909	.....	13,141

The balance of the nickel supply, *i.e.*, what is not produced in Canada, is largely controlled by France and comes from the mines of New Caledonia, which, in 1913, produced about 5,000 tons of matte.

The remaining countries that possess nickel deposits, small in size and importance, are the United States, Norway, Greece and others. Some of the mines, chiefly those in the United States and Norway, ceased operation owing to the great Ontario development. That their production was small is evidenced by the fact that fifteen years ago the annual production of nickel ranged around 7 tons.

The much-talked-of metal has an important use in nickel plating and coinage, but the publicity centering around it at the present time is because of its vastly greater use in the manufacture of nickel steel. Besides its consumption in bridges, etc., nickel steel is much used in the manufacture of armor plate and in many kinds of war munitions.

Since France and Canada, the producers of this coveted ingredient of material for siege guns, etc., are not allied with the manufacture, for Germany, of these and other instruments of war by Krupp's and Tyssen, it has been a matter of considerable comment as to the source of nickel supply that is being drawn upon at the present time by the enemy. In this connection it is interesting to go back to a number of years ago when the suggestion was made, and obtained considerable support, that the export of Ontario nickel ores, matte, or metal, should be prohibited, or limited, to all countries other than Great Britain. The question was considered of vital importance at the time, and since the outbreak of the present war it has received considerably greater attention. Late in October an Order-in-Council was issued by the Canadian government prohibiting the export of nickel to alien countries. It read: "To all foreign parts in Europe and on the Mediterranean and on the Black Seas, save Great Britain, France, Russia (except the Baltic ports), Spain, and Portugal."

As the result of this prohibition (considering it for its effect on mineral production alone), it must be expected that other countries will revive the mining of nickel to as large an extent as possible, and that nickel statistics for the next year or two will probably show the effect of this incentive. Norway's ore contains as high as 2% of the metal, and the electrolytic refineries at Christiansand, with a capacity of about 400 tons annually, are now reported to be at work. Something is to be said about electrolytic nickel, in that, although it has a high degree of purity, the power consumption is so large as to render the process uneconomical, except in a country where current is low priced, as in Norway. Except for a relatively small recovery of nickel in connection with the electrolytic refining of copper, the United States depends entirely upon the Sudbury mines for its supply.

Although Canada figures so prominently in supplying the world with nickel, she has neither nickel refineries nor nickel-steel mills of her own. Processes have been tried out during the past quarter century, but with no success from an economic point of view. The result is that our raw material leaves the country, the Mond Nickel Company sending its product to Wales, and the International Nickel Company refining its metal in New Jersey. Thus the question of what are purported to be economic conditions prevails over ideal conditions, and the Canadian nickel industry is an industry only in so far as it raids a very important natural resource.

Observations have been made, although there is no proof of foundation, that Germany has been drawing her supplies of nickel for naval armament indirectly from the Canadian nickel mines in the Sudbury district. Once the matte is exported, it is claimed, the refiners are at liberty to dispose of the refined product as they please. The proportion which under normal conditions finds its way into the German market, has been stated to be about 60%. The criticisms are illuminated by the allegation that the Krupp Company were, when the war broke out, influential stockholders in one of the nickel corporations. It is further stated that the requirements of the government, that companies with Dominion charters file a list of shareholders annually, has not been complied with in this particular instance.

Whether any or all of these observations are founded upon truth, it is hard to state. At any rate, the latter add fuel to the argument of the former, and to the implication that the Canadian government's Order-in-Council is not preventing an important product of the Dominion

finding its way to the enemy, to be used against the British Empire in the present conflict.

Mr. Monell, in his recent announcement, as president of the International Nickel Company, emphatically states that full information as to the destination of shipments of nickel, made by his company, has been in the possession of the Dominion authorities since the outbreak of the war, and that they are currently kept cognizant of all exports of nickel, as well as of all local shipments of the company. It has been stated that no sooner were hostilities declared than the government and the company had a mutual understanding, and the former was given assurances that no part of the output would be furnished either directly or indirectly to Germany or Austria.

This is the situation and we are not venturing any recommendation to the British Admiralty, in competition to a number that have already been given publicity, some of them displaying more crudeness than loyalty to the welfare of the Empire. It would appear that a number of writers on the subject have overlooked the fact that the British War Office is a remarkably wide-awake organization, and that it is impossible to conceive of its having overlooked the importance of the nickel situation. The co-operative scrutiny to which nickel is being subjected by the Canadian and British governments is such as to warrant a continued production, and assurances that no part of it is being employed by a country unfriendly to the Empire. At the same time, it brings clearly to our mind how desirable it would be if Canada at the present time handled the nickel situation from the ore to the finished product. It is to be hoped that the national security involved therein, as emphasized in the present controversy, will lead to a counteraction against the argument that refinement of nickel at the point of production is not, in this instance, the best procedure. To say that with the present state of the art any material change in such economic conditions (as at present exist) would react in a manner most detrimental to the Canadian nickel industry, is to make a statement that is not self-supporting.

PROPOSED STANDARD SPECIFICATIONS FOR ONE-COURSE CONCRETE STREET PAVEMENT.

IN our issue of December 17th, 1914 (page 753), appeared a set of proposed standard specifications for one-course concrete highway. These specifications are to be submitted, for adoption, at the February meeting of the American Concrete Institute. Another set to be submitted covers one-course concrete pavement and is almost identical with the specifications published in the article mentioned above. The clauses and other respects in which there is a difference are enumerated below.

The two sections devoted to materials and grading are identical, with the exception that the cross-sectional drawings and profile referred to as Fig. 1, in the former set, refer to Fig. 1 as presented herewith. Section 3 is as follows:—

17. Drainage.—The contractor shall construct tile or other drains as shown in the drawings attached hereto. Tile to be laid in the trench at least............inches wide, and............feet deep below the top of the adjacent curb. Such trench shall be back filled with crushed stone or pit run gravel with sand removed, which after light tamping shall be....... ....inches in depth.

18. All catch basin and manhole tops and all covers of openings of any kind shall be readjusted to the grade by the contractor at his expense.

Section 4, on subgrade, is identical with the exception of the second paragraph, which reads: "The street shall be graded from curb to curb to the proper subgrade to permit of the specified thickness of paving materials being laid to bring the finished surface of the pavement to the lines and grades as shown in the plans."

Section 5, devoted to forms, is the same in both specifications.

In Section 6, the note referring to crown and thickness of concrete reads as follows: "The thickness of the concrete at the edges shall not be less than six (6) inches. When pavements twenty (20) feet or less in width are to be built on approximately level ground and a flat subgrade is to be used sufficient fall for drainage at the sides of the pavement along the curb shall be provided by giving the roadbed the same grade as that proposed for the gutter. The crown of all pavements shall not be more than one-one-hundredth (1/100) of the width, except when deemed advisable by the engineer—the crown of a pavement built on a crowned subgrade may be increased to one-fiftieth (1/50) of the width to provide sufficient fall for drainage along the sides of the pavement at the curb."

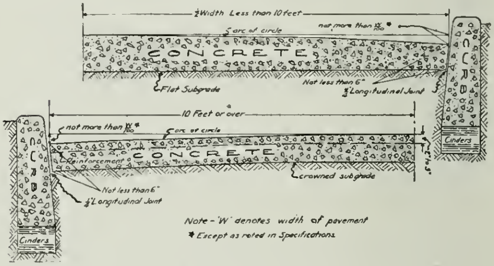

Fig. 1.—One-course Concrete Pavement.

In the section covering joints the figure referred to is Fig. 1, as shown herewith.

Specifications covering measuring materials, mixing concrete, reinforcing, are the same in both specifications. In the clauses covering the placing of concrete, that having to do with finishing, in this instance, reads as follows:—

36. Finishing.—The surface of the concrete shall be struck off by means of a template or strike board, which shall be moved longitudinally or crosswise of the pavement. Concrete adjoining the metal protection plates at transverse joints shall be dense in character, and any holes left by removing any device used in installing the metal protection plates shall be immediately filled with concrete.

After being brought to the established grade with the template or strike board, the concrete shall be finished from a suitable bridge, no part of which shall come in contact with the concrete. The concrete shall be finished with a wood float in a manner to thoroughly compact it and produce a surface free from depressions or inequalities of any kind. The finished surface of the pavement shall not vary more than one-quarter (¼) inch from the true shape.

The specifications relating to curing and protection, and to the construction of shoulders, are the same in both.

ENGINEERS' LIBRARY

Any book reviewed in these columns may be obtained through the Book Department of The Canadian Engineer.

CONTENTS.

BOOK REVIEWS.

Pumping by Compressed Air. By Edmund M. Ivens, B.E., M.E. Published by John Wiley & Sons, New York City; Canadian selling agents, Renouf Publishing Company, Montreal, Que. First edition, 1914. 244 pages, 106 illustrations, 6x9 ins., cloth. Price $3.00 net. (Reviewed by A. S. L. Barnes, Hydro-Electric Power Commission of Ontario.)

This book forms a welcome addition to the comparatively scant literature of the subject with which it deals. While the efficiency of this method of pumping is admittedly low, there are undoubtedly cases where its advantages in other ways outweigh this drawback. For example, to adopt it for pumping clean water to a high head, in a case where there would be men available for attending to the plant at all times would, in most cases, be fallacy but to pump sewage to a moderate head at, say, some underground point, as is frequently done, where special attendants would be needed to look after a comparatively small isolated plant there can be few systems comparable with pneumatic sewage ejectors, which carry out the functions of pumping by compressed air and can at the same time handle sewage as no ordinary form of pump could do, while their action is entirely automatic.

The author cites a case of an air pumping system, for water replacing an old steam pumping plant, in which an over-all efficiency of only 24 per cent. was obtained, albeit an over-all saving of $1,310 per annum was effected.

In this particular case it would, however, be interesting to know what saving could have been effected by putting in a modern steam engine and dynamo driving an electric motor coupled to a turbine pump.

Compressed air pumping is being rather extensively used now for another purpose, viz., pumping water from wells. To accomplish this, several different systems, all embodying the same basic principle, but differing in detail, have been devised. The idea is to force air down the well, under pressure, and allow it to bring up some water in traversing its natural upward path to the ground or some higher level.

Owing to the very low efficiency of these systems at high heads it is preferable, if the total lift be considerable, to carry it out in two or more stages if the conditions will warrant this being done.

Careful and well-illustrated descriptions of several of the best known systems of this kind are given in the book, together with a statement as to their advantages and limitations.

The book is well written, and where formulae are introduced they are of a simple and easily understood nature. The two closing chapters deal respectively with the "flow of compressed air in pipes" and the "flow of water in pipes." At the end is a copious index. The work should prove very useful to both the student and the engineer engaged in dealing with pumping problems.

Concrete-Steel Construction, Part I., Buildings. By Henry T. Eddy, C.E., Ph.D., Sc.D., and C. A. P. Turner, C.E. Minneapolis. First edition, 1914. Published by the authors. Cloth, 6x9 ins., pp. xv.+438, 98 illustrations. (Reviewed by C. R. Young, B.A.Sc., C.E., assistant professor of Structural Engineering in the University of Toronto.)

Although the object of the authors of this book is to advocate concrete-steel construction in general and the mushroom system in particular, the work shows some attempt to cover the general principles of design and execution of reinforced concrete work in buildings. In their efforts to secure the adoption of methods of design that will permit reinforced-concrete construction to successfully compete with timber construction, they do not always remain on firm, well-tried ground. To the discriminating reader, however, the book will be a valuable one.

The text is divided into fifteen chapters. Some of these are given captions, but for about half of them the variety of subjects treated in a single chapter is so great as to preclude their comprehension in a single heading.

Chapter I. is of general interest and applicability. It covers the origin of concrete construction, materials, mixing and handling of concrete and forms. The treatment of the last subject is meagre, the only design shown being one for a column used in connection with the mushroom system.

Chapter II. deals with general types of floor construction, variation of strength with thickness and span, theoretical treatment by proportion of typical panels and deflection of slabs.

Chapter III. is devoted to beams. The methods of analysis and design presented are those of the Joint Committee, except in the matter of diagonal tension and bond which are given original treatment.

In Chapter IV. beam action and slab action are compared through the application of the laws of bond shear and the theory of work, and in Chapter V. is presented the authors' theory of the strength and flexure of the standard mushroom type of construction. The method of analysis followed is, in general, that already set forth by Dr. Eddy in his book "The Theory of the Flexure and

Strength of Rectangular Flat Plates." Indeed, this monograph has been incorporated in the present volume. The soundness of the theory has already been the subject of discussion in the columns of *The Canadian Engineer*. (See issues of September 25th, November 6 and November 27th, 1913.)

Chapter VI. institutes many comparisons of the stresses and deflections as calculated and as shown forth by actual tests. The close agreement of the results is considered by the authors a convincing justification of their theory. So far as floor panels are comparable in size and proportions with those tested, the methods of calculation adopted will probably closely predict the actual behavior of the tested floors, but with any appreciable variation from these proportions the theory propounded by the authors would not likely receive such strong support.

Moments in two-way and four-way flat slabs are fully discussed in Chapter VII.

Chapter VIII. deals with columns and Chapter IX. with foundations. The remaining chapters cover the elements of economic construction and cost of reinforced concrete work, reinforced concrete as a fireproof form of construction, concrete under disintegrating forces, finishing, the relation of the engineer and the constructor to concrete building work, and many other matters.

As a general text for reinforced-concrete construction the book is inferior to at least two well-known treatises. Except so far as it applies to flat-slab construction, it is not so valuable a work on building construction in reinforced concrete as one of the books mentioned above. For those who have to do with flat-slab construction, however, the book is invaluable, but its usefulness so far as other forms of construction are concerned, is limited.

Mechanism of Steam Engines. By Prof. W. H. James and M. W. Dole, of the Massachusetts Institute of Technology. Published by John Wiley and Sons, New York; Canadian selling agents, Renouf Publishing Company, Montreal. First edition, 1914. 170 pages, 183 illustrations, 6 x 9 ins., cloth. Price $2.00 net. (Reviewed by R. W. Angus, Professor of Mechanical Engineering, University of Toronto).

This book is intended as an elementary treatment of the kinematics of steam engines and turbines. It discusses only the mechanisms and some of the resulting motions without any effort to deal with the properties of steam, and must not be mistaken for a general book on steam engines.

After a brief introduction a general description of the simple engine and indicator are given along with some illustrations. Chapters II., III. and IV. deal with descriptions and sectional illustrations of several simple valves and the analysis of the valve motions by diagrams, the Zeuner and Reuleaux valve diagrams being largely used, a knowledge of the principles of these diagrams being practically assumed as only very brief proof is given. The solutions of a number of problems are worked out in the book.

Chapters V. and VI. deal with the different methods of controlling engines either by throttling or automatic cut-off governor or by means of riding cut-off, corresponding valve diagrams being shown. Other chapters treat of multiple valve engines, e.g., Corliss, link motions and valve setting.

The remaining two chapters, X. and XI., are entirely devoted to steam turbines and their governors and valve mechanisms, the treatment being entirely descriptive.

Structural Engineers' Handbook. Data for the Design and Construction of Steel Bridges and Buildings. By Milo S. Ketchum, C.E., Dean of the College of Engineering and Professor of Civil Engineering, University of Colorado. Published by McGraw-Hill Book Co., New York City. First edition, 1914. 896 pp., 400 illustrations, 260 tables, 6 x 9 ins. Flexible leather. Price $5.00 net.

As the name implies, the handbook is expressly for the structural engineer, but its service extends itself to the student or, as the author states, "engineer who has had a thorough course in applied mechanics and the calculation of stresses in structures. One feature of the work that meets with approval at first sight is the size of book chosen, as we are more disposed to consider the 6 x 9-inch page as a standard. This size of page has proved a great factor in the book under consideration, as it has permitted a clear portrayal of diagrams, as well as an easily read type in large but important tabulated quantities. The printing and binding are excellent, and the index, which in the opinion of the reviewer requires more attention in a handbook than it usually receives, will be found exceedingly serviceable.

Proceeding into the subject-matter of the work, the chapters are found to be unusually complete and are here and there supplemented by carefully selected lists of references to which authorities the engineer may betake himself, if desired, for more detailed information.

The scope of the handbook, according to chapter headings, is as follows: Steel Roof Trusses and Mill Buildings; Steel Office Buildings; Steel Highway Bridges; Steel Railway Bridges; Retaining Walls; Bridge Abutments and Piers; Timber Bridges and Trestles; Steel Bins; Steel Grain Elevators; Steel Head Frames and Coal Tipples; Steel Stand Pipes and Elevated Tanks on Towers; Structural Drafting; Estimates of Structural Steel; Erection of Structural Steel; Engineering Materials; Structural Mechanics, and the Design of Steel Details. The book is divided into two parts, the first including (as the above chapter headings suggest) a discussion of the design of structures, together with data and details for the design of steel bridges and buildings; and the second part containing tables for structural design, including those giving the properties of rolled sections, and of built-up sections for chords, columns, struts, plate girders, etc., and data for standard structural details.

The author defines it to be a source book and not a treatise. He thus defines the function of a handbook, and it is evident that he has kept constantly in view the field which he desired the book to cover. Structural engineers, designers, draftsmen and students of the subjects of which it treats, cannot afford to overlook this handbook.

Mechanical Properties of Wood. By Samuel J. Record, M.A.M.F., assistant professor of Forest Products, Yale University, Forest School. Published by John Wiley and Sons, New York City; Canadian selling agents, Renouf Publishing Company, Montreal. First edition, 1914. 165 pp., 52 half-tone illustrations, 6 x 9 inches, cloth. Price $1.75 net.

Students of forestry to whom a knowledge of the technical properties of wood is essential, will find this a most instructive volume, quite free from highly technical treatments, and, in fact, quite readable by anyone interested in wood. An important feature of the work is the inclusion therein of a discussion of the factors affect-

ing these mechanical properties, and the methods of timber testing.

The work is presented in three parts, the first, the mechanical properties of wood, taking up fundamental considerations, tensile compressive, shearing and transverse strengths, toughness, torsion, hardness, and cleavability. The second part deals with factors affecting the mechanical properties of wood, such as rate of growth, weight, density, color, knots, insect and fungus injuries, temperature, preservatives, etc., etc. Part III. is devoted to timber testing, and takes up, forms of material used, moisture determination, machinery appliances, beam testing (large and small), and tests for impact, hardness, cleavage, tension, spike-pulling, etc. One appendix gives a sample working plan of the U.S. forest service. Another gives strength values for structural timbers. A bibliography in three parts well portrays the extent of literature on the subject.

Cement Specifications. By Jerome Cochrane, B.S., C.E., M.C.E. Published by D. VanNostrand Company, New York. First edition, 1912. 101 pp., illustrated, 6 x 9 ins., cloth. Price $1.00 net.

According to the full title of this work, it is a treatise on cement specifications, including the general use, purchase, storage, inspection and test requirements of Portland, natural, puzzolan (slag), and silica (sand) cement, and methods of testing and analysis of Portland cement. In the compilation of the work the author expresses himself as having endeavored at all times to present a set of specifications that would not only be consistent throughout, but which, at the same time, conform to modern practice. He recognizes the futility of endeavoring to draw up specifications which will meet all conditions of engineers and all constructional and manufacturing conditions of actual work, and he observes that it was useless to expect that all provisions incorporated in the specifications would be applicable to every class of construction work. This is mentioned by the way, for the reader will find that the presentation of the subject, growing in importance as the uses of cement are magnified, is clear, complete, and one well worthy of reference.

Besides the introduction, the divisions of the book are as follows: General Conditions Governing Use of Cement; Furnishing Cement to the Contractor; Purchase of Cement from Manufacturers; Delivery and Storage; Inspection and Tests; Test Requirements; Methods of Testing; Significance of Tests; Methods of Chemical Analysis; Bibliography of Specifications; same of Foreign Specifications.

Materials of Machines. By Albert W. Smith, director of Sibley College, Cornell University. Published by John Wiley and Sons, New York City; Canadian selling agents, Renouf Publishing Co., Montreal. Second edition, 1914. 215 pp., 36 illustrations, 5 x 7½ ins., cloth. Price $1.25.

The first edition of Prof. Smith's work was published about twelve years ago. The subject matter has been entirely re-written and brought up to date for the present edition. Its title may be better defined by stating that it is an elementary treatise on metallic materials used in the construction and operation of machines. This is presented in two parts, the first dealing with the manufacture of materials, to which four chapters are devoted, viz., Preliminary Considerations of Fuels; Electric Furnaces; Refractory Materials; Outline of the Metallurgy of Iron and Steel; and, the same of copper, lead, tin, zinc and aluminum. The second part deals with the physical properties of materials, as follows: Testing Materials; The Equilibrium of Iron and Carbon; Cast Iron; Steel; Heat Treatment of Steel; Non-ferrous Alloys; Selection of Materials for Machines. The first part is written as an essential preliminary to the study of the second, while the second part presents some very desirable information for those who design, construct and operate machines. The information which this book contains is not easily collected, and its presentation in a single, small volume will be welcomed with considerable interest by engineers interested any way in the construction and operation of machines.

Municipal Department of Hygiene and Statistics of Montreal.—Report for 1913, by Dr. S. Boucher, M.O.H. 104 pp.

United States Bureau of Mines.—Fourth Annual Report of the Director, for year ending June 30th, 1914. 101 pp.; 6 x 9 ins.

Agriculture and Immigration.—Report of Department, Province of Manitoba, for 1913. 125 pp.; illustrated; 6 x 9 ins.

Determination of the Co-efficient of Expansion of Mercury at Low Temperatures.—By C. B. James. A reprint from the transactions of the Royal Society of Canada. 8 pp.; illustrated.

Tide Tables.—Two bulletins, prepared by W. Bell Dawson, superintendent, Tidal and Current Survey, Department of Naval Service, Canada. One relating to Eastern coasts and the other to Western coasts.

Analyses of Mine and Car Samples of Coal.—Bulletin 85, United States Bureau of Mines, relating to samples collected in 1911, 12 and 13, giving tabulated analyses and descriptions of samples by states and counties. Illustrated.

The Crow's Nest Volcanics.—By J. D. MacKenzie. Published by the Geological Survey, Department of Mines, Canada, as museum bulletin No. 4. It relates to general geology, petrography, discussion, summary and conclusions. 37 pp.; illustrated.

Commission of Conservation, Canada.—Fifth Annual Report, 1914, giving proceedings of the fifth annual meeting, held at Ottawa, January, 1914. 288 pp.; illustrated; 6 x 9 ins.; cloth. James White, assistant to chairman, Commission of Conservation, Ottawa.

Department of Naval Service.—Annual Report for year ending March 31st, 1914. 100 pp.; illustrated; 6 x 9 ins. It contains reports on naval branch fisheries protection service, survey of tides and currents, hydrographic survey branch and radio telegraph branch.

The Expansive Force of Ice.—(See *The Canadian Engineer*, December 10th, 1914, page 741.) A 20-page reprint from the transactions of the Royal Society of Canada. Prepared by Prof. H. T. Barnes, and Messrs. J. W. Hayward and Norman M. McLeod. Illustrated.

Notes on the Sampling and Analysis of Coal.—By A. C. Fieldner for the United States Bureau of Mines. Published as technical paper 76. 61 pp.; illustrated. Collection of samples; methods of analysis; interpretation and accuracy of analytical results; classification, etc.

Ontario Highway Legislation.—A compilation of Ontario highway laws, prepared under the direction of Mr. W. A. McLean, commissioner of highways, and appended to his annual report on highway improvement, 1914. (See *The Canadian Engineer*, December 17th, 1914, page 767.)

Dundee Falls and Falls Village Developments.—A handsomely illustrated booklet, descriptive of these developments for S. D. Warren and Co. and Connecticut Power Co., respectively. Reprint from Stone and Webster Public Service Journal. S. and W. Engineering Corporation, New York.

Fire Prevention.—Reports on various activities of the British Fire Prevention Committee, 8 Waterloo Place, Pall Mall, London, S.W. 40 pp.; illustrated, including Committee's record for 1913; portable chemical fire extinguishers; self-contained smoke helmets; the Committee's inquiry office, etc.

Geographic Board of Canada.—Thirteenth Report, ending March 31st, 1914. It contains all decisions from inauguration of Board up to that date. Also list of counties in Canada and townships in Ontario, Quebec and Nova Scotia, and parishes in New Brunswick. As an appendix, it has an outline of the physical geography of Canada.

Analysis of Coal with Phenol as a Solvent.—A 41-page illustrated bulletin (No. 46), issued by the Engineering Experiment Station, University of Illinois, Urbana, Ill., prepared by S. W. Parr and H. F. Hadley. Deals with the division of bituminous coal with phenol as a solvent for resinic material while the cellulose residuum is insoluble.

American Society for Testing Materials.—Committee reports, being Part I. of the proceedings of the 17th Annual Meeting (1914). It includes reports on ferrous metals; non-ferrous metals; lime, cement and clay products; miscellaneous materials; preservative coatings, etc.; miscellaneous subjects. 484 pp.; illustrated; 6 x 9 ins. Secretary, Ed. Marburg, University of Pennsylvania, Philadelphia, Pa.

CATALOGUES RECEIVED.

Matheson Joint Pipe.—A handsomely illustrated 40-page booklet, descriptive of this system of piping for high and low pressures. Issued by the National Tube Co., Pittsburgh, Pa.

Directory of Piston Ring Sizes.—A 68-page booklet for users of automobiles, motor cycles, cycle cars, trucks, tractors, and engines. Issued by the Burd High Compression Ring Co., Rockford, Ill.

Variable Release Air-Brake Equipment. — A 12-page booklet describing this type of automatic air-brake equipment, its chief advantages, general design, operation, etc. Issued by the Canadian General Electric Co.

Drag-Line Excavators.—Leaflets descriptive of glasses, B, H, and K, of the Lidgerwood line, setting out specifications and illustrating the machine in use. Exclusive agents in Canada, Canadian Allis-Chalmers, Limited.

Lackawanna Deseaming Process for Rail Sections.—A bulletin published by the Lackawanna Steel Co. describing this method of improving the quality of rails. A most interesting discussion of the subject, well presented and carefully illustrated.

Worm-Gear Chain-Blocks.—A 4-page leaflet (Bulletin B 10) on the construction of a chain-block designed for a load of 60 tons, and regularly tested to 90 tons. Issued by the manufacturers, the Herbert Morris Crane and Hoist Co., Limited, Montreal and Toronto.

Oxy-Acetylene Welding and Cutting and its Applications.—An extensive publication issued by L'Air Liquide Society, Toronto, Montreal and Winnipeg, enumerating and illustrating the application of the Autogenous welding process in the different trades. Fully illustrated.

Hoisting Machinery.—A 144-page catalogue, well illustrated and durably bound. Published as Catalogue No. 3 of Marsh and Henthorn, Limited, Belleville, Canada. Sales agents, Mussens, Limited, Montreal. Fully descriptive of their types of hoisting engines and auxiliary apparatus.

Gas-Electric Motor Cars and Locomotives.—Bulletin No. 44,300; 8 pp.; illustrated; of special interest to railway men on branch line service of steam roads and on interurban railway service, to which this class of equipment is specially adapted, issued by the Canadian General Electric Co., Toronto.

Cochrane Multiport Valves.—A handsome, well-illustrated, 72-page catalogue of multiport valves for back-pressure service, atmospheric relief in vacuum service, flow service, and bleeder or extraction service. Catalogue 601. Harrison Safety Boiler Works. Selling agents in Canada, Canadian Allis-Chalmers, Limited, Toronto.

REPORTS OF COMMITTEES, CANADIAN SOCIETY OF CIVIL ENGINEERS.

THE Council of the Canadian Society of Civil Engineers has recently issued, for the consideration of members prior to the Annual Meeting of the Society in Montreal, January 26-28, 1915, the reports of a number of standing committees. Ample opportunity is thus being given to each member for acquiring a thorough knowledge of the findings, as submitted, so that intelligent action may be taken with regard to them when they come up for consideration at the afternoon session of the first day of the meeting. We present herewith a summary of the submitted reports.

Report of Committee on Rails.—The committee, consisting of Mr. H. G. Kelley, chairman, and Messrs M. J. Butler, G. A. Mountain, J. M. R. Fairburn and A. F. Stewart, recommended the adoption by the Society of the rail specifications of the American Railway Engineering Association. The investigations and experiments of the engineers of the committee of that association have been carefully studied by the above committee and their findings, covering both chemistry and mill practice, have produced the specification now well known as the "A.R.E.A." rail specification. A copy of it is presented.

Report of Committee on Track.—This committee consists of Mr. H. R. Safford, chairman, and Messrs. W. A. Bowman, C. B. Brown, S. B. Clement, A. Crumpton, F. P. Gutelius, R. M. Hannaford, R. L. Latham, D. MacPherson, E. W. Oliver, A. F. Stewart, J. G. Sullivan, C. Warnock and A. C. MacKenzie.

The committee devoted itself to the study of two subjects: (1) Size and spacing of ties. (2) The proper method of measuring efficiency of track forces. The study of another subject, viz., Terminal facilities in cities for freight, including private sidings and cartage arrangements was, with the consent of the Council, postponed for the present. For a study of the two above-mentioned subjects the committee presents forms for the purpose of collecting from the membership as much needed data as possible bearing upon the question of track maintenance. Thereby relative values of the various features entering into track work may be arrived at, the idea behind the study being to work out some basis for equating these values as an aid to the proper distribution of allowances for track work.

The committee expresses its belief that the present method of apportioning track expenditures is too general and that no well-defined means exists for properly measuring the relative needs of the different sections and districts, with the vastly different conditions which affect cost. A good deal of data must be collected to this end.

Progress is reported on the specifications for the size and spacing of rails and discussion is invited. Suggested programs for study are presented. (For the 1913 report of the committee on track the reader is referred to *The Canadian Engineer* for January 22, 1914, page 203).

Report of Committee on General Clauses and Specifications.—This committee consists of Mr. H. Holgate, chairman, and Messrs. E. G. M. Cope, R. de L. French, W. Chipman and J. G. G. Kerry. A carefully compiled form of general clauses is presented, from which it is evident that much correspondence, study, revision and alteration has been devoted to the subject. By the use of it, it is suggested, the form of contract and of specifications may be very much abbreviated.

The committee recommends that all contracts should embrace, in one document: (1) The agreement or contract itself; (2) the tender or a certified copy of it; (3) the specification; (4) the general clauses; (5) the signed drawings as tendered on, and (6) any modified drawings agreed to prior to signing of contract.

Report of the Committee on Concrete and Reinforced Concrete.—The committee consists of Mr. Walter J. Francis, chairman, and Messrs. S. Baulne, E. Brown, E. Brydone-Jack, J. Galbraith (deceased), P. Gillespie, H. M. Mackay, E. S. Mattice, C. N. Monsarrat, Michael Morssen, P. B. Motley, and H. Rolph.

This committee presented a draft at the annual meeting last January of the standard general specifications for concrete and reinforced concrete. It brought forth a certain amount of discussion at the meeting. (For the draft and this discussion relating thereto, see *The Canadian Engineer*, January 22, 1914, page 198, and February 5, 1914, page 274, respectively). Subsequent discussions from branches and individual members were invited and varied contributions totalling 30,000 words, were received.

In his letter of transmittal, Mr. Francis refers to the loss the committee suffered in the death of Dr. John Galbraith.

The series of tests advocated at the last annual meeting were made during the year. The Atlas Construction Company, Limited, through their president, Mr. C. M. Morssen, M. Can. Soc. C.E., a member of the committee, made sixty-four 8 in. x 12 in. concrete beams, 11 ft. long. In the laboratories of McGill University these beams were tested under the direction of Prof. H. M. MacKay and Prof. Ernest Brown, both members of the committee. All the beams were tested to destruction, some at the age of two months and the balance at the age of three. The results were most conclusive, and were subsequently considered by the committee. Since that time weekly sessions of the committee were held, and the draft was analyzed and deliberated upon in greatest detail.

Nickel in the form of nickel sulphate and as metallic nickel is saved from the electrolytes used in refining blister copper. Most, if not all blister copper carries a little nickel which goes into solution, and gradually accumulates in the electrolyte. During 1913, according to the United States Geological Survey, an equivalent of 481,565 lbs. of nickel, valued at $79,393, was thus saved by refineries. About one-fourth of the product was produced as electrolytic nickel.

Coast to Coast

Ottawa, Ont.—A new road is proposed between Ottawa and Prescott, to be financed in a manner similar to the Toronto-Hamilton road. It is estimated to cost $10,000 per mile, and is 58 miles in length.

Ottawa, Ont.—Mr. D. W. McKughlin, engineer-in-charge of the Hudson's Bay terminal works at Port Nelson, reports that splendid progress has been made on the terminal and harbor works during the past season.

Vancouver, B.C.—As a result of some vessel dragging an anchor or grappling-hook while passing through the First Narrows one of the two 18-inch water mains recently laid across the bed of the Narrows, and supplying the city with 3,000,000 gallons of water per day from Capilano, was pulled apart, and the other dislodged from its proper position.

Saanich, B.C.—The long-proposed extension and improvement of the Lake Road in South Saanich municipality is about to become a reality. Tenders are already in hand, and it is expected that the contract will be awarded without delay. The estimated cost is $29,500. This improvement involves the construction of a subway under the Victoria and Sydney Railway, and a culvert to drain surplus water from the Swan Lake district. Considerable grading is required on a section of the road about 6,000 yards in length. Another road improvement in this vicinity entails the expenditure of about $30,000 on Shelbourne Street.

Port Arthur, Ont.—The Western Dry Dock and Shipbuilding Co., Limited, of Port Arthur, have taken out a building permit for a forge shop to cost about $30,000. Besides the construction of steamships, this company will manufacture engines and boilers of all kinds, hoisting and excavating machinery, structural steel and cabinet work. In the last two years they have turned out several large steamships, and are well equipped for the manufacture of the above machinery. This company have also received a large order from the British Government for shells and other war materials.

Edmonton, Alta.—The next piece of construction that will be effected by the Canadian Northern Railway is reported to be a branch line from Edmonton to Peace River Landing or Dunvegan the key to the Peace River and Grande Prairie country. Already a line from Edmonton has been completed for a distance of sixty miles to a point in the immediate neighborhood of the source of the Prairie River. From this point the branch will be directed north-west to either of the two places, thus giving an all-rail route from Edmonton to the homesteading country in the Peace River and Grande Prairie district.

Moose Jaw, Sask.—Bills before the Dominion government asking for new railway charters include one relating to the Brule, Grand Peace River Railway Co., seeking the right to construct railway, telegraph and telephone lines, commencing at Brule Lake, on the main line of the Grand Trunk Pacific and Canadian Northern Railways, north-westerly to Grande Prairie, thence north-westerly to a point in British Columbia, connecting with the terminus of the Pacific and Great Eastern Railway at or within the Peace River block, also commencing at Grande Prairie northerly to the Pacific, Peace River and Athabasca Railway at or near the point where the railway crosses the Montagneuse River, passing at or near Spirit River settlement, and crossing the Peace River at or near Dunvegan, approximately 400 miles in all.

PERSONAL.

Capt. A. J. McPHERSON, Deputy Minister of Public Works for the Province of Saskatchewan, is commanding the Regina Field Company of Canadian Engineers.

A. C. MORRISON, of Ottawa, has been appointed inspector of gas and electricity for the Ottawa Inspection district, to succeed Mr. A. A. Couvrette, resigned.

K. S. MacLAUGHLIN, B.A.Sc., superintendent of Metals Chemicals, Limited, Welland, Ont., is suffering from serious injuries sustained in a laboratory explosion last week.

R. S. WINTER, of Medicine Hat, Alta., has been appointed gas superintendent in succession to Mr. Wm. Craft, who has resigned from this civic position owing to ill-health.

G. H. FERGUSON has been appointed Minister of Lands, Forests and Mines for the Province of Ontario, assuming the position held by Premier Hearst prior to the latter's being appointed Premier.

Capt. T. C. IRVING, M. Can. Soc. C.E., of the Irving-Moffat Electric Steel Co., and vice-president of Robert W. Hunt and Co., will command the divisional engineers of the Canadian expeditionary force, about to leave Salisbury Plain for service in France and Belgium.

H. C. BARBER has joined the sales force of the Standard Underground Cable Co. of Canada, Limited, of Hamilton. Mr. Barber is a graduate of the Faculty of Applied Science of the University of Toronto. He has been with the Toronto Hydro System and the Hamilton Hydro Department, also with the Packard Electric Company, of St. Catharines.

E. G. MATHESON, M. Can. Soc. C.E., superintendent for the Foundation Co., Limited, on the construction of the substructure for the Canadian Pacific Railway bridge over the Pitt River, described the undertaking in an illustrated address given at the regular meeting of the Vancouver Branch of the Canadian Society of Civil Engineers, held on December 18th last.

OBITUARY.

At Kingsville, Ont., Mr. A. W. Weatman, superintendent of the W.E. and L.S. Railway, was electrocuted last week while engaged in putting a snowplough into service.

Thos. Blackwood, Deputy Inspector of Mines in the Province of Nova Scotia, lost his life by an explosion in one of the shafts at Stellarton, N.S., last week. Mr. James Brown, superintendent of the mine for the Acadia Coal Co., accompanied Mr. Blackwood on his trip of inspection, and was also killed, and Mr. Alex. Sutherland, manager of the mine, had a very narrow escape.

The death occurred on December 17th of Mr. F. X. Dion, president of the Lauzon Engineering Co., Limited, engineers and contractors, of Levis, Que. The late Mr. Dion was a well-known figure in business circles in the Province of Quebec.

The extraction of gasoline from natural gas, according to a bulletin issued by the United States Geological Survey, has become one of the chief adjuncts of the natural gas industry in the United States. The production in 1913 was almost double that in 1912.

Recent elections to the class of Associate Member in the American Society of Civil Engineers included the names of Mr. G. W. Harris, office engineer, Mackenzie, Mann and Co., Limited, Port Arthur, Ont.; Mr. C. S. Millard, manager and chief engineer for Francis S. Swales, architect, Vancouver, B.C.; and Mr. L. R. Thomson, designer, Dominion Bridge Co., Limited, Montreal.

PRESERVATION OF RAILWAY TIES.

At a recent meeting of the Society of Chemical Industry in Montreal two interesting papers were read on the subject of timber preservation. Dr. John S. Bates, director of the Forest Products Laboratories of Canada, gave an account of the work which has been done in the laboratories, and summarized investigation of conditions governing the durability of timber. The work has included a study of pulp and paper-making. Mr. W. B. Campbell, B.Sc., a member of the laboratory staff, read a paper on the preservation of wood, dealing with the various forms of rot which affect timber and clearly showed that the best method of increasing the durability of timber used for railway ties was to impregnate the wood with some substance poisonous to the organism that caused rot. In this connection he mentioned substances soluble in water, such as zinc chloride, and substances oily in nature, such as creosote oil. Mr. Campbell dwelt upon the advances of properly creosoted wood block paving, etc. The papers were followed by some valuable discussion, some of the participants being Prof. W. D. Walker, of Queen's University; Dr. Milton Hersey, Mr. J. A. DeCew, Mr. Fred. B. Brown, and Dr. S. Kirsch.

A committee was formed to investigate the feasibility of rendering wood fireproof, and to make specific proposals to the Government for legislation that would encourage the establishment of such a chemical study. The following were appointed to this committee: Mr. T. H. Wardleworth, chairman of the local branch of the Society; Dr. R. F. Ruttan, Dr. Milton Hersey, Mr. J. A. DeCew, Mr. C. F. Bardorf and Mr. A. G. Spencer.

COMING MEETINGS.

AMERICAN FORESTRY ASSOCIATION. — Annual meeting to be held in the Woolworth Building, New York City, January 11th, 1915. Secretary, P. S. Ridsdale, Washington, D.C.

CANADIAN NATIONAL CLAY PRODUCTS ASSOCIATION.—Annual Convention to be held at the King Edward Hotel in Toronto, January 26, 27, and 28, 1915. Secretary, G. C. Keith, 32 Colborne Street, Toronto.

CANADIAN SOCIETY OF CIVIL ENGINEERS.—Twenty-ninth annual meeting, to be held in Montreal, January 26th, 27th and 28th, 1915. Secretary, Prof. C. H. McLeod, 176 Mansfield Street, Montreal, Que.

AMERICAN CONCRETE INSTITUTE.—Eleventh Annual Meeting, to be held in Chicago, February 9th to 12th, 1915. Secretary, Edward E. Krauss, Harrison Building, Philadelphia, Pa.

EIGHTH CHICAGO CEMENT SHOW.—To be held in the Coliseum, Chicago, Ill., from February 10th to 17th, 1915. Cement Products Exhibition Co., J. P. Beck, General Manager, 208 La Salle Street, Chicago.

AMERICAN WATERWORKS ASSOCIATION. — The 35th annual convention, to be held in Cincinnati, Ohio, May 10th to 14th, 1915. Secretary, J. M. Diven, 47 State Street, Troy, N.Y.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.—Annual meeting to be held at the Iowa State College, Ames, Iowa, June 22nd to 25th, 1915. Secretary, F. L. Bishop, University of Pittsburgh, Pittsburgh, Pa.

In a paper read before the Duluth meeting of the American Peat Society, Dr. Peter Christianson calls attention to some of the possibilities of peat as a metallurgical fuel, especially in the iron and iron-ore industry of the Lake Superior iron district, that is, in the beneficiation or preliminary treatment, and in the smelting, of the ore.

IMPROVEMENT OF HIGHWAY CONTRACT WORK.*

By John J. Ryan,
Secretary, New York State Road Builders' Association.

LATE fall, winter and early spring are the best for highway lettings, inasmuch as the contractor has practically closed his work and has plenty of time to go over new jobs, being in a position to bid intelligently on these contracts. The municipality would gain by having lettings at these times, as they would receive more bids and, undoubtedly, fairer prices for work.

There seems to be a reluctance on the part of most highway departments to furnish information to bidders. Never yet has money been lost by allowing a contractor to know in advance all that there was to be known about a contract which was advertised for letting. In New York State it has been the practice, after advertising highway contracts, to furnish the contractors with the engineer's figures showing how the engineer has arrived at his estimate by computing basic prices, with profit allowance. While some of the old guard of contractors state that they prefer no engineer's estimates, yet, in general, the road builder in New York looks for these estimates on each road and checks up the same with his own idea of cost prices, making allowance for methods and supervision. It has yet to be found that New York lost any money by this procedure; rather has it benefited by it, because the contractor, when furnished with full information as to the contract, is in a position to bid closer and know what he is doing when bidding.

On the day appointed for the letting the bids should be in at a specified hour, opened at that time and read publicly, item by item, with the total amount of contract price. This practice advises the contractor immediately whether he is low, and he is in a position to make arrangements about plant, material and labor, pending the official award. This award should not be held up more than twenty-four hours, unless for some unforeseen cause. It ought not to take more than twenty-four hours to make a recapitulation of any number of highway bids. In New York State, where on one day they have as many as thirty roads with three hundred bidders, the checking up is done at the same time the bids are read, and the award is made that day or the next morning. This allows the contractor to arrange for his bonds and the other necessities in connection with the preliminary part of his contract.

Bonds and Monthly Estimates.—Performance bonds for highway contracts should exceed 50 per cent. of the contract price. Such a bond becomes a liability when the contractor signs it, and while it may be called paper liability, yet it has effect upon his credit and sometimes acts as a hindrance in securing other contracts. Some states ask for a bond of 100 per cent., which is quite needless and an inheritance of old and obsolete requirements.

The monthly estimate is the vital thing to the contractor. There can be no successful contract without prompt monthly estimates. These must not be irregular nor must they be pruned. Monthly payments to the builder are as food to the body. In some states 90% of the monthly estimates taken about the 20th of the month are paid before the first of the next month; that is, practically all monthly estimates are paid within 10 days.

When the first monthly estimate comes around the contractor should have his cost data and his monthly reports figured so that he knows how much work has been done and at what cost, and is in a position to take up the matter with the engineer. Together they can check up and agree upon what the estimate should be, so that there will be no deficiency when the check comes to the contractor.

*Read at the Atlanta Congress, Nov. 9-14, 1914.

CANADIAN PRODUCTION OF COAL IN 1913.

CANADA'S coal situation is very clearly portrayed by Mr. John McLeish, B.A., chief of the division of mineral resources and statistics, Department of Mines, Canada, in his recently issued report on the production of coal and coke in Canada during 1913. The coal fields and deposits, which are probably the most extensive and best known of the country's mineral resources, are found principally in the coast provinces and in Alberta. The central provinces, Ontario and Quebec, in which the major portion of Canadian population is still concentrated, and which are without coal fields, find it more economical to use coal from Ohio and Pennsylvania. Besides, Pennsylvania anthracite is used in great quantity in eastern as well as central Canada.

Canadian coal is chiefly bituminous and lignite, although an output of about 200,000 tons of anthracite is produced yearly at the Bankhead mines in Alberta.

Mr. McLeish gives the total production of coal in 1913 to be 15,012,178 short tons, valued at $37,334,940, or an average of $2.49 per ton. This production was obtained by about 227 operating companies employing an average of 27,917 men at a wage cost of approximately $22,065,141. Compared with 1912, in which year the production was 14,512,829 short tons, valued at $36,019,044, an increase is shown of 499,349 tons or 3.44 per cent. in quantity. These values are partially estimated or assumed since complete returns have not been received with respect to the total value received for coal sold. In the case of Nova Scotia an average value of $2.50 per long ton is placed upon the total production, while for British Columbia an average value of $3.50 per long ton is used. The values placed upon the Alberta production are those furnished by the operating companies.

The total exports of domestic coal from Canada in 1913 were 1,562,020 tons valued at $3,961,351 as compared with 2,127,133 tons valued at $5,821,593 in 1912. There is also a small export of coal "not the produce of Canada."

The total imports of coal in 1913 were 18,201,953 tons valued at $47,949,119, as compared with imports in 1912 of 14,595,810 tons valued at $39,478,037.

The total consumption of coal in 1913 was 31,582,545 tons or 4.07 tons per capita, as compared with 26,934,800 tons or 3.59 tons per capita in 1912.

The increased use of oil fuel for locomotives in British Columbia and for coast vessels has in some slight measure reduced the market for coal in western Canada. According to statistics published by the Department of Railways and Canals, the total consumption of coal in locomotive boilers during the twelve months ending June 30, 1913, was 9,045,625 tons, which is equivalent to very nearly one-third the total consumption of coal in Canada. During the twelve months ending June, 1912, there was used for locomotives 1,729,577 gallons of oil, whereas during the twelve months ending June, 1913, the quantity so used was 31,087,252 gallons. This consumption of oil in 1913 would probably be equivalent to about 310,000 tons of Nanaimo coal and, taken in conjunction with the oil used on coast vessels, indicates in some degree the extent to which coal has been displaced as a fuel in this market.
